Immune animals challenged with capripoxvirus by intradermal inoculation develop a delayed-type hypersensitivity reaction at the challenge site. This may not be apparent in animals with high levels of circulating antibody. It has been suggested that the very severe local response shown by some cattle at the site of vaccination against LSD may be a hypersensitivity reaction due to previous contact with the antigens of parapoxvirus.

There is total cross-immunity between all strains of capripoxvirus, whether derived from cattle, sheep, or goats.

Prevention and Control

In temperate climates, capripox can be effectively controlled by slaughter of affected animals, and movement control of all susceptible animals within a 10 km radius for

6 months. In tropical climates, particularly in humid conditions when insect activity is high, movement restrictions are not sufficient and vaccination of all susceptible animals should be considered. In outbreaks of LSD, it is not considered necessary to vaccinate sheep and goats, although theoretically cattle strains of virus could infect them. Similarly, in outbreaks of capripox in sheep and goats, cattle are not normally vaccinated.

Countries in which capripoxvirus is absent can maintain freedom by preventing the importation of animals from infected areas. There is always a possibility that skins from infected animals could introduce infection into a new area, although there have been no proven examples of this. The insect transmission of capripoxvirus into Israel from Egypt over a distance of between 70 and 300 km would indicate that it is impossible for countries neighboring enzootic areas to totally secure their borders.

In enzootic areas, annual vaccination of susceptible animals with a live vaccine will control the disease. Calves, kids, and lambs up to 6 months of age may be protected by maternal antibody, but this would only occur if the mother had recently been severely affected with capripox. Although maternal antibody will inactivate the vaccine, it is advisable to vaccinate all stock over 10 days of age. No successful killed vaccines have been developed for immunization against capripoxvirus infection, other than those that give only very short-term immunity.

Future Perspectives

Capripox of sheep and goats is present in most of Africa and Asia, whereas LSD is restricted to Africa. There is no good explanation as to why LSD has not spread into the Middle East and India, carried by the considerable trade in live cattle. Unless there is a reservoir host in Africa which is required for the maintenance of the cattle-adapted capripoxvirus, it can be anticipated that LSD will spread out of Africa, with major economic consequences.

While considerable attention has been given to vaccinia virus as a vector of other viral genes for development as a recombinant vaccine, little attention has been given to capripoxvirus as a potential vector vaccine. Although its use would be restricted to the not inconsiderable capripoxvirus enzootic area, it would have the advantage of not being infectious to humans, and be a useful vaccine in its own right.

The high degree of homology between the genomes of capripoxvirus isolates from different species and the apparent differences between their virulence and host preference would make them good candidates for studying the genetic basis of virulence and host specificity.

Glossary

Coat protein The protein which is the structural building block for the nucleic acid container part of the virion.

DNA encapsidation or DNA packaging The process of enclosing a nucleic acid inside the protein coat of a virion.

Head The icosahedrally symmetric portion of *Caudovirales* virions that contains the nucleic acid.

Portal protein The *Caudovirales* protein through which DNA enters and exits the coat protein shell; it is present at only one of the 12 otherwise identical icosahedral vertices.
Procapsid or prohead The virion precursor particle that contains no nucleic acid; it is the preformed container into which the nucleic acid is packaged.
Scaffolding protein A protein that directs the proper assembly of the coat protein, but is not present in the completed virion.
Tail The portion of *Caudovirales* virions that binds to cells bearing the correct surface receptor and through which DNA traverses during delivery from the virion into the cell. The tail is attached to the portal protein of the head in the complete virion.
Triangulation (T) number Formally, T is the number of smaller equilateral triangles (facets) into which each of the 20 icosahedral faces is subdivided in an icosadeltahedron. In viruses, this is directly related to the number of coat protein subunits (S) per virion ($S = 60T$), since there are typically three subunits per facet and 20 faces in icosahedral viruses.
Virion The stable virus particle that is released from infected cells and is capable of binding to and infecting other sensitive cells.

History and Overview

The structure of bacterial viruses (bacteriophages or phages) remained a mystery for over a quarter of a century after their original discovery in about 1910, and even then early electron micrographs of phage T4 showed only a vague outline of its complex features. The invention in the late 1950s of negative staining with heavy metal salts and high-resolution metal evaporation techniques allowed electron microscopy to be used to visualize virions with a resolution of a few nanometer – a big step forward, but most individual protein components could still not be resolved. Meanwhile, viruses were shown to be made up primarily of protein on the outside and nucleic acid inside. It is worth noting that phage T2 was a major participant in the proof that DNA is in fact the genetic material, when Hershey and Chase used it to show that during an infection the virion's DNA entered the cell and the bulk of the protein remained outside. After their discovery that DNA is the genetic material, in 1953, Crick and Watson also recognized that virus chromosomes could not encode a single protein molecule large enough to enclose their nucleic acid molecules, and they correctly postulated that virions had to be constructed with repeating arrays of protein molecules. They also noted that there are only two ways of building virions with symmetric arrays of coat proteins that enclose a space suitable for a virion's nucleic acid, and those are arrays built with cubic or helical symmetry (the former includes icosahedral, octahedral, and tetrahedral arrays which would be built from 60, 24, and 12 identical protein subunits, respectively). In 1962, Caspar and Klug deduced that many viruses must be built from icosahedral shells that contain more than 60 subunits, and developed a geometric theory for such arrangements if the subunits were given some flexibility in bonding to their neighbors (referred to as 'quasi-equivalence', since the flexibility gives rise to subunits that are not quite identical in their conformation and/or bonding properties). Some viruses, especially the tailed phages (*Caudovirales*), which are in large part the subject of this article, were found not to be this 'simple' and their repeating arrays of proteins are embellished with parts that are not icosahedrally symmetric. These asymmetric parts can be very complex; for example, phage T4 virions contain over 40 different protein species, of which a substantial majority are not icosahedrally arranged like the coat protein. Recent determination of the complete atomic structure of virions, procapids, or parts of them by X-ray diffraction (usually 2–4 Å resolution) and three-dimensional (3-D) reconstruction by superposition of electron micrographs of many particles and averaging of the resulting structure about the icosahedral rotational symmetry axes (current best is 6–8 Å resolution) has given rise to much detailed information about the structure of protein arrays in viruses in general and phages in particular, and very recent advances have allowed structural determination of virions' asymmetric parts to below 20 Å in advantageous cases (**Figure 1**).

As structural information about virus particles and other macromolecular assemblies accumulated, scientists naturally wondered how such structures were built. Animal and plant viruses were difficult to study inside infected cells, and so the assembly of the bacterial viruses in the easier-to-study bacterial cells became an important model for understanding the mechanisms utilized in the assembly of many macromolecular structures in addition to the viruses themselves. Critical in these studies was the determination of 'parts lists' for the bacteriophages under study, and these were determined both biochemically by delineation of the different protein components and genetically by identification of the genes that encode the protein components; both approaches were crucial in understanding the true nature of phage virions and how they assemble. Although some eukaryotic virions do include host encoded proteins, this has not been found to be the case for phages; all of their protein components are encoded by their own genomes. Although small organic molecules (e.g., putrescine) have been found in phage virions, none have been shown to be essential structural components.

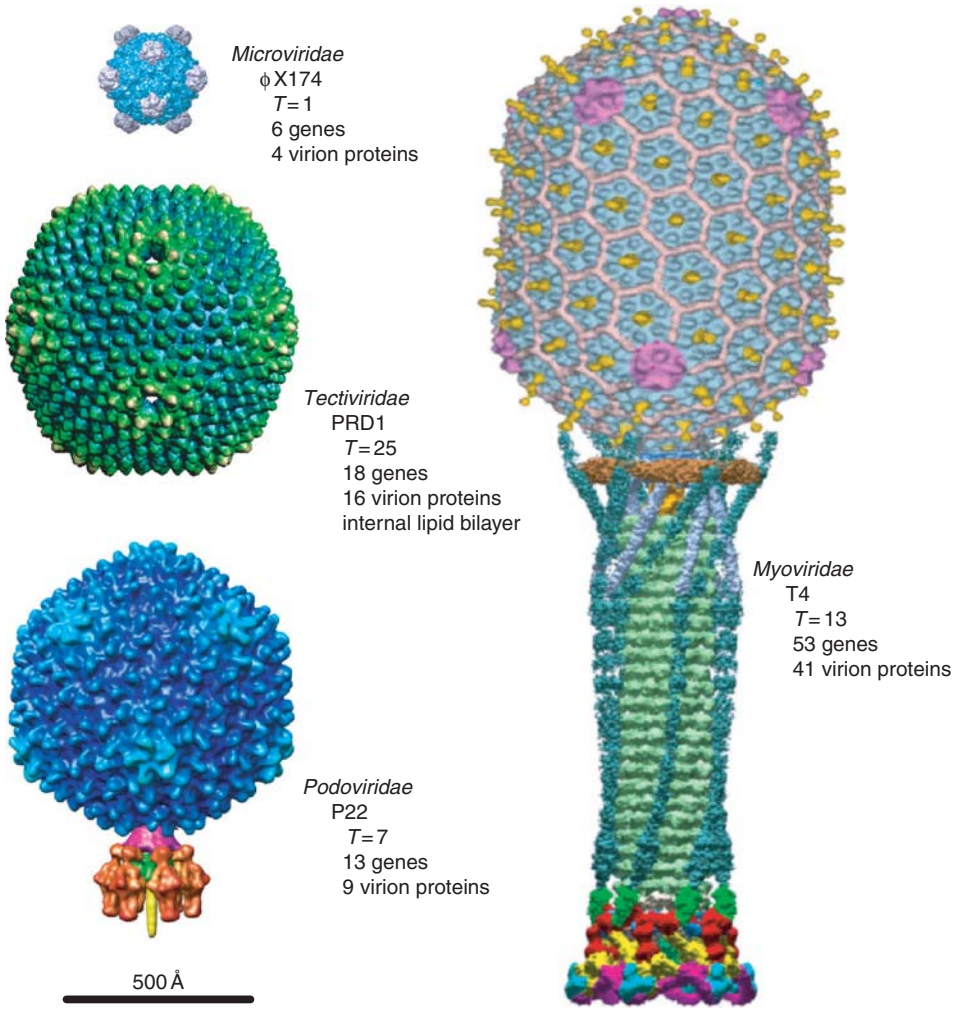

Figure 1 Bacterial virus structures. The structures of representatives from four bacteriophage families are shown at the same scale. The images are shown at 20 ± 5 Å resolution. The 'number of genes' indicated in the figure is the number of genes currently known to be involved in virion assembly and the 'virion proteins' is the number of these present in the completed virion. In ϕX174, DNA packaging into the virion is dependent upon DNA replication but the genes that encode the replication machinery are not included. In each case, different structural proteins visible from the outside are shown as different colors. The PRD1 structure shown is not the actual virion but only the arrangement of coat proteins. The T4 virion is shown in its 'tail fiber up' conformation, in which the tail fibers (dark green) are folded up and the whiskers are folded down, and both are lying along the body of the tail. The T4 image was provided by V. Kostyuchenko, A. Fokine, and M. Rossmann, the P22 image was provided by G. Lander and J. Johnson, and the other two images are from the Virus Particle Explorer website (http://viperdb.scripps.edu/index.php).

Phages are known that contain any one of the four types of nucleic acid, single-stranded DNA (ssDNA), double-stranded DNA (dsDNA), single-stranded RNA (ssRNA), and double-stranded RNA (dsRNA), and they are built with icosahedral symmetry, helical symmetry, and a combination of the two. **Table 1** lists the eight formally named phage orders which appear to be largely unrelated to one another, and one of these, the *Caudovirales*, has been divided into three families with different tail types. Note that there are poorly studied phages that infect the bacteria class Mollicutes that have not yet been formally classified, and viruses that infect the Archeas are not discussed here. Given this great diversity of phage structures and assembly mechanisms, it is not possible to describe them all in detail here, and the reader is urged to consult other articles in this volume for more specific information on the various bacteriophage systems. In this article, we explore phage virion structure and the strategies and mechanisms by which virions assemble. Focus is largely upon the *Caudovirales*, since their assembly is the best understood, but other phage phyla will be mentioned as they are relevant.

Assembly Pathways

A major theme that emanates from the early study of phage assembly is the idea of an 'assembly pathway'.

Table 1 Types of bacteriophages

Phage type	*Best-studied phages*	*Major virion symmetry*	*Virion nucleic acid*	*Comments*
Microviridae	ϕX174	Icosahedral; protein fold A[a]	Circular ssDNA; 4–6 kbp	$T = 1$
Inoviridae	f1, M13	Helical	Circular ssDNA; 5–9 kbp	Special proteins at both ends
Caudovirales Myoviridae	T4, P2	Icosahedral head; protein fold B[a]; long helical contractile tail	Linear dsDNA; 30–500 kbp[b]	*Caudovirales* heads range from $T = 3$ to $T = 52$ and can be isometric or elongated
Caudovirales Siphoviridae	λ, HK97, SPP1	Icosahedral head; protein fold B[a]; long noncontractile tail	Linear dsDNA; 22–140 kbp[b]	Heads can be isometric or elongated
Caudovirales Podoviridae	P22, T7, ϕ29	Icosahedral head; protein fold B[a]; short tail	Linear dsDNA; 18–75 kbp[b]	Heads can be isometric or elongated
Tectiviridae	PRD1	Icosahedral; protein fold A[a]	Linear dsDNA; 13–15 kbp	$T = 25$; contains internal lipid bilayer
Corticoviridae	PM2	Icosahedral	Circular dsDNA; 10 kbp	$T = 21$; contains internal lipid bilayer
Plasmaviridae	L2	Pleomorphic	Circular dsDNA; 2 kbp	Contains lipid bilayer
Leviviridae	MS2, R17	Icosahedral; protein fold C[a]	Linear ssRNA; 3.5–4.3 kbp	$T = 3$
Cystoviridae	ϕ6	Icosahedral; protein fold D[a]	Linear dsRNA; 13–14 kbp	$T = 13$; three different dsRNA molecules in virion; contains external lipid bilayer

[a]The protein folds (named arbitrarily in the table) of typical *Microviridae*, *Caudovirales* (*Siphoviridae*), *Leviviridae*, and *Tectiviridae* coat proteins have been determined by X-ray diffraction; that of *Cystoviridae* is suspected from its arrangement in virions which is similar to other dsRNA viruses.
[b]Approximate size ranges – *Caudovirales* phages are extremely diverse and the limits of genome sizes are not fully known.

The complex phages (*Caudovirales*), which can have as many as 50 different proteins in their virions, typically do not synthesize these different proteins in the temporal order of their assembly. Instead, the different proteins are all synthesized simultaneously, and the inherent properties of the proteins dictate their order of assembly. Thus, virion assembly proceeds via a specific 'pathway' in which the components assemble in an orderly manner. How is such a program of assembly achieved? The generally accepted mechanism for this type of control, which is now known to occur in the construction of many macromolecular structures, not just phages, is that the component proteins change conformation upon binding to the growing structure. Thus, once an initiator complex (of say protein A) is generated, protein B binds to it and changes its conformation so that protein C can bind, protein C in turn changes its conformation so protein D can bind, etc. In some cases, the precise juxtaposition of proteins B and C on the growing structure may also contribute to the creation of a binding site for D. In such a scheme, the unassembled proteins B, C, and D have no affinity for each other and so do not assemble in alternate ways. Thus, an ordered 'assembly pathway' of protein A first creating an initiation complex, then B, then C and then D binding in this defined order is determined solely by the properties of A, B, C, and D proteins. Because of these properties, when one component is missing, in most cases the assembly intermediate to which the missing component would have bound accumulates, and downstream components remain unassembled. This has allowed the examination of many such intermediates in the characterization of phage assembly pathways. The isolation in relevant genes of conditionally lethal nonsense mutations, which are particularly tractable in phage systems, made this approach extremely productive. Several issues regarding the assembly pathway strategy remain poorly understood, and these include such questions as: What controls initiation of the assembly process? Control could simply be the synthesis and proper folding of a limiting amount of protein A in the example above, but in some situations such as procapsid assembly (below) it appears to be more complex. And what is the exact nature of the conformational changes that occur upon binding? These remain fertile ground for research.

Assembly Strategies and Mechanisms

Branched Pathways, Subassemblies, and Quality Control

Phages have apparently evolved ways of maintaining quality-control systems in virion assembly. One such system is assembly though 'subassemblies' or discrete assembly intermediates that are unable to join with other subassemblies unless they are properly assembled. Thus, if an incorrectly built subassembly (say missing one of 10 protein molecules) is defective and unusable, it is

much less costly than if a complete virion (containing hundreds to thousands of protein molecules) were rendered defective due to one missing or defective protein molecule. Thus in the *Caudovirales*, for example, head precursors called procapsids are built first and most likely only package DNA if they are correctly assembled, tails are built independently (though a series of smaller subassemblies), and DNA-filled heads and tails only join when both are successfully completed. A second quality-control system may be that phage proteins have evolved to minimize assembly problems by ensuring that the participating proteins do not assemble unless their C-terminus is intact. Such a strategy ensures that prematurely terminated polypeptides (arguably the most probable translation error) are unable to participate, since they are missing their assembly site. Although this is an evolutionary argument, the fact that among the many phage assembly genes and proteins that have been studied, very few of the N-terminal fragments have 'dominant negative' genetic characteristics or are incorporated into the assembling virion.

Assembly of Symmetrical Protein Arrays

Assembly and maturation of icosahedral arrays

The use of an icosahedral protein shell to enclose phages' virion chromosomes appears to have evolved independently at least four times. Phage coat proteins are sufficiently ancient that even those with common ancestors are often not recognizably similar in amino acid sequence. We are thus left with comparison of their folded (secondary and tertiary) structures to deduce common or separate ancestries, and such structural information is not known for most phages. Nonetheless, high-resolution atomic structures are known by X-ray diffraction for a few members of several groups and those from the *Caudovirales*, *Tectiviridae*, *Microviridae*, and *Leviviridae* form three very different coat protein folding groups that are certainly not related. But do coat proteins from all members within each of these groups have a common ancestor? Our current limited knowledge suggests that this may well be true. High-resolution 3-D reconstructions of electron micrographs of several members of the *Podoviridae* and *Myoviridae* strongly suggest that all *Caudovirales* have the same unusual protein fold that has been determined for phage HK97. Finally, the *Cystoviridae* are thought to have a fourth type of subunit that is related to dsRNA viruses that infect eukaryotes.

Although much is understood about the actual structures of the phage (and other virus) icosahedral arrays that encase the nucleic acid in so many virions, in different viruses the size and shape of these arrays can vary greatly and control of these variations is poorly understood. No octahedral or tetrahedral viruses have been discovered. The geometry of icosahedral arrays is well understood, and if strict conformational and bonding identity is maintained among the participating chemically identical coat proteins, only exactly 60 subunits can be accommodated in the shell. However, if some flexibility (quasi-equivalence, above) is allowed, then the number of subunits (S) allowed in an isometric icosahedral shell is equal to $60T$ where $T = h^2 \times hk \times k^2$, where h and k are any integer including zero. This gives rise to the infinite series $T = 1, 3, 4, 7, 9, 12, \ldots$ and $S = 60, 180, 240, 420, 540, 720, \ldots$, respectively. Such shells can be thought of as having pentamers of the coat protein at each of the 12 icosahedral vertices and different numbers of hexamers making up the 20 triangular faces in different-sized shells. Phage heads are known with T numbers ranging from 1 to 52. Little is understood about exactly how the assembly of such shells is initiated or how their size is controlled. In many cases, the coat protein by itself will assemble into several sizes of shell as well as long tubes and irregular structures. In some cases (notably phages T4 and ϕ29), the icosahedral shell is elongated along the tail axis, and evidence from the systems under study suggests that both portal protein and scaffolding protein (see below) can be involved in this control, so factors beyond the innate coat protein properties clearly participate in the control of the spatial aspect of shell assembly.

Coat protein shells of the dsDNA phages assemble into a metastable 'immature' procapsid shell which undergoes a maturation that consists of a conformational transition to its final more stable state at about the time of DNA packaging. This maturation transition is typically accompanied by a significant expansion of the shell, the release of the scaffolding protein, and any proteolytic cleavage of the head proteins that might occur. This transition is surprisingly complex, and in the case of phage HK97, where it has been studied at the highest resolution, it proceeds through at least five separable coat protein conformational/organizational stages, in which there is little or no refolding of the main structural domain of coat protein, but there are significant changes in the orientations of the coat protein and the conformations of surface parts of the protein that are not within the central domain (**Figure 2**). The trigger(s) for this transition is not fully understood, but it clearly requires the successful completion of procapsid assembly. DNA entry and/or head protein proteolysis may be the natural signal for the transition to occur. This transition is universal in the assembly of tailed phages, and it has been suggested that topological difficulties in the construction of a closed shell with building units that have uneven surfaces might demand building a loosely bonded shell first, which subsequently rearranges into a more tightly bonded structure. The transition could also be part of a quality-control mechanism to ensure the structure is correctly built, and the concomitant expansion increases the available internal space for occupation by the DNA.

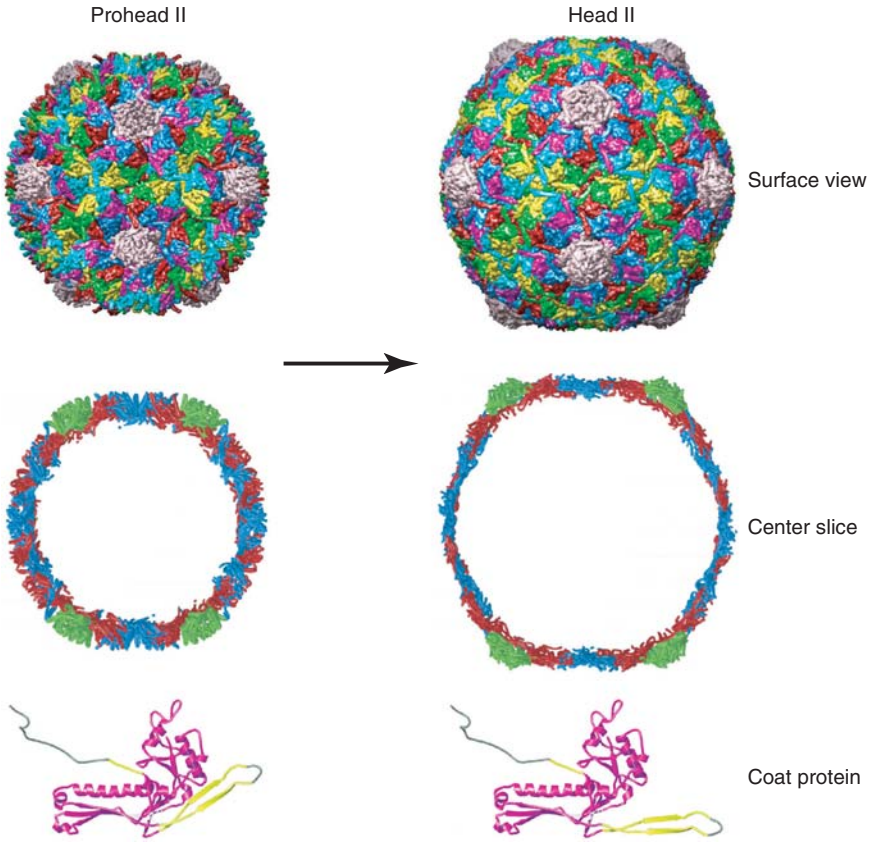

Figure 2 The maturation transition of the bacteriophage HK97 head. HK97 coat protein assembles into procapsids, its N-terminal 102 residues are removed by proteolytic cleavage, and the resulting structure is called prohead II. This coat protein shell undergoes a several-stage transition to become head II, which has expanded in diameter and has a thinner shell. In the surface view, the seven different 'quasi-equivalent' coat subunit locations are given different colors. In the slice view, the penton subunits are green and hexon subunits red or blue. In addition to subunit reorientation during the transition, the loop (called the E loop) shown at the lower right of the coat protein ribbon diagrams (the bottom tier) undergoes a major change in conformation during the transition. The images were provided by Lu Gan, Jack Johnson, and Roger Hendrix.

Symmetry disruptions and symmetry mismatches

The tails of the tailed phages (*Caudovirales*) and the portal of the *Tectiviridae* disrupt the icosahedral symmetry of coat protein shells of these virions, by being present at only one of the 12 otherwise identical vertices. How does this occur? Where it is known (phages P22, T4, T7, ϕ29), this 'disruption' replaces exactly one of the coat pentamers and it is present in the procapsid before the tail joins to the head. In procapsids, a dodecameric (12-mer) ring of portal protein occupies the position of the coat protein pentamer and tails will eventually bind to this portal protein. A single unique vertex is most simply explained if the portal protein forms the site that initiates coat shell assembly, and, in agreement with this idea, it has been shown that the absence of portal protein affects the spatial aspects of coat protein assembly in several phages (e.g., T4, λ, ϕ29). However, in some other phages, such as P22, coat assembles quite normally in the absence of portal protein. In all these systems, other factors, especially scaffolding protein (below), clearly play an as yet imprecisely defined role in initiation of coat protein assembly and in creating the unique portal vertex. The 12-fold symmetry of the portal ring and the fivefold symmetry of the capsid at the portal vertex means that there is a 'symmetry clash' between these two parts of the virion, and thus there cannot be identical interactions between the individual coat and portal subunits; it has been suggested that this could allow rotation of the portal with respect to the coat shell, but this has not yet been shown experimentally to be the case.

Helical arrays

Cylindrically shaped helical and stacked-ring protein arrays are present in the long tails of *Myoviridae* and *Siphoviridae*. In both types of viruses, these arrays assemble (in the cases studied) from the tail tip up to the head proximal end to give rise to the tail subassembly. Both types of tails have a complex baseplate (or tail tip) structure at their head-distal ends. Baseplates assemble first,

and when they are complete, they form the site at which the helical tail shaft begins to assemble. But helical arrays can be indefinitely long; so how are the discrete tail lengths programmed? Phage tails use a protein template (discussed in more detail below) to determine tail length, and when this length is attained, other proteins bind to the growing tip to block further growth. There are three types of helix (or stacked ring) building proteins, the *Myoviridae* tail tube (inner) and sheath (outer) proteins and the *Siphoviridae* tail shaft protein. Of these three, the sheath proteins are most highly conserved, and in many (but not all) tailed phages they are recognizably related in amino acid sequence. The other two are extremely variable, and with no structural information it is impossible to know whether or not they form discrete groups of distantly related proteins. Thus, there is no convincing evidence that the *Myoviridae* tail core and sheath and the *Siphovirdiae* tail shaft subunits have a common ancestor, and their different functionalities and roles suggests that they may have independent origins.

The *Inoviridae* or filamentous phages, unlike most other bacterial viruses, do not escape the host cell by lysing it. Their helical coat is assembled from subunits embedded in the cell membrane as the DNA is extruded through a complex assembly machine built into the membranes of the infected cell. Since they assemble in a such a different manner from the other phages under discussion here, and the detailed mechanism of their assembly is not understood in detail, they will not be considered in depth here.

Catalysis and Assembly

Scaffolds, templates, and jigs

Scaffolding proteins are proteins that assemble in fairly large numbers into procapsids but are not present in the completed virion. They act transiently to help in the proper assembly of coat protein shells and in the tailed-phage cases in the determination of the one unique vertex (above). The precise mechanisms by which scaffolding proteins perform these functions is unknown, but typically the interior space of *Caudovirales* procapsids contains several hundred molecules of scaffolding protein that are essential for proper procapsid assembly. They are then either proteolytically destroyed or released intact before DNA is packaged. Among the latter type, the scaffold of phage P22 has been shown to participate in an average of five rounds of procapsid assembly and so clearly acts catalytically in the assembly process. Stable oligomeric complexes between coat and scaffold molecules have not been found, yet scaffold 'nucleates' coat assembly (in the absence of all other proteins) at concentrations at which coat fails to assemble by itself. Scaffold remains as small oligomers in the absence of coat protein. It is not clear whether scaffold is forming a template whose surface guides coat assembly or is transiently binding and modifying the coat conformation so that it assembles correctly. *Microviridae*, in spite of their 'simple' $T=1$ coat protein shell, have both an internal and external scaffolding protein. In addition to roles in both temporal and spatial control of coat protein assembly, scaffolds may also function to fill the interior and thus exclude cellular macromolecules from the procapsid interior.

Perhaps the best example of an assembly template is the assembly of the *Caudovirales* tail shafts. *Siphoviridae* tail shaft subunits require two things to assemble, an initiation site on the completed baseplate and a template along which to assemble. This template has been best studied in phage λ, but even there tail shaft assembly is complex and not yet fully understood. It has been shown that the phage λ gene *H* (or 'tape measure') protein serves as a template for the assembly of the shaft subunit outward from the distal tip structure, and it is the length of the extended tape measure protein that determines the length of the tail shaft; shortening the tape measure protein causes the formation of a commensurately shorter tail. Interestingly, in these virions, the tape measure is thought to occupy the lumen of the tail, through which DNA must pass during injection, and the tape measure protein is ejected from the virion along with the DNA during the infection process. A second type of tape measure has been suggested for assembly of the phage PRD1 $T=25$ coat protein shell. The protein product of PRD1 gene *30* is stretched along the face edges of the icosahedral structure and may determine the length of the face and thus the size of the icosahedron.

A third type of spatial control of assembly is the 'jig', of which the phage T4 whisker is the prime example. This fiber protrudes from the head–tail junction, and its distal end binds to the elbow of the bent tail fiber, holding it in the correct position for joining of the tail fiber to the baseplate. The use of such a jig here may reflect some inherent difficulty in successfully attaching the tail fibers (see below).

Assembly enzymes and chaperonins

Aside from the scaffolding proteins, there are other well-studied examples of proteins that act catalytically during phage virion assembly. Perhaps the most curious of these is the gene *63* product of phage T4. This protein is required for the addition of tail fibers to the otherwise completed virion, but it is not present in virions. Its exact mechanism of action is not known, but it has been suggested that it and the jig described above are required to allow the creation of a flexible ball-and-socket joint between the fiber and the rest of the virion, which in turn might allow the fiber to 'search' more efficiently for its binding site on the surface of bacterial cells. In addition, T4 gene *38* protein appears to bind to and catalyze efficient trimerization of the subunit that forms the outer half of the bent tail fiber, but then it is released and not found in virions. Chaperonins are required in the folding of many proteins and so can be critical to phage assembly in that the proteins must be properly folded to participate

in the assembly process. It is interesting to note that the chaperonin protein-folding function was discovered during the genetic analysis of the host's role in phage λ head assembly, and that some phages (e.g., T4) encode replacement subunits for the GroE chaperonin to ensure that their proteins are folded correctly.

Other catalytic actions during phage assembly are the ATP cleavage-dependent action of DNA translocases that move the DNA into the procapsid through the portal ring and the cleavage of overlength replicated DNA to virion length by the phage-encoded enzyme called 'terminase' in the *Caudovirales* (the nucleic acid packaging process is less well understood in other phages). Both of these enzymatic functions are essential for tailed-phage assembly, and the reader is referred to the article in this volume on nucleic acid encapsidation for a more detailed discussion. In addition, enzymatic proteolytic modification of virion proteins is often essential during assembly (below).

Nucleic Acid Encapsidation

The packaging of nucleic acid within virions is covered in more depth in other articles of this volume, but it is noted here that different phages utilize very different strategies to build a virion with nucleic acid on the inside and protein (and lipid in some cases) surrounding that nucleic acid. The packaging of an ssRNA within the virion molecule by members of the *Leviviridae* family occurs by concomitant assembly of coat protein molecules into a $T = 3$ icosahedral structure and condensation of the RNA (which is predicted to be rather compact due to extensive secondary structure) by a process that is not understood in detail. Here, as apparently in all phages, recognition of a particular sequence in the viral nucleic acid is required to initiate packaging, thereby ensuring that only virus-specific nucleic acid is encapsidated. The other phage types either assemble a procapsid into which the nucleic acid is inserted by an energy-consuming nucleic acid translocase (*Caudovirales*, *Tectiviridae*, *Cystoviridae*) or assemble the virion around the ssDNA as it is extruded from the cell (*Inoviridae*).

Covalent Protein Modifications during Assembly

Protein cleavage

A common, but not universal, feature of phage assembly is the controlled proteolytic cleavage of some protein participants. This is best studied in the *Caudovirales*, and so they will be discussed here. It was discovered early that an N-terminal portion of all of phage T4's coat protein molecules are removed by proteolytic cleavage during assembly, and that this cleavage is dependent upon proper assembly of the coat protein shell. It has been suggested that the role of such coat protein trimming, which is common, is to make assembly irreversible, allow coat protein to find a more stable folded state, to alter coat protein function between virion assembly and DNA delivery, to help create room inside for the DNA, to be a kind of quality control, and/or to simply to remove part of the virion that is no longer needed after successful assembly. These of course are not mutually exclusive roles. Assembly-dependent cleavage of other virion assembly proteins such as portal proteins, scaffolding proteins and tape measure proteins, as well as the phage-encoded protease itself, have also been observed. Where it has been studied, a phage-encoded protease co-assembles into the procapsid and subsequently proteolyzes the head proteins, including itself. Tail protein cleavage is less well understood, and the protease that trims, for example, the C-terminus of phage λ tape measure protein has not been identified, but a host protease is responsible for the essential but non-assembly-dependent removal of the N-terminal region of a phage P22 virion protein that is injected with the DNA.

Protein cross-linking

Escherichia coli phage HK97 typifies a subset of *Siphoviridae* that are known to covalently cross-link all of their coat proteins as the final step in head shell maturation. Other covalent cross-links have been described between a few of the coat protein molecules of phage λ and a fragment of its putative head protease, but their role in assembly is not known. In HK97, each coat subunit is joined to its neighbors through lysine–asparagine side-chain isopeptide bonds. The topology of these cross-links is such that they form covalent rings of five and six subunits that are interlocked, thus making a sort of molecular 'chain mail'. This cross-linking is catalyzed by the coat protein itself after the shell has expanded, and the cross-links contribute to the stability of the head.

Lipid Membrane Acquisition

Several bacterial virus families have lipid bilayers in their virions (**Table 1**). These have been studied most in the *Tectiviridae* phage PRD1, which has a lipid bilayer between the icosahedral capsid shell and the internal dsDNA. This layer may aid in the protection of the intravirion nucleic acid, but also participates in DNA delivery into sensitive cells. Members of the *Tectiviridae*, *Cystoviridae*, and *Corticoviridae* all appear to acquire their lipid membrane in the cytoplasm from the host's membrane by as yet poorly understood mechanisms, after virus-encoded proteins have been inserted into the host membrane. Information is available on some of the virion proteins that interact with the lipid bilayers, but little is known about the detailed mechanism of the assembly of the membrane into these phages' virions. The *Plasmaviridae* phage L2, which infects a member of the bacterial *Mycoplasma* family, appears to bud from the host cell membrane. This kind of release may only be possible in the mycoplasmas, since they are the only bacteria that have no cell wall, but the morphogenesis of L2 has not been studied in detail.

Summary

Clearly, there is no single 'mechanism of bacteriophage capsid assembly'. Bacterial viruses are varied and complex, and they utilize many different mechanisms on the road to assembling completed virions. Two major take home lessons regarding phage assembly are (1) the ubiquitous use of obligate pathways in assembly processes and (2) the use of proteins that are essential for assembly but which are not present in the completed virion. The latter means that assembly cannot be understood by simply examining the properties of the components of the completed virion. In addition, the protein and lipid parts of virions are not simple containers designed solely for the protection of the nucleic acid inside. They are also sophisticated molecular devices that are designed to deliver their nucleic acid payloads into sensitive cells by mechanisms that are as varied as the ways in which they are assembled. No doubt, this requirement that virions be metastable 'spring-loaded' structures, that can spontaneously release their nucleic acid when the right external signal is received, is largely responsible for the complexity of phage virion structure and assembly. Because of this diversity and complexity, the study of phage assembly has shed considerable light on the mechanisms of many other macromolecular assembly processes.

History

The genus *Cardiovirus* contains two species, *Encephalomyocarditis virus* and *Theilovirus* (**Table 1**). The first report of a cardiovirus was by Theiler in 1934. He reported that a neurological disease of mouse could be transmitted by intracerebral or intranasal inoculation, and was caused by a virus, which persisted in the central nervous system (CNS). This virus is known as Theiler's murine encephalomyelitis virus (TMEV). The disease was described as a polio-like infection with destruction of neurons of the anterior horns of spinal cord. Later, similar agents were isolated from the intestinal contents of normal mice and other rodents. Initially, some of these viruses were confused with poliomyelitis virus. In the early 1950s, Daniels *et al.* reported that a recently isolated strain of Theiler's virus, the DA strain, was responsible for a chronic white matter disease characterized by focal demyelination. A comprehensive picture was finally given in the mid-1970s by Lipton who showed that the DA strain, as well as the strains originally isolated by Theiler, cause a biphasic disease characterized by an initial polio encephalomyelitis with destruction of neurons followed by a chronic inflammatory and demyelinating disease of white matter resembling multiple sclerosis.

The first strain of encephalomyocarditis virus (EMCV), Columbia SK, was isolated from cotton rats (*Sigmodon hispidus*) by Jungeblut and Sanders in 1940. Immunological studies showed that this agent, which caused a flaccid paralysis of the hind limbs of mice followed by death, was a new and different neurotropic virus. This first description was followed by the isolation of MM virus in 1943, of EMCV in 1945, and Mengo virus in 1946. A last member of this serological group was isolated in 1949 by Gronnert, from the intestinal tissues of a sick mouse; this was called mouse-encephalomyelitis or maus-Elberfeld (ME) virus. A close relationship between all these viruses was soon recognized. Warren and Smadel in 1948 reported that sera from humans or animals containing neutralizing antibodies against EMCV would also neutralize Columbia SK and MM viruses. In 1949, Dick demonstrated cross-neutralization between Mengo and EMC viruses. Since the late 1960s, EMCV infection in laboratory animals has been used extensively as a research tool and model for human diseases. Extensive work has

been carried out using animal models for diabetes mellitus, cardiovascular diseases, polymyositis, and diseases of the CNS. More recently, EMCV has been recognized as a viral pathogen of domestic animals, especially swine. Clinical outbreaks of EMCV infection in pig herds were first encountered in Panama in 1958 and in Florida in 1960. Subsequently, clinical outbreaks in pigs have been reported in North America, New Zealand, Australia, Brazil, Cuba, Greece, Italy, Belgium, and Cyprus. In addition, EMC virus or antibodies have been detected in several species, including rodents, domestic and wild mammals, birds, and humans, often without evidence of clinical disease.

Properties of the Virion and Genome

The virion of all cardioviruses contains single-stranded positive-sense RNA of 2.6×10^6 Da enclosed in an icosaedral capsid. The genome varies in length from 7800 to 8000 nt and is composed of the leader protein followed by the four structural proteins (VP1–4) and seven nonstructural proteins (2A, 2B, 2C, 3A, 3B, 3C, 3D). The coding region is surrounded by two untranslated regions (UTRs) at the 5′ and 3′ ends. The 5′ UTR comprises an internal ribosome entry site (IRES) from which viral protein translation is initiated. EMC viruses, but not theiloviruses, contain an unusual polypyrimidine (poly C) tract within the distal region of their 5′ UTRs. This tract could be involved in viral virulence, although its exact role remains unclear, and can vary in length from 60 to 420 residues, depending upon the strain of virus. In all cardioviruses, the 3′ UTRs terminate with a heterogeneous poly (A) tail, being involved in the binding process of the viral RNA-dependent RNA polymerase, whose encoding gene is located upstream to the 3′ UTR.

Cardioviral proteins and their precursors take their names (L, P1, P2, P3) from their sequential locations within the polyprotein (**Figure 1**). The leader or L proteins are present only in the EMC viruses and the persistent strains of TMEV. The EMC L proteins play an undefined role in host or tissue tropism and may also be involved in translational regulation of the IRES. The four P1 peptides are the capsid proteins 1A, 1B, 1C, and 1D. The middle portion of the polyprotein (P2) contains peptides 2A, 2B, and 2C. Protein 2C is an ATPase, not a polymerase, and its contribution to the replication cycle remains unclear. The P3 peptides, 3A, $3B^{VPg}$, $3C^{pro}$, and $3D^{pol}$ are more closely associated with genome replication. Protein 3B is VPg, the peptide covalently linked to the 5′ end of the genome. VPg sequences are rich in basic, hydrophilic amino acids and have only one tyrosine residue (the attachment site) at position 3 from the amino end of the peptide. Protease $3C^{pro}$ is the central enzyme in the viral cleavage cascade.

Taxonomy and Classification

The cardioviruses constitute a separate genus, *Cardiovirus*, within the family *Picornaviridae*. They are distinguished from other picornaviruses by their pathological properties, genome organization, and the dissociability of their virions at pHs between 5 and 7 (in 0.1 M NaCl). The genus *Cardiovirus* consists of two species, *Encephalomyocarditis virus* and *Theilovirus*. Comparative analysis of RNA sequencing of different isolates has shown a clear difference between the two species (**Table 1**; **Figures 2** and **3**).

Encephalomyocarditis virus is represented by a single serotype of the same name. Mengovirus, Columbia SK virus, and Maus Elberfeld virus are strains of EMCV, based on serological cross-reaction and sequence identity. The species *Theilovirus* consists of three viruses (which are probably distinct serotypes): TMEV, Vilyuisk human encephalomyelitis virus (VHEV), and rat Theiler's-like virus (TLV). A fourth virus, rat encephalomyelitis virus (REV), is probably a strain of TMEV, although conclusive sequence data are awaited. Theiloviruses are also divided into two subgroups, based on neurovirulence (see the section titled 'Pathogenicity').

Virus Propagation

Cardioviruses replicate in primary or continuous cell lines originating from a variety of species, including murine, bovine, porcine, human, primate, guinea pig, and hamster. Baby hamster kidney (BHK-21) and Vero cells are most commonly used. The virus also replicates in baby mice and chicken embryos and is pathogenic to many laboratory animals. EMC virus hemagglutinates guinea pig, rat, horse, and sheep erythrocytes. Serial passages of EMC viruses in cell culture can alter *in vitro* growth characteristics, reduce virulence, and affect hemagglutinating activity.

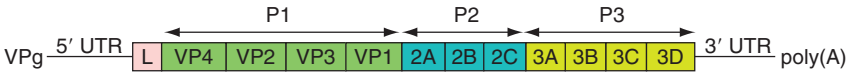

Figure 1 Diagram of the cardiovirus RNA genome, showing the genome-linked VPg at the 5′ end, the 5′ untranslated region (5′ UTR), the leader protein (L), the three viral protein coding regions P1 (VP4, VP3, VP2, VP1), P2 (2A, 2B, 2C), and P3 (3A, 3B, $3C^{pro}$, $3D^{pro}$), the 3′ untranslated region (3′ UTR), and the poly (A) tail.

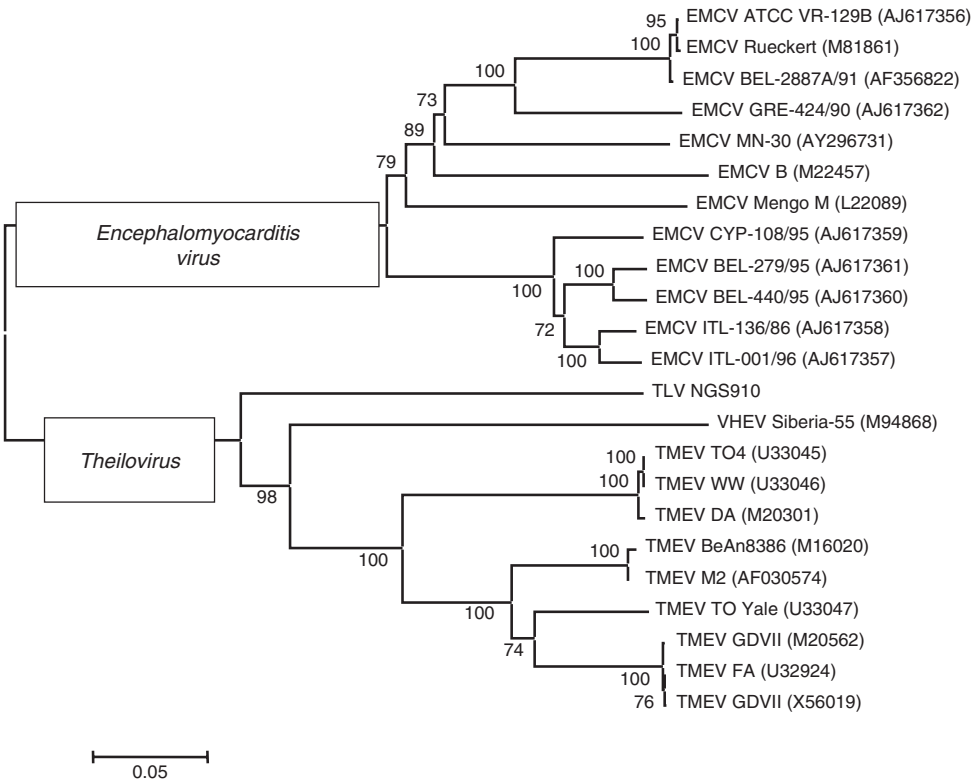

Figure 2 Neighbor-joining tree based on a comparison of nucleotide similarities of P1 capsid polypeptides of EMCVs and theiloviruses. The tree was generated with the MEGA 3.1 program. Neighbor-joining trees were constructed from a different matrix employing the Kimura two-parameter correction. One thousand bootstrap pseudoreplicates were used to test the branching (shown as percentages). For abbreviations, see **Table 1**. Data provided by Dr. N. J. Knowles, Institute for Animal Health, Pirbright Laboratory, UK.

Replication

The virus particle attaches to a cell receptor and is taken into the cell. The RNA genome is then uncoated and translated into a single polyprotein which is cleaved in a cascade of events catalyzed by the viral protease $3C^{pro}$, and possibly by protein 2A in the case of the 2A/2B cleavage. The viral RNA is replicated by the RNA polymerase $3D^{pol}$ through a complementary negative strand. Notably, proteins L and 2A are not required for viral replication in BHK-21 cells, although they may play important roles *in vivo*. Provirions are assembled by packaging RNA within capsid pentamers to form infectious particles. The replication takes place in the cell cytoplasm (**Figure 7**). However, in the case of EMCV, dense and empty viral particles have also been found in the nucleus of cardiac muscle cells (**Figure 8**).

Evolution

The complete genome sequences of P1 capsid-coding region (CCR) of 12 EMC viruses, nine TMEVs, a Theiler's-like virus of rats, and a Vilyuisk human encephalomyelitis virus have been deposited in GenBank databases. Phylogenetic and molecular evolutionary analyses using MEGA 3.1 confirmed that two distinct species exist: EMCVs and theiloviruses. The 12 EMCVs formed one cluster, while the second cluster comprised all theiloviruses. These clusters differed by an average of approximately 42%. The maximum nucleotide variation among EMCVs was 21.70%, whereas within Theilovirus group it was 29.70%. The tree constructed from amino acids shows how viruses within a serotype are more closely related than they appear on the tree constructed from nucleotides, while members of different serotypes are still more distantly related (**Figures 2** and **3**).

Genetic analysis of European pig EMC viruses, in comparison with Mengo virus, have been performed with sequences of the $3D^{pol}$ gene and the VP3/VP1 junction. These studies showed clustering of all the European isolates in two lineages, A and B, with a similar tree topology for both genome regions. A correlation between the phylogeny and the geographic origin was demonstrated, but no link was established with the clinical picture induced in pigs. Phylogenetic analyses of nucleotide sequences of the coding regions (the Leader gene, the CCR, and the end of $3D^{pol}$ gene) also confirmed the A and B subgroups of

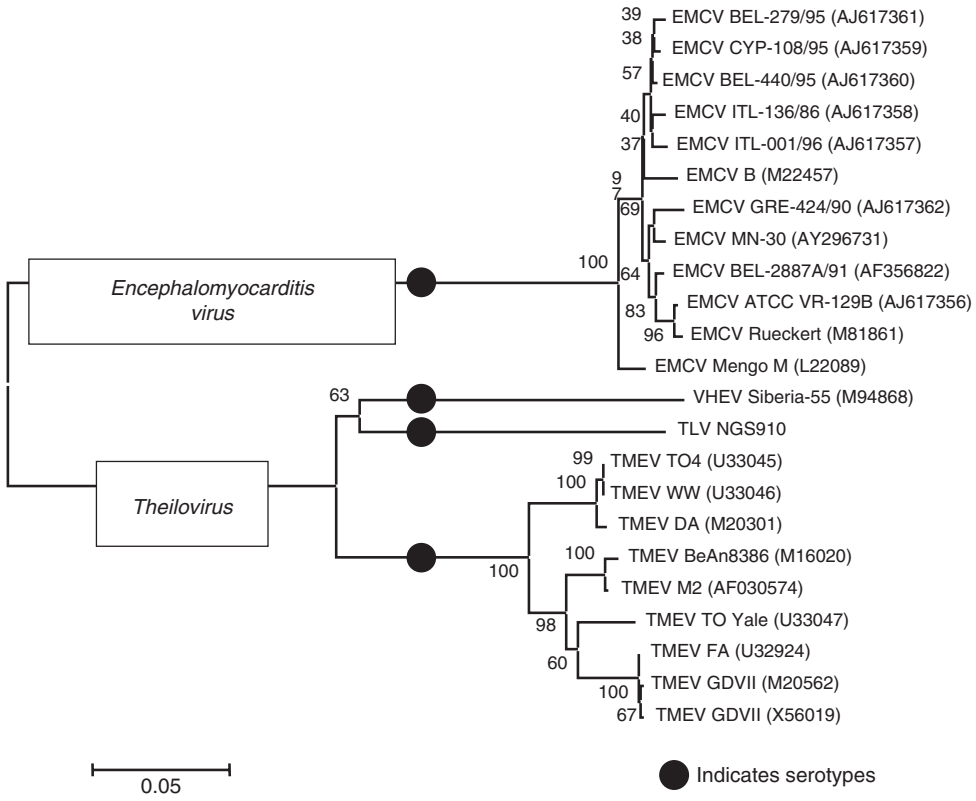

Figure 3 Neighbor-joining tree based on a comparison of amino acid similarities of P1 capsid polypeptides of EMCVs and theiloviruses. The tree was generated with the MEGA 3.1 program. Neighbor-joining trees were constructed from a different matrix employing the Kimura two-parameter correction. One thousand bootstrap pseudoreplicates were used to test the branching (shown as percentages). For abbreviations, see **Table 1**. Data provided by Dr. N. J. Knowles, Institute for Animal Health, Pirbright Laboratory, UK.

EMCV. In addition, the topology of the tree constructed on the 5′ UTR showed that a Greek isolate, with complex clinical picture, was different, and most closely related to Mengo, in comparison to the others. The divergence of this isolate was also observed for the sequence of the 3′ UTR reduced by the 14 nt upstream to the poly (A) tail. This short adenosine-rich region involved in RNA polymerase binding influenced considerably the topology of the tree. It also appeared that the length of the poly (C) tract was not related to the difference in virulence observed between various EMCV isolates as it has been described for other EMCV strains in the past.

Serial passages *in vivo* of an EMCV pig isolate had a limited impact on the nt and aa sequence of the regions targeted, with an exception of the 2A gene and VP1, but it had a critical effect on the virulence of the virus by inducing its attenuation. A large deletion of 115 aa was found within the 2A gene which encodes a protein able to affect a co-translational break in the polyprotein chain at its own C-terminus releasing P1–2A. The N-terminal cleavage of 2A from P1 CCR is achieved by the virus-encoded proteinase $3C^{pro}$. The EMCV 2A protein also contains a nuclear localization signal, which allows it to migrate to nuclei and nucleoli where it is involved in inhibition of cellular mRNA transcription and inhibition of cap-dependent mRNA translation, respectively. The deletion, which had been reported in the *in vitro*-passaged EMCV, removed all of 2A except the 18 aa necessary for the N- and C-terminal protein processing; thus, this deletion could, at least in part, be responsible for the attenuation observed experimentally. In addition, the mutation located at position 62 of VP1, which is adjacent to the aa responsible for the ability of certain EMCV strains to induce diabetes in mice, could also be involved in attenuation. Moreover, the low variability that has been detected after *in vivo* passages revealed that EMCV is stable in pigs.

Epidemiology (Geographic Distribution, Host Range, and Transmission)

Cardioviruses have a worldwide distribution and are associated with a wide variety of species. Rodents, especially rats, are considered to be the natural host and reservoir of EMCV. In wild rodents, the virus usually persists without causing disease, whereas infection in laboratory rodents,

especially baby mice, commonly produces fatal encephalitis and/or myocarditis. In pigs, natural infections with EMCV have different clinical characteristics, probably depending on different EMCV strains, which act with different pathogenicity. The infection has been recognized either as a cause of mortality in young pigs, due to acute myocarditis, or reproductive failure in sows. Clinical outbreaks of EMCV infection in pig herds were reported in Europe, Australia, New Zealand, and America. In Europe, the myocardial form has been reported in Greece, Italy, Cyprus, and Belgium. The reproductive form has only been reported in Belgium. In addition, apparently subclinical infections were reported in British and Austrian pigs, with a serological prevalence of 28% and 5%, respectively.

Two major routes of infection are suggested for the introduction and/or subsequent spread of the virus within a pig farm. The first infection route is ingestion of feces or carcasses of infected rodents, as many outbreaks have been linked with rodent plagues. The second route is horizontal pig-to-pig transmission through virus excretion by acutely infected pigs for 1–4 days. The virus can also be transiently excreted from persistently infected pigs, after reactivation of the infection. Transplacental infection has also been described as a potential route of virus spread. Other factors, such as infectious dose, route of infection, and age of pigs, have been found to be important in the spread of the virus under experimental conditions.

Clinical outbreaks in zoological parks and research institutions, involving several animal species, including elephants, artiodactyls, marsupials, mongooses, porcupines, and primates, have also been reported. In addition, EMCV virus or antibodies have been detected in domestic and wild mammals, birds, and humans, often without evidence of clinical disease.

There have been reports that humans are susceptible to EMCV. However, most of the evidence has been indirect, based on the presence of antibodies. In the 1950s, only a few documented cases of EMCV infection in humans were associated with fever, neck stiffness, lethargy, delirium, and headache. Human cases have been reported in Australia, in an area with a high incidence of EMCV in pigs. An EMCV outbreak in a zoo in the US, involving multiple animal species, did not result in illness in humans, although a zoo attendant who cared for EMCV-infected primates demonstrated a high antibody titer. Recent serological surveys indicate that human EMCV infections are relatively common in certain areas of the world (i.e., Austria, Greece), but generally are asymptomatic or unrecognized. Recent advances toward using pig tissues as a means of overcoming the acute shortage of transplantation tissues and organs for humans have made it necessary to determine the risk of transmitting this zoonotic virus from pigs to humans. The experimental infection of mice by transplanting pig organs infected with EMCV demonstrates that the risk is real.

TMEV is a natural enteric pathogen of mice that causes asymptomatic infection, but on rare occasions the virus will invade the CNS. TMEV shares many biological characteristics in common with poliovirus, another member of the picornavirus family, that may include spread from host to host via the fecal–oral route or the oropharyngeal–oral route.

Pathogenicity, Clinical Features, and Pathology

Encephalomyocarditis Virus

The expression of clinical disease in animals depends upon both viral and host factors. In susceptible species, strains of EMCV vary in virulence and/or tissue tropism. In the natural hosts, wild rodents, the virus usually persists without causing disease. Among laboratory animals, clinical manifestations and pathogenesis of EMCV are variable. Certain virus strains cause predominantly fatal encephalitis, widespread myocardial damage, or specific destruction of pancreatic β-cells. The course of infection varies in rats, mice, guinea pigs, hamsters, gerbils, rabbits, and monkeys, depending on the age of the animals and the virus strain used.

On the basis of organ tropism in mice, Graighead in 1966 classified EMCV into two variants, E (neurotropic) and M (myocardiotropic). EMCV-M also shows tropism for the β-cells of the pancreas, producing a disease syndrome similar to insulin-dependent diabetes mellitus. In 1980, Yoon *et al.* established a highly diabetogenic D variant and a nondiabetogenic B variant by repeated purification of EMCV-M. In addition, EMCV strains vary in pathogenicity and tissue tropism. In adult rats and mice experimentally infected with two myocardial EMCV strains of pig origin, no clinical signs or gross lesions were observed. Regardless, virus was isolated from several tissues from the third day post infection until the end of the observation, at 62 days post infection. EMCV was most frequently isolated from Peyer's patches and thymus. The results suggested that these tissues represent a site of persistence. Furthermore, EMCV antigen was detected in various organs but consistently in the heart and thymus.

In zoo animals, the disease is characterized by sudden death due to acute myocarditis. With the exception of pigs, domestic animals are generally resistant to overt clinical EMCV infection. In pigs, disease due to EMCV may take one of two main forms, depending on the tropism of the viral strain: an acute myocarditis (usually in piglets) or reproductive failure in sows. Each form of the disease in pigs (myocardial or reproductive) seems to be restricted to certain geographical areas, probably reflecting the character of viral strains originating from local rodent populations. Pig age at the time of infection is an important determinant of clinical severity. Extremely

high mortality, approaching 100%, is limited to pigs of pre-weaning age. Infections in pigs from post-weaning age to adulthood are usually subclinical, although some mortality may be observed even in adult pigs. The myocardial form is most commonly characterized by acute disease with sudden death due to myocardial failure. Other clinical signs may be observed, including lethargy, inappetence, trembling, staggering, paralysis, vomiting, and dyspnea. Persistent infection has been demonstrated, the virus persisting in lymphoid tissues and transiently excreted in the feces following reactivation. Macroscopical lesions vary in severity and consist of multiple white-gray linear or circular areas, which are visible in the wall of the ventricles, especially those of the right ventricle (**Figure 4**). Histopathological lesions are characterized mainly by interstitial mononuclear cell infiltration, degeneration, and necrosis of cardiac muscle cells and occasionally calcium deposits (**Figures 5** and **6**). Electron microscope examination reveals presence of the virus intracytoplasmically in cardiac muscle cells, Purkinje fibers, and endothelial cells of the capillaries and intranuclearly in cardiac muscle cells (**Figures 7** and **8**). In breeding females, clinical signs may vary from no obvious illness to various forms of reproductive failure, including poor conception rates, embryo resorption, mummification, stillbirths, abortions, and neonatal death.

Theiler's Virus

Theiloviruses are divided into two subgroups, based on neurovirulence following intracerebral inoculation of mice: GDVII and Theiler's Original (TO). The GDVII group includes GDVII and FA strains; it is extremely neurovirulent and induces acute fatal polioencephalomyelitis without demyelination. The TO group is less

neurovirulent and includes the TO4, TO-Yale, BeAn, WW, and DA strains. These strains cause a biphasic disease in which the early phase is characterized by an acute encephalomyelitis. If the virus persists, the animals will develop a chronic demyelinating disease in the CNS.

A large number of detailed pathogenesis studies in mice have been reported and reviewed. Generally, no clinical signs are observed, but on rare occasions the virus may invade the CNS and cause neurological disease. After ingestion, the virus replicates in the pharynx or the lower gastrointestinal tract, spreads to local and regional lymphatic tissue, and then invades the blood stream before penetrating and replicating in the nervous system, resulting in unilateral or bilateral flaccid paralysis of the hind limbs and rarely other neurological signs. It is postulated that invasion of the CNS is taking place via the circulation and crossing the blood–brain barrier (BBB) or through lymphatic channels. The BBB is composed of specialized cerebrovascular endothelial cells, which restrict vesicular transport and protect the CNS from harmful substances circulating in the blood. Hematogenous virus entry into the CNS may involve endothelial cells and/or macrophages. TMEV viral RNA has been detected in vascular endothelial cells, neurons, and glial cells in the brain and spinal cord. Moreover, mononuclear cells isolated directly from the CNS inflammatory infiltrates of TMEV-infected mice were found to contain infectious viral antigens, and TMEV was found to replicate in brain macrophages. Several studies also suggest that the main viral dissemination route for Theiler's virus may occur by infection of peripheral organs, such as muscle, followed by viral entry from these secondary sites via peripheral neural routes.

Diagnosis

Encephalomyocarditis Virus

In piglets, the disease is often characterized by sudden death without any prior clinical signs. The most striking lesions are white-gray linear or circular areas under the endocardium and epicardium. All age categories may be affected, but mostly pigs 20–40 days are involved. In sows, a clinical history of reproductive failure and pre-weaning piglet mortality is suggestive of EMCV infection. EMCV-induced reproductive problems should be differentiated from other pathogens, such as porcine reproductive and respiratory syndrome, Aujeszky's disease, and porcine parvovirus.

Histopathological examination may contribute to diagnosis. A variable degree of nonsuppurative interstitial myocarditis is characteristic of EMCV infection. The presence of virus antigen both in the cytoplasm and in the nucleus of cardiac muscle cells by immunohistochemical examination with the use of monoclonal antibodies further strengthens the diagnosis. A conclusive diagnosis of EMCV should be demonstrated by virus isolation in sensitive cell culture (e.g., BHK-21) and identification by cross-serum neutralization with a reference antiserum. Virus isolation should be attempted mainly from heart and spleen tissues of acutely infected piglets. Experimental infection in piglets demonstrated that the virus could be easily isolated during the period of viremia, that is, from 1 to 5 days post infection. Nucleic acid probes and reverse transcription-polymerase chain reaction (RT-PCR) may provide sensitive and specific methods of diagnosis.

The commonly used serological test is virus-neutralization test. Enzyme-linked immunosorbent assay (ELISA) may also be used, if available. However, serology should not be used alone, as EMCV antibodies have been detected in areas with no clinical disease, presumably due to nonpathogenic EMCV strains.

Theiler's Virus

Molecular detection by PCR is highly sensitive and specific for TMEV. It is used for monitoring laboratory mouse colonies. Serological detection of the virus is inadequate, especially in nude or immunocompromised mice.

Prevention and Control

There is no specific treatment for EMC. In pigs, avoiding stress or excitement in affected animals may minimize mortality. EMCVs appear to persist in rodents and are most likely to affect pigs and zoo animals when rodent populations are high. Elimination or reduction of feral rodent populations is recommended in the prevention

and control of EMCV in order to minimize environmental contamination with virus. Prompt and proper disposal of animals that have died of the disease is also recommended. EMCV is inactivated by the use of disinfectants labeled for use against nonenveloped viruses. Autogenous and commercial killed vaccines or a genetically engineered vaccine have been used for the prevention of the myocardial form in pigs or zoo animals.

Recent studies demonstrated that the vaccination of mice with cDNA encoding the capsid proteins of TMEV could alter the course of TMEV-induced demyelinating disease. A single vaccination with cDNA encoding VP1 led to increased pathology in the CNS and increased clinical expression of disease. In another study, vaccinating mice three times with cDNA encoding the capsid proteins VP2 and VP3 reduced TMEV-induced disease, as demonstrated by a decrease in clinical expression of disease and reduce CNS pathology.

Glossary

Symptomless Having no apparent symptoms of disease.

Triple gene block (TGB) A specialized evolutionarily conserved gene module of three partially overlapping ORFs involved in the cell-to-cell and long-distance movement of some plant viruses.

Introduction

The genus *Carlavirus* derived from the name of the type species *Carnation latent virus* is one of nine genera in the family *Flexiviridae* and contains a large number of members and tentative members. The carlavirus-infected natural host plants usually have very mild symptoms or remain symptomless, and thus the term 'latent' appears in the names of many species of the genus *Carlavirus*. The natural host range of individual species is restricted to a few plant species. This tendency toward mild or latent (symptomless) infection, a characteristic feature of carlaviruses, has led to carlaviruses and carlavirus-associated diseases failing to attract any special attention from phytopathologists and phytovirologists. However, many members of the genus have been identified in the last few decades and most of them have been associated with more serious diseases when plants are co-infected with other viruses. Most species are transmitted by aphids in a nonpersistent manner but two species (*Coupea mild mottle virus* and *Melon yellowing-associated virus*, CPMMV and MYaV) are transmitted by whiteflies (*Bemisia tabaci*).

Taxonomy and Classification

The genus *Carlavirus* belongs to the family *Flexiviridae*. The type species of the genus is *Carnation latent virus*. The name carlavirus was derived from the type species. The genus contains a large number of members. In total, 68 members of the genus *Carlavirus* (39 definitive species and 29 tentative species) are listed in **Table 1**. Some members listed as species and all members listed

as tentative species have no sequence data, and therefore the taxonomic status of these members is yet to be verified.

Carlaviruses are either closely or distantly related to each other and these relationships have been confirmed by phylogenetic analysis of some viral proteins. The phylogenetic tree analysis of sequenced carlaviruses is presented in **Figure 1**.

Species demarcation criteria in this genus include the following:

1. distinct species have less than about 72% nucleotides or 80% amino acids identical between their coat protein (CP) or replicase genes;
2. distinct species are readily differentiated by serology, and strains of individual species are often distinguishable by serology;
3. distinct species do not cross-protect in infected common host plant species, and each distinct species usually has a specific natural host range and distinguishable experimental host ranges.

Virus Structure and Composition

Virions are slightly flexuous filaments that are not enveloped, and measure 610–700 nm in length and 12–15 nm in diameter. Nucleocapsids appear longitudinally striated. Virions have helical symmetry with a pitch of 3.3–3.4 nm. Virion M_r is about 60×10^6 with a nucleic acid content of 5–7%. Virions contain a monopartite, linear, single-stranded, positive-sense RNA that has a size range of 7.4–9.1 kbp in length. The 3′ terminus has a poly(A) tract and the 5′ terminus occasionally has a methylated nucleotide cap, or a monophosphate group. CP subunits are of one type, with size 31–36 kDa. The genome is encapsidated in 1600–2000 copies of CP subunit. Purified preparations of carlaviruses such as potato virus S and helinium virus S (PVS, HVS) contain small amounts of encapsidated subgenomic RNAs.

Physicochemical Properties

Virus particles in purified preparations have a sedimentation coefficient of 147–176 S. Isoelectric point of virions is about pH 4.5. The UV absorbance spectra of carlaviruses have maxima at 258–260 nm and minima at 243–248 nm, with A_{max}/A_{min} ratios of 1.1–1.3, and the A_{260}/A_{280} ratio of purified preparation is 1.08–1.40. Physical properties of viruses in this genus are: thermal inactivation point (TIP) 50–85 °C, longevity *in vitro* (LIV) 1–21 days, and dilution endpoint (DEP) 10^{-2}–10^{-7}. Infectivity of sap does not change on treatment with diethyl ether. Infectivity is retained by the virions despite being deproteinized by proteases and by phenols or detergents.

The CPs of the carlaviruses are partly degraded during purification and storage of virus preparations. The carlavirus virions are susceptible to and can be broken down by denaturing agents such as sodium dodecyl sulfate (SDS), urea, guanidine hydrochloride, acetic acid, and alkali.

Genome Structure and Gene Expression

The genome is a single-stranded RNA (ssRNA), 7.4–9.1 kbp in size, which contains six open reading frames (ORFs), encoding the replicase, three putative protein components of movement proteins called triple gene block (TGB), the CP, and a putative nucleic acid-binding regulatory protein, from the 5′–3′-end in that order (**Figure 2**). In genome organization, the genus *Carlavirus* particularly resembles the genera *Allexivirus*, *Foveavirus*, *Mandarivirus*, and *Potexvirus* but is distinguished from them by its six ORFs and a large replication protein. The genome RNA is capped at the 5′ end and polyadenylated at the 3′ end. The 223 kDa viral replicase ORF is translated from the full-length genomic RNA. For expression of its 3′-proximal viral genes, the virus utilizes at least two subgenomic RNAs. The genome structure of potato virus M (PVM) (8553 nt) is represented in **Figure 2**. PVM RNA has 75 nt 5′ untranslated region (UTR) at the 5′ terminus and 70 nt 3′ UTR followed by

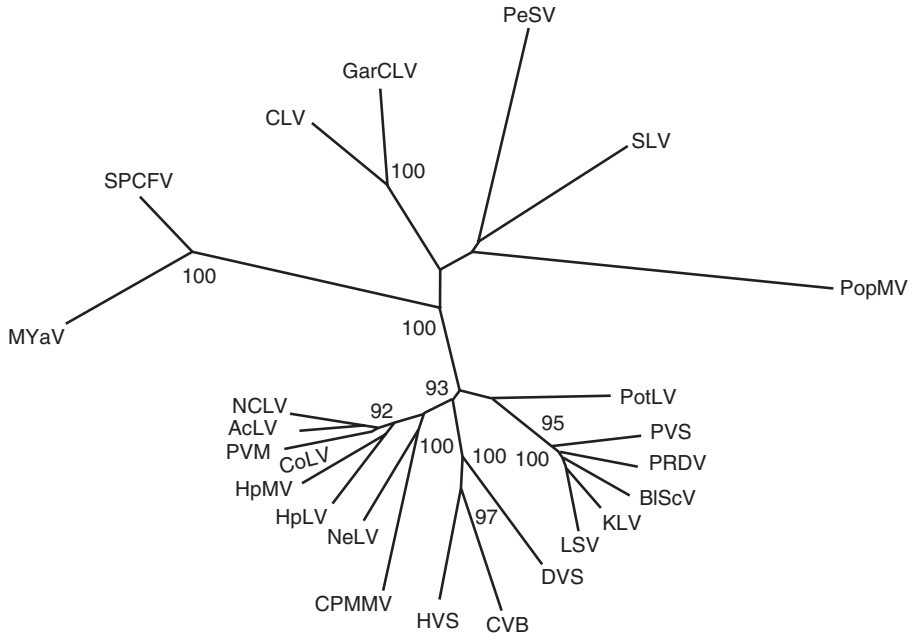

Figure 1 Phylogenetic tree of carlaviruses derived from multiple-aligned deduced amino acid sequences of CP. See **Table 1** for abbreviations of carlavirus names.

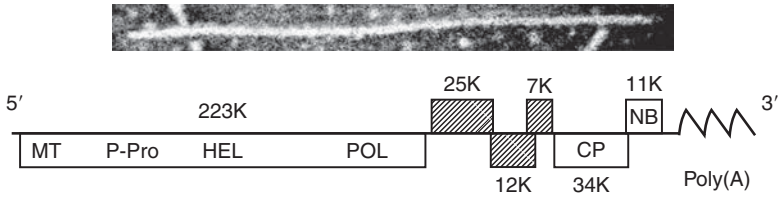

Figure 2 Particle morphology and genome organization of potato virus M (PVM), showing a typical genome structure for the genus *Carlavirus* in the family *Flexiviridae*. The 5′-proximal one large ORF encodes an RNA-dependent RNA polymerase (viral replicase), three overlapping ORFs encode the putative MPs (TGBs), and two ORFs encode CP and nucleic acid binding protein (NB). Motifs in the replicase are methyltransferase (MT), papain-like protease (P-Pro), helicase (HEL), and RNA-dependent RNA polymerase (POL).

a poly(A) tail at the 3′ terminus and intergenic UTRs of 38 and 21 nt between three large blocks of coding sequences. Carlavirus-infected plants contain double-stranded RNA (dsRNA) whose molecular mass corresponds to that of genomic RNA.

ORF1 encodes a 223 kDa polypeptide that is presumed to be the viral replicase. It contains motifs of methyltransferase, a papain-like protease, helicase, and RNA-dependent RNA polymerase. With blueberry scorch virus (BLScV) and probably other carlaviruses, the 223 kDa viral replicase is proteolytically processed by papain-like protease activity, which results in about 30 kDa being removed. ORFs 2–4 form the TGB encoding polypeptides of 25, 12, and 7 kDa, respectively, which facilitate virus cell-to-cell movement. ORF5 encodes the 34 kDa CP, and ORF6 encodes a cysteine-rich 11 kDa protein. The function of the 3′-proximal 11 kDa polypeptide has yet to be elucidated, but its ability to bind nucleic acid and agroin-filtration-mediated transient expression studies suggest that it may facilitate vector transmission, may be involved in viral RNA transcription, or may be a viral pathogenicity determinant for plant defense system.

Putative promoters for the subgenomic RNA synthesis have been identified for several carlaviruses, C/UUUAGGU, 19–43 residues upstream from both putative subgenomic RNA initiation sites.

Complete genomic sequences have recently been obtained for some carlaviruses: BLScV (8512 nt), chrysanthemum virus B (CVB) (8870 nt), daphne virus S (DVS) (8739 nt), hop latent virus (HpLV) (8612 nt), lily symptomless virus (LSV) (8394 nt), PVM (8553 nt), PVS (8478 nt), shallot latent virus (SLV) (8363 nt), aconitum latent virus (AcLV) (8657 nt), poplar mosaic virus (PopMV) (8741 nt), passiflora latent virus (PLV) (8386 nt), narcissus symptomless virus (NSV) (8281 nt),

sweetpotato chlorotic fleck virus (SPCFV) (9104 nt), and narcissus common latent virus (NCLV) (8539 nt).

Infectious cDNA clones have been reported for two carlaviruses, BlScV and PopMV.

Viral Transmission

Carlaviruses are spread by mechanical contact, by horticultural and agricultural equipment, and transmitted in a nonpersistent or semipersistent manner by aphids with varying efficiencies, or by whiteflies. Some members are not transmitted by mechanical inoculation. Seed transmission may occur with some legume-infecting carlaviruses, but is not common. Transmission by root grafts may occur in the case of PopMV. Those viruses that infect vegetatively propagated hosts persist in the propagated parts.

Cytopathology

The distribution of carlaviruses in the infected plant is not tissue specific. Virions are usually found in the cytoplasm, or sometimes in chloroplasts or in mitochondria of infected tissues, or may occur in membrane-associated bundle-like or plate-like aggregates. Inclusions are present in infected cells of some members. They occur as crystals in the cytoplasm, as amorphous X-bodies, membranous bodies, and viroplasms and they sometimes contain virions.

Host Range

Infection by most members of this genus is symptomless in the natural host. The individual natural host ranges are, usually narrow, although a few species can infect a wide range of experimental hosts.

Symptomatology

Carlavirus infection often results in no apparent symptoms in natural hosts. Symptoms vary cyclically or seasonally or may disappear soon after infection. If symptoms are evident, more severe symptoms such as mosaics appear in early stages of infection. Some carlaviruses such as PVM, PVS, and BlScV cause diseases that are of economic importance on their own; however, most of them are associated with more serious diseases when the plants are co-infected with other viruses.

Serology

Carlavirus virions are good immunogens. Serological relationships among carlaviruses may be close or distant or sometimes undetectable: some species are serologically interrelated but others apparently distinct. A number of carlaviruses are more or less closely interrelated serologically, with serological differentiation indices (SDIs) ranging from about 3.5 to 6.5.

Geographical Distribution

Some carlaviruses are found wherever their natural hosts are grown, but the geographical distribution of many species is restricted to only certain parts of the world. Those infecting vegetatively propagated crops are usually widely distributed. Most species commonly occur in temperate regions, but whitefly transmitted carlaviruses are restricted to tropical and subtropical regions.

Viral Epidemiology and Control

Most carlavirus-associated diseases are usually very mild or symptomless and few efforts are made to control them. However, crops such as potatoes, certain legumes, and blueberries that may contain more damaging carlaviruses require suitable control measures. Seed potatoes and vegetatively propagated materials must be screened continuously to certify a virus-free status. Rapid removal of infected plants is particularly important for plants associated with aphid- or whitefly-vectored carlaviruses. PVS is the only carlavirus for which transgenic plants (potato and *Nicotiana debney*), which are resistant to virus infection, have been reported so far.

Carmovirus

F Qu and T J Morris, University of Nebraska, Lincoln, NE, USA

© 2008 Elsevier Ltd. All rights reserved.

Taxonomy, Classification and Evolutionary Relationships

Carmovirus is one of eight genera in the family *Tombusviridae*. Members of this family all have icosahedral virions of about 30 nm in diameter with $T = 3$ symmetry that consists of 180 coat protein (CP) subunits of about 38–43 kDa and a single-stranded (ss) RNA genome ranging in size from 4.0 to 4.8 kbp. Carmoviruses share recognizable yet varied sequence similarity with members of other genera of *Tombusviridae*.

Carmoviruses contain a single-component positive-sense genome of about 4.0 kbp. The genome, as exemplified by turnip crinkle virus (TCV) in **Figure 1**, consists of five definitive open reading frames (ORFs) which encode proteins of about 28, 88, 8, 9, and 38 kDa from the 5′ to the 3′ end, respectively. Some carmoviruses such as hibiscus chlorotic ringspot virus (HCRSV) have additional ORFs of unknown functions. The virions are icosahedral in symmetry and consist of 180 CP subunits of approximately 38 kDa. The genus name is derived from the first member of the genus to be sequenced, carnation mottle virus (CarMV). Much more detailed knowledge about virus structure and genome function is, however, known for TCV because its crystal structure has been determined and it was the first carmovirus for which infectious transcripts were produced from a cDNA clone of the genome.

To date, the nucleotide sequences of 12 definitive carmoviruses have been determined (see **Table 1**). These sequenced members share similar morphological and physicochemical properties with about a dozen other viruses listed in **Table 1** that are recognized as species or tentative species depending on the level of detail of the molecular characterization of the viral genomes. Various carmoviruses are sufficiently distant from each other that they do not cross-react in standard RNA hybridization or serological tests.

Carmoviruses share properties with viruses belonging to other genera of the family *Tombusviridae*. Their particle structure and CP sequences are closely related to tombus-, aureus-, diantho-, and avenaviruses. Their RNA-dependent RNA polymerase (RdRp) genes share significant homology with viruses of the following genera: *Machlomovirus*, *Panicovirus*, *Necrovirus*, *Aureusvirus*, and *Tombusvirus*. Carmovirus RdRp genes also share similarity with more distantly related viruses outside of *Tombusviridae*, such as umbraviruses and luteoviruses. In a broader context, phylogenetic comparisons of viral RNA polymerase genes have identified the *Tombusviridae* as a representative plant virus cluster for one of three RNA virus supergroups with relatedness to animal viruses of *Flaviviridae* and small RNA phage (*Leviviridae*).

Distribution, Host Range, Transmission, and Economic Significance

Carmoviruses occur worldwide and are generally reported to cause mild or asymptomatic infections on relatively restricted natural host ranges. Most accumulate to high concentrations in infected tissues and are mechanically transmitted. Beetle transmission has been reported for some carmoviruses as has transmission in association with soil and/or irrigation water, and in some cases in association with fungal zoospores.

A number of carmoviruses have been identified in association with ornamental hosts and have been widely distributed in such hosts by vegetative propagation. CarMV is the most noteworthy, being widespread in cultivated carnations, and recognized as one of the more important components of viral disease complexes in this crop worldwide. It accumulates to high concentrations without producing severe symptoms and spreads primarily by contact transmission and vegetative propagation. It has a broad experimental host range that includes over 30 species in 15 plant families. Pelargonium flower break virus (PFBV) is widespread in vegetatively propagated *Pelargonium* species causing disease in association with other viruses. The incidence of narcissus tip necrosis virus (NTNV) in narcissus cultivars and HCRSV in hibiscus primarily reflects distribution of infected nursery stock.

Numerous small RNA viruses have been reported to naturally infect cucurbits causing significant disease problems. Several of these viruses are recognized tombusviruses while others such as melon necrotic spot virus (MNSV) and cucumber soil-borne virus (CSBV) have been identified as carmoviruses based on sequence and genome organization properties. MNSV occurs worldwide in greenhouse cucurbits and is both soil and seed transmitted, while CSBV has been primarily restricted to infrequent outbreaks around the Mediterranean. Both have been reported to be transmitted in association with the fungus *Olpidium bornovanus*.

Several carmoviruses have been discovered in natural leguminous hosts, with glycine mottle virus (GMoV) being potentially the most important, causing serious disease losses in legumes in Africa. Bean mild mosaic virus (BMMV) has been reported to be a latent virus

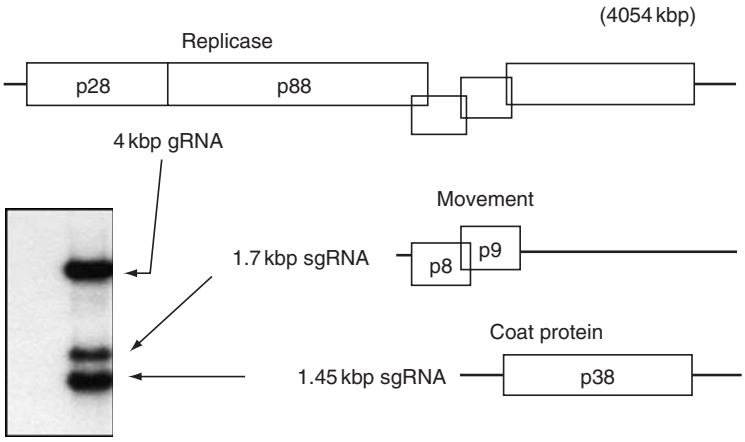

Figure 1 Genome organization of a typical carmovirus as represented by turnip crinkle virus (TCV). The boxes represent open reading frames with the sizes of the encoded proteins indicated within the boxes, in kilodaltons. The two proteins required for replication (p28 and p88) are translated from the 4 kbp genomic RNA with the p88 protein translated by readthrough of an amber codon at the end of the p28 gene. Two small proteins involved in cell-to-cell movement (p8 and p9) are translated from a 1.7 kbp subgenomic RNA. The viral coat protein (p38) is translated from a 1.45 kbp subgenomic RNA. The panel on the left is a Northern blot showing the typical pattern of accumulation of genomic and subgenomic RNAs in carmovirus-infected cells.

Calibrachoa mottle virus	(CbMV)
Elderberry latent virus	(ELV)
Glycine mottle virus	(GMoV)
Narcissus tip necrosis virus	(NTNV)
Plaintain virus 6	(PlV-6)
Squash necrosis virus	(SqNV)
Tephrosia symptomless virus	(TeSV)

widely distributed in bean cultivars in El Salvador, and backgram mottle virus (BMoV) has been found in *Vigna* species in Asia. Beetle vectors have been identified for these viruses, but seed transmission may also be an important factor in their distribution.

TCV is neither common nor widespread in nature in spite of the fact that it is reportedly beetle transmitted. It has a relatively wide experimental host range in some 20 plant families including experimentally useful species such as *Arabidopsis* and *Brassica* in which it accumulates to extremely high concentrations, often approaching a level equivalent to 0.5% of the fresh weight of the plant tissue. Cardamine chlorotic fleck virus (CCFV) was first discovered in the Mount Kosiusko alpine region of Australia in *Cardamine lilacina*, a wild perennial of the family Brassicaceae. It has also been shown to infect *Arabidopsis* and other Brassicaceae species.

Other carmoviruses have been isolated worldwide from natural hosts with little apparent disease and are presumably of little agricultural concern. These include tephrosia symptomless virus (TeSV) from legumes in Kenya, GMoV from glycine in Australia, saguaro cactus virus (SCV) from saguaro cactus in Arizona galinsoga mosaic virus (GaMV) from potato weed in Australia, and plaintain virus 6 (PlV-6) from plantain weed in England. The infrequent isolation of these genetically similar viruses in remote locations around the world has prompted the speculation that ancestor carmoviruses may have been introduced into their natural hosts well before the last Ice Age and have since co-evolved in isolation in their diverse host plants.

Virion Structure and Assembly

Four carmoviruses (TCV, CarMV, cowpea mottle virus (CPMoV), and HCRSV) have now been analyzed in structural detail, with TCV being the first and most thoroughly studied by high-resolution X-ray crystallography. The detailed information about CP structure and

intersubunit interactions established that TCV and tomato bushy stunt tombusvirus (TBSV) show marked structural conservation. In this regard, the common structural features shared by other members of the family *Tombusviridae* have been primarily deduced from alignment of the amino acid sequence of the coat proteins of TBSV and TCV. TCV consists of a $T = 3$ icosahedral capsid of 180 subunits of the 38 kDa CP. The individual CP subunit folds into three distinct domains typical of CP subunit of tombusviruses. The relatively basic N-terminal R domain extends into the interior of the virus particle and presumably interacts with viral RNA. The R domain is connected by an arm to the S domain which constitutes the virion shell. The S domain is attached through a hinge to the P domain which projects outward from the virion surface. The protein subunits are believed to form dimers in solution and during assembly.

TCV is also the only carmovirus on which detailed *in vitro* assembly studies have been performed. The virion has been shown to dissociate at elevated pH and ionic strength to produce a stable RNA–CP complex (rp-complex) and free CP subunits. Reassembly under physiological conditions in solution could be demonstrated using the isolated rp-complex and the soluble CP subunits. This rp-complex, consisting of six CP subunits tightly attached to viral RNA, could be generated *in vitro* and was shown to be important in selective assembly of TCV RNA. A model for assembly was proposed in which three sets of dimeric CP interact with a unique site on the viral RNA to form an initiation complex to which additional subunit dimers could rapidly bind. Preliminary characterization of the 'origin of assembly' for this virus identified two possible sites based on the identification of RNA fragments in the rp-complex protected from RNase digestion by CP. Further *in vivo* studies narrowed the assembly origin site to a bulged hairpin-loop of 28 nt within a 180 nt region at the 3′ end of the CP gene.

Genome Structure

Complete nucleotide sequences have been determined for 12 carmoviruses as listed in **Table 1**. Comparative studies of the deduced ORFs revealed that all of these viruses encode a similar set of genes that are closely related and in the same gene order as illustrated for TCV in **Figure 1**. The genome organization of the carmoviruses is quite compact with most of the identified ORFs overlapping each other. Both the product of the most 5′ proximal ORF (26–28 kDa) and its readthrough product (86–89 kDa) are essential for replication of the TCV genome. The 3′ proximal gene encodes the viral CP which varies from 37 to 42 kDa for the different viruses. All of the sequenced carmoviruses characteristically encode two small ORFs in the middle of the genome that both have been shown in TCV to be indispensable for cell-to-cell movement (movement proteins or MP). Although the genome organizations of all sequenced carmoviruses are quite similar, there are some unique features evident in the individual carmoviruses. For example, the two small central ORFs in MNSV (p7a and p7b) are connected by an in-frame amber codon that could result in the production of a 14 kDa fusion protein of the two ORFs by a readthrough mechanism. The CPMoV as well as HCRSV are predicted to encode a sixth ORF nested within the 3′ proximal CP gene. HCRSV has also been reported to encode another novel protein that is nested within the RdRp gene.

The 5′ end of the genome is not capped. The 5′ noncoding region varies from 34 nt in CPMoV to 88 nt in MNSV. No extensive sequence homology was observed within this region. The 3′ noncoding region of carmoviruses varies from about 200 to 300 nt in length and possesses neither a poly-A tail nor a tRNA-like structure.

Replication and Gene Expression

Carmoviruses replicate to very high concentrations in protoplasts, with the genomic RNA accumulating to levels approaching that of the ribosomal RNAs. Upon infection of susceptible plants, carmoviruses transcribe two 3′ coterminal subgenomic RNAs (sgRNAs) for expression of the MP and CP genes. The smaller sgRNA (*c.* 1.5 kbp) is the mRNA for CP. The larger sgRNA (*c.* 1.7 kbp) presumably functions as the mRNA for the two MP genes utilizing a leaky scanning mechanism. Results involving transgenic expression of the p8 and p9 gene products of TCV in *Arabidopsis* plants have demonstrated that both of them are essential for viral cell-to-cell movement and that they function by in *trans*-complementation in the same cell.

Carmoviruses are thought to replicate through a (−) strand intermediate because virus-specific double-stranded RNAs (dsRNAs) corresponding in size to the genomic RNA and sgRNAs characteristically accumulate in infected plant tissue. The product of the 5′ proximal ORF (p28 in TCV) and its readthrough product (p88 in TCV) are the only virus-encoded components of the polymerase complex. When expressed from two separate mRNAs, p28 and p88 complemented *in trans* to enable the genome replication. The only host factor found to augment TCV replication so far is the eukaryotic translation initiation factor 4G (eIF4G) of *Arabidopsis*, presumably through more efficient translation of viral genes. Recently, a membrane-containing extract prepared from evacuolated protoplasts of uninfected *Arabidopsis* plants has been shown to faithfully produce both genomic and subgenomic RNAs from a full-length TCV RNA template. Such an extract should be useful in

characterizing viral as well as host elements required for virus replication.

Recent studies have demonstrated that, besides the virus-encoded proteins, a plethora of structural elements in the viral RNA play critical roles in the genome replication of carmoviruses. These elements are located throughout the entire viral genome and occur in both the (+) and (−) strands. Their roles range from promoters, enhancers, or repressors for RNA replication and transcription, enhancers for translation, and specificity determinants for virus assembly. The current knowledge of these RNA structures suggests that different secondary structural motifs, some of them mutually exclusive, are formed at the different stages of virus multiplication, and the highly coordinated nature of their formation ensures optimal utilization of the compact viral genome.

Satellites, Defective-Interfering RNAs

TCV is the only carmovirus in which replication of associated small subviral RNAs in infected plants has been characterized, and the situation for this virus is curiously complex. TCV infections are associated with defective interfering (DI) RNAs derived totally from the parent genome (e.g., RNA G of 342–346 nt), satellite RNAs of nonviral origin (e.g., RNAs D, 194 nt and F, 230 nt), and chimeric RNAs (e.g., RNA C of 356 nt) with a 5′ region derived from sat RNA D and a 3′ region derived from the 3′ end of the TCV genome. All three types of small RNAs depend on the helper virus for their replication and encapsidation within the infected plant. The different satellite and DI RNAs have been shown to affect viral infections in different ways. Both RNA C and G intensify viral symptoms while interfering with the replication of the helper virus, while RNAs D and F seem to produce no detectable effects on either expression of symptoms or helper virus replication.

Virus–Host Interaction

Considerable progress has been made in the last decade in our understanding of the molecular mechanisms of virus–plant interactions with significant contributions coming from studies utilizing TCV and its host plant *Arabidopsis*. Most notably, one ecotype of *Arabidopsis thaliana* has been determined to be resistant to TCV infection and the resistance gene (*HRT*) and its encoded protein have been characterized. Additional host factors that contribute to the resistance response have also been elucidated including the identification of a novel transcription factor (TIP) whose interaction with TCV CP is critical for the initiation of the resistance response. The determination that TCV CP is targeted by HRT resistance protein suggests that TCV CP plays a key role in combating antiviral defense mechanisms of the plant host, in addition to being required for virus assembly. Interestingly, recent studies have also established that TCV CP is a strong suppressor of RNA silencing, a host defense mechanism that targets invading RNA. RNA silencing is a potent defense mechanism that is conserved in nearly all eukaryotic organisms. Accordingly, TCV CP is an effective silencing suppressor in both plant and animal cells. Silencing suppressor activity has also been associated with several other carmovirus CPs, establishing this activity as a conserved feature of the structural subunit.

TCV CP is also important in satellite RNA C interactions in the host plant. Normally, the presence of RNA C results in symptom intensification in TCV infections. However, when the TCV CP ORF is either deleted or replaced by the CCFV CP ORF, RNA C attenuates symptoms caused by the helper virus suggesting that CP either downregulates the replication of RNA C or enhances its own competitiveness.

Finally, the replicase gene has also been implicated in the symptom modification by satellite RNA C by two independent groups. The 3′ end of the TCV genome, a sequence common in TCV RNA, RNA C, and DI RNA G, was also suggested to be a symptom determinant. Environmental conditions also affect the extent of resistance of *Arabidopsis* plants to TCV. In conclusion, it is clear that recent intensive studies of TCV have established this small RNA virus as an ideal model for unraveling the complicated processes involved in viral pathogenesis.

Glossary

Agroinoculation An inoculation technique in which *Agrobacterium tumefaciens* is used to deliver a full-length infectious clone of a virus into a plant cell.
Plasmodesmata A narrow channel of cytoplasm that functions as a bridge between two plant cells to facilitate movement of macromolecules.
Reverse transcriptase An enzyme that utilizes an RNA template for synthesis of DNA.
Ribosome shunt A translational mechanism in which ribosomes enter the RNA at the 5′ end and scan for a short distance before being translocated to a downstream point.
Semipersistent transmission Vector acquires the virus in minutes to hours, and can transmit to other plants for hours after the initial feeding.
Transgene A gene introduced into an organism through any one of a number of genetic engineering techniques.

Introduction

The members of the family *Caulimoviridae* are plant viruses that replicate by reverse transcription of an RNA intermediate and whose virions contain circular, double-stranded DNA (dsDNA). They replicate by reverse transcription, but unlike the true retroviruses, integration into the host chromosomes is not required for completion of their replication cycle. The circular DNA encapsidated in virions is not covalently closed, as it contains at least one discontinuity in each DNA strand, and these discontinuities occur as a consequence of the replication strategy of the virus. There are six genera in this family and they can be divided into two groups based on virion morphology; the members of the genera *Caulimovirus*, *Petuvirus*, *Cavemovirus*, and *Soymovirus* contain viruses that form icosahedral particles that are largely found within amorphous inclusion bodies in the cell (**Figures 1(a)** and **1(b)**). In contrast, the members of the genera *Badnavirus* and *Tungrovirus* form bacilliform particles that are not associated with inclusion bodies (**Figure 1(c)**). Their virions are found in the cytoplasm either individually or clustered in palisade-like arrays.

Cauliflower mosaic virus (CaMV), a member of the type species *Cauliflower mosaic virus* of the genus *Caulimovirus*, was the first of the plant viruses to be shown to contain dsDNA in its icosahedral virion by Shepherd in 1968. This discovery led to an extended investigation into its replication strategy throughout the 1970s and early 1980s, culminating in Pfeiffer and Hohn's study in 1983 that showed that CaMV replicates through reverse transcription of an RNA intermediate. Perhaps because the genome of CaMV is composed of dsDNA, it was also the first of the plant viruses to be completely sequenced and cloned into bacterial plasmids in an infectious form.

In the early 1980s, CaMV was thought to have some promise as a vector for foreign genes in plants. However, the effort to convert CaMV into a vector was scaled back when it was shown that the virus genome could tolerate only small insertions of up to a few hundred basepairs of DNA. A few small genes, such as dihydrofolate reductase and interferon, were eventually expressed in plants via a CaMV vector, but other viruses have been shown to be much more versatile as vectors for foreign genes. Although the caulimoviruses have had only limited utility as plant virus vectors, they continue to have a great impact on plant biotechnology. The 35S promoter of CaMV is capable of directing a high level of transcription in most types of plant tissues. This promoter was used to drive expression of one of the first transgenes introduced into transgenic plants, and it is still widely used for expression of transgenes for both research and commercial applications. The promoter regions of several other

caulimoviruses have also been evaluated for expression of transgenes in both monocots and dicots, and they can be good alternatives to the CaMV 35S promoter.

The feature that was used initially to characterize the caulimoviruses was the presence of circular dsDNA encapsidated into icosahedral virions of approximately 50 nm diameter. However, as icosahedral viruses continued to be isolated from a variety of hosts and their genomes sequenced, it was discovered that their genome structure diverged from that of CaMV. These differences were significant enough for the International Committee on Taxonomy of Viruses (ICTV) to create three new genera in its VIII ICTV Report. Consequently, *Soybean chlorotic mottle virus*, *Cassava vein mosaic virus*, and *Petunia vein clearing virus* became the type species of the genera *Soymovirus*, *Cavemovirus*, and *Petuvirus*, respectively.

For many years, only plant viruses that had icosahedral virions of 50 nm in diameter were thought to have genomes composed of dsDNA. However, in 1990, Lockhart showed that the bacilliform virions of commelina yellow mottle virus (CoYMV) contained circular, dsDNA, and *Commelina yellow mottle virus* became the type species for the genus *Badnavirus*. Lockhart showed that nucleic acid isolated from the bacilliform virions was resistant to RNase and degraded by DNase. Furthermore, DNA treated with S1 nuclease revealed that the CoYMV genome contained at least two single-stranded discontinuities, a hallmark of the plant viruses that replicate by reverse transcription. In addition to CoYMV, Lockhart also purified DNA from banana streak virus, kalanchoe top-spotting virus (KTSV), and canna yellow mottle virus, providing evidence that they should also be placed in the new genus *Badnavirus*. There are now 18 species in the genus *Badnavirus* (**Table 1**), many of which cause economically important diseases in the tropics. However, new badnaviruses have been characterized since the publication of the VIII Report of the ICTV, so this number will almost certainly be revised upward in the near future.

Soon after the discovery that CoYMV was a DNA virus, the bacilliform component of rice tungro disease was also shown to contain circular, dsDNA. Rice tungro is the most important virus disease of rice in South and Southeast Asia, with annual losses approaching $1.5 billion dollars. The disease is caused by a complex of an RNA virus, called rice tungro spherical virus (RTSV) coupled with the bacilliform dsDNA virus called rice tungro bacilliform virus (RTBV). The genus *Tungrovirus* is distinguished from the genus *Badnavirus* because RTBV has one more open reading frame (ORF) than CoYMV and overall, the RTBV genome has only 20–25% nucleotide sequence identity with members of the genus *Badnavirus*. There is only one species in the genus *Tungrovirus*, although several isolates of the species *Rice tungro bacilliform virus* have been collected and sequenced.

Taxonomy and Classification

The family *Caulimoviridae* consists of six genera (**Table 1**), and they can be conveniently divided into two groups based on virion morphology. Viruses with icosahedral virions (**Figure 1(b)**) include the genera *Caulimovirus*, *Petuvirus*, *Soymovirus*, and *Cavemovirus*. Viruses with bacilliform virions (**Figure 1(c)**) include the genera *Badnavirus* and *Tungrovirus*. Genera can be further distinguished because of differences in genome organization and nucleotide differences in common genes such as the reverse transcriptase. All members of the family *Caulimoviridae* infect only plants. There are no animal or insect viruses in this family.

Virion Structure and Composition

The viruses in the genera *Caulimovirus*, *Cavemovirus*, *Soymovirus*, and *Petuvirus* form nonenveloped, isometric particles that vary in size from 43 to 50 nm. The virion is

composed of 420 subunits with a $T = 7$ structure. The viruses in the genera *Badnavirus* and *Tungrovirus* form nonenveloped, bacilliform particles that are 30 nm in width, but can vary in length from 60 to 900 nm. The length most commonly observed is 130 nm. Their structure is based on an icosahedron, in which the ends are formed from pentamers and the tubular section is made up of hexamers.

The virions of the family *Caulimoviridae* contain a single, circular dsDNA that is 7.2–8.3 kbp in length. Complete and partial nucleotide sequences of members of the family *Caulimoviridae* are listed in **Table 1**. Only a single accession number is given for CaMV and RTBV, although multiple strains of each have been sequenced.

Genome Organization and Expression

Several genome features are common to all members of the family *Caulimoviridae*, in addition to their circular dsDNA genomes. For example, the dsDNA is not covalently closed; it has at least two discontinuities, but may have up to four. Furthermore, all of the ORFs are found on only one of the DNA strands and all of the viruses have at least one strong promoter that drives the expression of a terminally redundant mRNA. In addition, all of the viruses have a reverse transcriptase, and in most cases it is located downstream from the coat protein. Several active sites can be identified within the reverse transcriptase protein, including a protease, the core reverse transcriptase, and RNaseH activity. The reverse transcriptase of PVCV is distinguished from all other members of the family *Caulimoviridae* because it has the core features of an integrase function, in addition to other functions. The most significant difference among the caulimoviruses concerns the arrangement and number of ORFs, and this is illustrated in an examination of the genome organization and expression strategies of CaMV and CoYMV (**Figure 2**).

The genome of CaMV is approximately 8000 bp in size and it contains three single-stranded discontinuities (**Figure 2(a)**). One discontinuity occurs in the negative-sense DNA strand and, by convention, this is the origin of the DNA sequence. Two other discontinuities occur in the positive-sense strand, one at nucleotide position 1600 and a second at approximately nucleotide position 4000. The virus genome consists of seven ORFs. ORF1 encodes a protein necessary for cell-to-cell movement (P1). ORF2 and -3 (proteins P2 and P3) are both required for aphid transmission. P2 is responsible for binding to the aphid stylet, whereas P3 is a virion-associated protein. To complete the bridge for aphid transmission of virions, the C-terminus of P2 physically interacts with the N-terminus of P3. Recent evidence also indicates that P3 may have an additional role in cell-to-cell movement. ORF4 encodes the coat protein, and ORF5 encodes a reverse transcriptase that also has protease and RNaseH domains. With the exception of PVCV, none of the reverse transcriptases of the *Caulimoviridae* have evidence for an integrase function. The ORF6 product (P6) was originally described as the major inclusion body protein, but it also has a function as a translational transactivator (TAV). It physically interacts with host ribosomes to reprogram them for reinitiation of translation of the polycistronic 35S RNA. Furthermore, P6 is an important symptom and host range determinant. No protein product has been found for ORF7. Its nucleotide sequence appears to play a regulatory role in aligning ribosomes for translation of other CaMV gene products.

Two transcripts are produced from the CaMV genomic DNA. The 19S RNA serves as the mRNA for P6, whereas the terminally redundant 35S RNA serves as a template for reverse transcription and as a polycistronic mRNA for ORFs 1–5. One feature common to many of the caulimoviruses is the ribosomal shunt mechanism of translation. The ribosomal shunt has undoubtedly evolved over time to compensate for the complexity and length of the leader sequence of the genomic RNA. In the case of CaMV, this

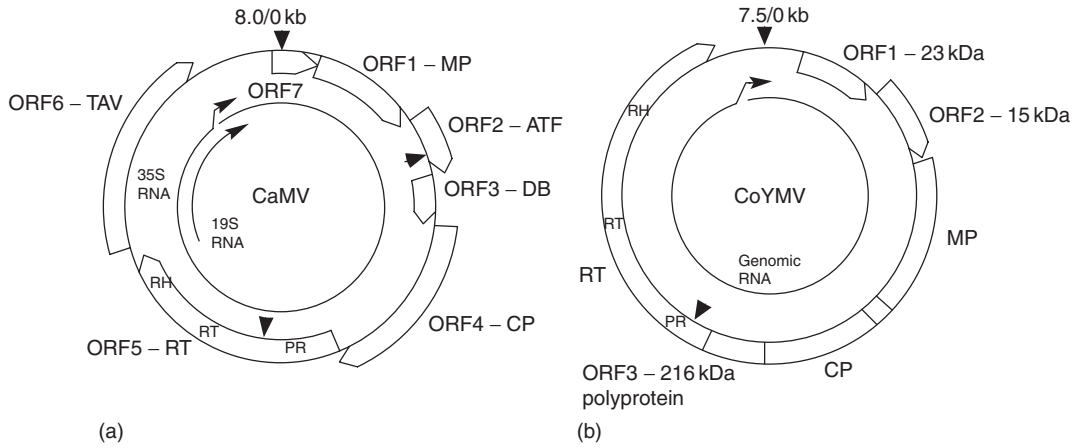

Figure 2 Genomic maps of (a) CaMV and (b) CoYMV. The single-stranded discontinuity in the negative-sense DNA strand is indicated by the triangle outside of the circle, whereas single-stranded discontinuities in the positive-sense DNA strand are indicated by triangles inside the circle. The mRNAs for each virus are represented by the inner circles and the 3′ end of the RNA is indicated by the arrowhead. The functions for each of the ORFs are MP, cell-to-cell movement protein; ATF, aphid transmission factor; DB, DNA-binding protein, which also has role in aphid transmission; CP, coat protein; RT, reverse transcriptase; TAV, translational transactivator and major inclusion body protein. The domains within the reverse transcriptase are: PR, protease; RT, reverse transcriptase domain; and RH, ribonucleaseH activity. ORF3 of CoYMV encodes a 216 kDa polyprotein that is cleaved to produce the MP, CP, and RT proteins.

leader sequence is approximately 600 bp in length and it contains up to nine short ORFs that vary in size from 9 to 102 nt. The complexity of the CaMV 35S RNA leader sequence is bypassed through the formation of a large stem–loop structure, which allows ribosomes to bypass most of the leader and to initiate translation at ORF7. CaMV utilizes several other strategies for expression of the 35S RNA, including splicing and reprogramming of host ribosomes by the TAV for reinitiation of translation.

The genome of CoYMV is approximately 7500 bp in size, and the circular DNA contains two single-stranded discontinuities, one in each strand (**Figure 2(b)**). As with CaMV, the discontinuity in the negative-sense DNA strand serves as the origin of the DNA sequence, whereas the discontinuity in the positive-sense strand is found at approximately nucleotide position 4800. CoYMV encodes a single transcript that is terminally redundant, with 120 nucleotides reiterated on the 5′ and 3′ ends. The virus genome consists of three ORFs, encoding proteins of 23, 15, and 216 kDa, respectively. Both the 23 and 15 kDa proteins are associated with the virions. The 23 kDa protein contains a coiled-coil motif and by analogy with the P3 protein of CaMV, may be necessary for cell-to-cell movement. The 216 kDa P3 protein is a polyprotein that contains motifs for a movement protein, coat protein, aspartate protease, reverse transcriptase, and RNase H.

Replication

Caulimoviruses replicate by reverse transcription of an RNA intermediate, but integration of the viral DNA into host chromosomes is not required to complete the replication process. **Figure 3** illustrates the replication of an icosahedral caulimovirus, but the same steps are applicable for the bacilliform viruses. After virions enter a plant cell, the viral DNA becomes unencapsidated and is transported into the nucleus. The viral DNA contains two to four single-stranded discontinuities, which form as a consequence of the reverse transcription process. Once in the nucleus, the single-stranded discontinuities are covalently closed and the DNA is associated with histones to form a minichromosome. The host RNA polymerase II is responsible for synthesizing an RNA that is terminally redundant; the sequence on the 5′ end is reiterated on the 3′ end. In the case of CaMV, the terminal redundancy is 180 nt in size, whereas the terminal redundancy in the CoYMV RNA is 120 nt. The terminally redundant RNA is transported out of the nucleus into the cytoplasm where it can either serve as a template for translation of viral proteins or as a template for reverse transcription. Reverse transcription is thought to occur in nucleocapsid-like particles.

First strand DNA synthesis is primed by a methionine (Met) tRNA that binds to a complementary sequence near the 5′ end of the terminally redundant RNA. In the case of CaMV, the Met tRNA binds to a sequence approximately 600 nt from the 5′ end of its 35S RNA. The virally encoded reverse transcriptase synthesizes DNA up to the 5′ end of the terminally redundant RNA and the RNase H activity of the reverse transcriptase degrades the 5′ end of the RNA. The terminal redundancies present in the genomic RNA provide a mechanism for a template switch, as the reverse transcriptase is able to switch from the 5′ end of the genomic RNA to the same sequences on the 3′ end of the genomic RNA and continue to synthesize the first strand of DNA.

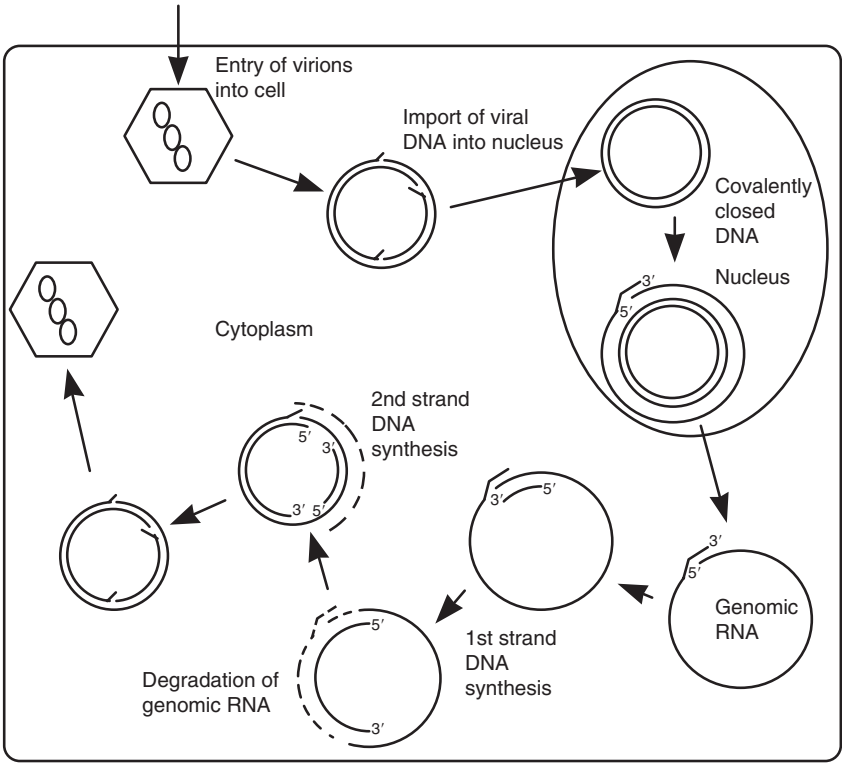

Figure 3 Replication strategy of the family *Caulimoviridae*.

The RNase H activity of the reverse transcriptase degrades the viral RNA template and small RNA fragments serve as the primers for second strand DNA synthesis. The RNA fragments bind to guanosine-rich tracts present in the first DNA strand, and these priming sites determine the positions of the discontinuities in the second DNA strand. A second template switch is required to bridge the gap from the 5′ to the 3′ end of the first DNA strand. The completion of the second DNA strand results in the formation of a dsDNA molecule that contains the characteristic single-stranded discontinuities.

Integration of Some Petuviruses, Cavemoviruses, and Badnaviruses into Host Chromosomes

Although caulimoviruses do not integrate into the host as part of their replication strategy, the sequences of several viruses have been detected in the genomes of their hosts. Furthermore, the integrated copies of several of these viruses, the banana streak viruses, TVCV and PVCV, can be activated to yield episomal infections. All three viruses can form virions once episomal infections are initiated, but they differ in their capacity to be transmitted to other plants. Banana streak virus can be transmitted by mealybugs, whereas PVCV is transmitted only by grafting. TVCV and PVCV are transmitted vertically, through seed, but this probably involves only the integrated copies of the virus rather than the episomal forms.

The sites of integration are complex, as the viral sequences have undergone rearrangements, and multiple copies are arranged in tandem. Banana streak virus is integrated at two loci in *Musa* chromosomes, TVCV is integrated at multiple loci in *Nicotiana edwardsonii* chromosomes, and PVCV is integrated into four loci in *Petunia hybrida* chromosomes. The mechanism that results in episomal infections remains to be elucidated, but there are some features common to all three viruses. First, the infections arise in interspecific hybrids. Consequently, each parent plant must contribute some factor to activate the integrated virus. Second, the infections arise after the hybrid has been exposed to some sort of stress. PVCV is activated when plants are exposed to water or nutrient stress, or the plants are wounded. TVCV infections arise in *N. edwardsonii* in the winter months in the greenhouse and are thought to be related to changes in light quality or duration. Integrated banana streak virus sequences are activated in otherwise healthy *Musa* species when they are subjected to tissue culture. In each case, the virus is likely released through a series of recombination events or through reverse transcription of an RNA template.

Portions of other DNA viruses have been detected in plant chromosomes, but they have not been associated with episomal infections. This has led to speculation that plant DNA viruses might be capable of recombination in every

infected plant, likely through a mechanism involving nonhomologous recombination. However, since episomal forms of the caulimoviruses and badnaviruses have not been found in tissues fated for seed formation, the integrated forms would not appear in the next generation of plants. Consequently, the banana streak viruses, TVCV, and PVCV must have gained access to germline cells at some point such that their integrants would be passed through seed. This is likely to have been a relatively rare event.

Transmission and Host Range

Most members of the genus *Caulimovirus* are transmitted by as many as 27 species of aphids in a semipersistent manner. The virions are acquired rapidly by the aphid and can be transmitted immediately upon acquisition. Virions can be maintained by the aphid for as little as 5 h up to 3 days, but are not retained after the aphid molts and are not passed on to aphid progeny. The protein products encoded by ORF2 (P2) and ORF3 (P3) are both required for aphid transmission. P3 forms a tetramer that binds to both the virion and to the C-terminus of P2. P2 is responsible for the binding of this complex to the aphid, as the N-terminus of P2 binds to a site in the aphid foregut. No insect vectors have been identified for species in the genera *Petuvirus*, *Soymovirus*, or *Cavemovirus*.

None of the virions of the icosahedral viruses in the genera *Caulimovirus*, *Petuvirus*, *Soymovirus*, or *Cavemovirus* are transmitted through seed or pollen. Most are transmitted after mechanical inoculation, but there are a few exceptions, as PVCV, TVCV, blueberry red ringspot virus, and strawberry vein banding virus cannot be mechanically inoculated. In addition, most of these viruses are transmitted by grafting. In particular, dahlia mosaic virus and blueberry red ringspot virus infections in the field may be initiated through vegetative propagation or through grafting of infected plant material.

Badnaviruses are transmitted primarily by mealybugs, but a few are transmitted by aphids. Badnaviruses transmitted by mealybugs include the banana streak virus species, the sugarcane bacilliform viruses, cacao swollen shoot virus, dioscorea bacilliform virus, kalanchoe top spotting virus (KTSV), piper yellow mottle virus, taro bacilliform virus, and schefflera ringspot virus. These viruses are transmitted in a semipersistent manner and can be retained after molts, but do not multiply in the mealybug and are not transmitted to progeny. The badnaviruses shown to be transmitted by aphids include gooseberry vein banding-associated virus, rubus yellow net virus, and spiraea yellow leafspot virus.

Other modes of transmission of the badnaviruses vary with the species. For example, CoYMV and KTSV can be mechanically inoculated, cacao swollen shoot virus and piper yellow mottle virus are mechanically inoculated with some difficulty, and rubus yellow net virus and taro bacilliform virus have not been shown to be mechanically inoculated. The preferred method for inoculation of infectious badnavirus clones is agroinoculation. Some of the badnaviruses are transmitted through seed, including the banana streak virus, KTSV, and mimosa bacilliform virus. KTSV is very efficiently transmitted by seed, with transmission rates from 60% to 90%, and is also transmitted in pollen.

RTBV is dependent on the RNA virus, RTSV, for its transmission. RTSV is vectored by a leafhopper, but causes only very mild symptoms. RTBV is only transmitted by the leafhopper in the presence of RTSV, but is responsible for the severe symptoms associated with the rice tungro disease. RTBV is not mechanically transmitted or carried in seed or pollen.

The host range of most caulimoviruses is fairly narrow, as in nature they generally infect plants within a single family (**Table 1**). Their experimental host range may extend to members of one or two other families, but in many instances, they may only infect a single genus of plants. There are a few exceptions. For example, the sugarcane bacilliform viruses have a broader host range than most badnaviruses, as they can infect *Sorghum*, *Rottboellia*, *Panicum*, rice, and banana. A limited host range can also be associated with similar limitations in the geographic distribution of the virus. For example, soybean chlorotic mottle virus has only been recovered from a few samples in Japan. Perhaps the virus with the smallest geographic distribution is stilbocarpa mosaic bacilliform virus, which has only been found on a single, small island in the Subantarctic, midway between Tasmania and Antarctica. Other viruses, such as CaMV, carnation etched ring virus, and dahlia mosaic virus are found worldwide, wherever their hosts are grown. Furthermore, the distribution of viruses that originate from integrated copies in their host's genomes, PVCV, TVCV, and the banana streak virus species, are also closely aligned with the locations of their hosts. Interestingly, the icosahedral viruses of the caulimoviruses tend to infect hosts in temperate climates, whereas the bacilliform viruses of the badnavirus group are more likely to infect hosts in tropical or subtropical climates.

Virus–Host Relationships

Caulimoviruses induce a variety of systemic symptoms in their hosts, from chlorosis, streaking, and mosaics, to necrosis. The best-characterized pathogenicity determinant is the P6 protein of CaMV, as it has been shown to play a key role in the formation of chlorotic symptoms in turnips. This virulence function was first associated with P6 through gene-swapping experiments between CaMV isolates. It was confirmed when P6 was transformed into

several species of plants, and in most cases, they exhibited virus-like symptoms. The P6 protein is also responsible for triggering systemic cell death in *Nicotiana clevelandii*, as well as a non-necrotic resistance response in *N. glutinosa*, and a hypersensitive resistance response in *N. edwardsonii*.

One feature that distinguishes the icosahedral viruses from the bacilliform viruses is that the former have the capacity to aggregate into amorphous inclusion bodies (**Figure 1(a)**), whereas the latter do not form inclusions. The inclusion bodies formed by the icosahedral viruses are not bound by a membrane, can range in size from 5 to 20 μm, and occur in virtually all types of plant cells. The inclusions can be visualized with a light microscope in strips of epidermal tissue that has been stained with phloxine B. Close examination of CaMV inclusion bodies by electron microscopy reveals that there are actually two types. One type contains many vacuoles and consists of an electron-dense, granular matrix that is composed primarily of the P6 protein (**Figure 1(a)**). A second, electron translucent type is made up of the P2 protein, a protein required for aphid transmission. Both types of inclusions are thought to have a role in the biology of the virus. The vacuolated inclusion bodies may be considered pathogen organelles, as they are thought to serve as the sites for replication of the viral nucleic acid, as well as translation of the 35S RNA and assembly of the virions. The electron translucent inclusions are considered to have a role in aphid transmission.

A second feature characteristic of the caulimoviruses is that the plasmodesmata of infected cells are enlarged enough to accommodate the 50 nm virions, as electron micrographs have revealed the presence of CaMV and CoYMV virions in the enlarged plasmodesmata. For both CaMV and CoYMV, the alteration in size is mediated by their proteins required for cell-to-cell movement. In infected protoplasts, the CaMV P1 protein has been shown to induce the formation of tubular structures that extend away from the protoplast surface. It is hypothesized that virions are assembled in the cell and then are escorted to the enlarged plasmodesmata by the cell-to-cell movement proteins.

Viruses of the Genus *Caulimovirus*

Several viruses have been assigned to the genus *Caulimovirus*, characterized by their content of open circular DNA, their icosahedral capsid, and their arrangement of seven open reading frames (ORFs) (**Table 1**). They have a narrow host range, usually restricted to one of the plant families. The genus *Caulimovirus* is one of six genera of the family *Caulimoviridae*, or plant pararetroviruses, which include three more genera of icosahedral viruses,

Table 1 Caulimoviruses species

Species	*Abbr.*	*Host range*	*Sequence*
Cauliflower mosaic virus	CaMV	Cruciferae	V00141; X02606; J02046
Carnation etched ring virus	CERV	Caryophyllaceae	X04658
Figwort mosaic virus	FMV	Scrophulariaceae	X06166
Strawberry vein banding virus	SVBV	Rosaceae	X97304
Horseradish latent virus	HRLV	Cruciferae	AY534728 - 33
Dahlia mosaic virus	DMV	Compositae	
Mirabilis mosaic virus	MiMV	Nyctaginacea	NC_004036
Thistle mottle virus	ThMoV	*Cirsium arvense*	

Note that *Blueberry ringspot virus and Cestrum yellow leaf curl virus*, originally classified as caulimoviruses, are not included because they belong to the genus *Soymovirus*.

Soymovirus, *Cavemovirus*, and *Petuvirus*, and two genera of bacilliform viruses, *Badnavirus* and *Tungrovirus*. Besides the differences in capsid structure of the two categories, the genera are distinct in the details of their genome arrangement and expression strategies (**Figure 1**).

Although members of the family *Caulimoviridae* (plant pararetroviruses), unlike retroviruses, do not integrate obligatorily into the host genome, 'illegitimately' integrated sequences have been found for several genera to date, that is, caulimo, petu-, cavemo-, badna-, and tungroviruses. These have been named commonly 'endogenous plant pararetroviruses' (EPRVs). EPRVs can be found in the pericentromeric region of chromosomes, are passively replicated together with the host DNA, and are inherited from generation to generation.

Properties of the Virion and Inclusion Bodies

Members of the genus *Caulimovirus* are icosahedral ($T = 7$), 45–50 nm in diameter and sediment between 200 and 250S. The main capsid components of Cauliflower mosaic virus (CaMV) are proteins with mobilities of 37 and 44 kDa on sodium dodecyl sulfate polyacrylamid electrophoresis. They are derived from ORF IV. The capsid is further decorated with 420 subunits of loosely bound 15 kDa virus-associated protein (VAP) derived from ORF III. In addition, CaMV particles contain minor amounts of other polypeptides: protease and reverse transcriptase derived from ORF V, and host casein kinase II. In cells infected with CaMV or a number of other caulimoviruses large numbers of virus particles accumulate in typical stable inclusion bodies, the matrix of which is the virus-encoded transactivator/viroplasmin (TAV) protein of 62 kDa, derived from ORF VI. Inclusion bodies are visible in the light microscope and can be stained with phloxin.

Properties of the Genome

The genome of the members of the family *Caulimoviridae* is built from 7200 to 8200 bp. It exists (1) in infected plant nuclei as supercoiled DNA bound to nucleosomes (minichromosome), (2) in infected cytoplasm as RNA with a ~180 nt redundancy, and (3) in virus particles as open circular dsDNA. The open form is due to nicks at specific sites in both strands with short 5′ overlaps (**Figure 2**), remnants of the reverse transcription process, which are apparently removed in the infected nucleus. The sequences of several of the caulimoviruses are known (**Table 1**). They contain seven ORFs in the order VII (dispensable unknown function), I (cell-to-cell movement), II (aphid transmission factor), III (VAP), IV (capsid protein precursor), V (protease, reverse transcriptase, RNase H), and VI (multifunctional protein, transactivator of translation/viroplasmin).

Properties of the Proteins

Movement Protein

CaMV and probably all the other members of the family *Caulimoviridae* with icosahedral capsid move from cell to cell as particles through tubular structures spanning the cell walls between adjacent cells. In CaMV the 37 kDa movement protein (MOV), coded for by ORF I, is responsible for the formation of these tubules and also provides their main component.

Aphid Transmission Factor

In general, aphids transmit viruses of the genus *Caulimovirus* and probably other genera of icosahedral (but not bacilliform) Caulimoviruses. In the case of CaMV, ORF II codes for the 18 kDa aphid transmission factor (ATF). Some of the viral inclusion bodies in CaMV-infected cells consist mainly of ATF. ATFs interact with the virus particles via their VAP and with tubulin and also with the cuticulum lining the tip the aphid's stylet. ATF mutants can still be transmitted by mechanical inoculation and by aphids that had previously be in contact with wild-type ATF either by feeding on plants infected with a related virus or on nutrient solutions supplied with artificially produced ATF.

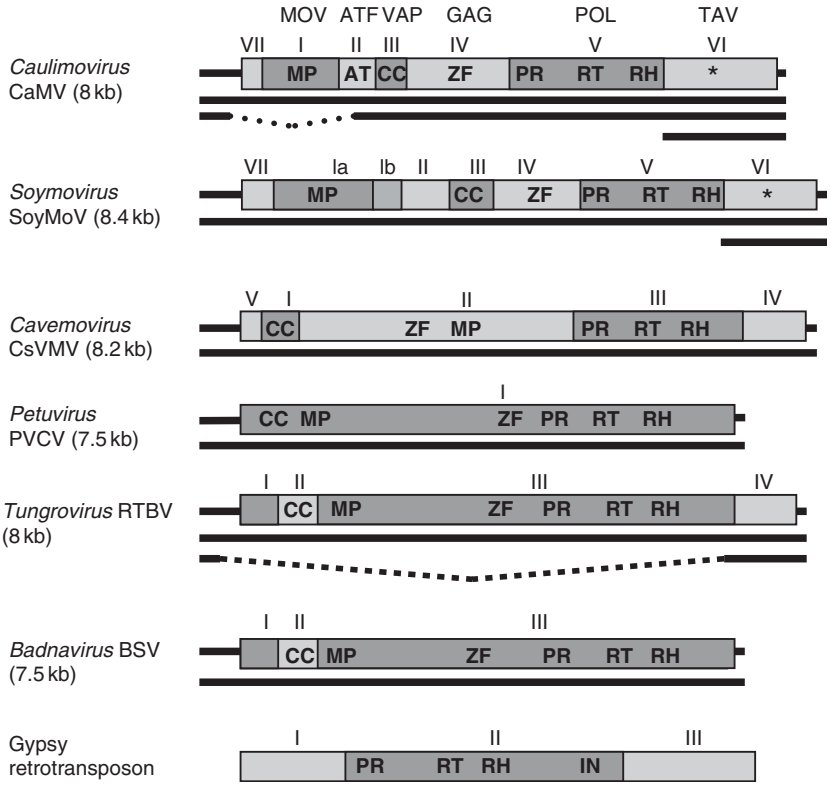

Figure 1 Open reading frame (ORF) arrangement in *Caulimovirus* and the other genera of the family *Caulimoviridae*. Examples of each of the six genera are shown, as well as the retrotransposon 'Gypsy' for comparison. For CaMV, the ORFs code for dispensable unknown function (VII), movement protein (I, MOV), aphid transmission factor (II, ATF), virion-associated protein (III, VAP), capsid protein precursor (IV, GAG), Pol polyprotein (V, POL), and transactivator/viroplasmin (VI, TAV). Although the number of final proteins might be similar for the other genera, the number of original ORFs differs, with soymoviruses having the most ORFs and petuviruses the least, namely only one original ORF, meaning more work for the protease to produce individual proteins. Key motifs are conserved in the family *Caulimoviridae*, movement protein motif (MP), coiled-coil domain (CC), zinc-finger (ZF), protease domain (PR), reverse transcriptase domain (RT), RNase H domain (RH), transactivator domain (*). In contrast to retroviruses and retrotransposons, an integrase domain (IN) is missing in members of the family *Caulimoviridae*.

Virion-Associated Protein

The VAP provides for coupling between virions and the movement and insect transmission factors and is therefore required for both insect transmission and cell-to-cell movement.

MOV, ATF, and VAP have no counterpart in retroviruses, reflecting the differences in cell-to-cell movement and infection routes used by animal and plant viruses. However, the movement proteins of plant pararetroviruses are related to a corresponding class of genes in most other plant viruses. In animals, viruses usually move from cell to cell by endocytosis and budding, while in plants, passage through modified plasmodesmata is used.

Capsid Proteins and Their Precursor

The product of CaMV ORF IV has a molecular weight of 56 kDa and an electrophoretic mobility of 80 kDa. It is flanked by very acidic regions, which are removed from the mature capsid proteins, which have a mobility corresponding to proteins of 44 and 37 kDa, although their molecular weight is probably smaller. The sequence of p37 is included within p44 and thus antibodies against p37 react also with p44. p44, but not p37, is phosphorylated. It is not known whether both proteins are required for full infection, or whether only one of them is the true functional capsid protein. It might be that p44 is the mature form and p37 a degradation product. Alternatively, p37 might be the mature form and p44 still a precursor. Both these proteins include a Zn-finger motif, which is implicated in RNA binding. Furthermore, large stretches of basic amino acids at the C-termini of both proteins constitute DNA- and RNA-binding motifs.

The precapsid protein has a nuclear localization signal which is masked by the N-terminal acidic domain. Upon virus assembly and removal of the acidic regions, the NLS becomes exposed and virus particles are transported to the nuclear pore where they release the DNA into the nucleus.

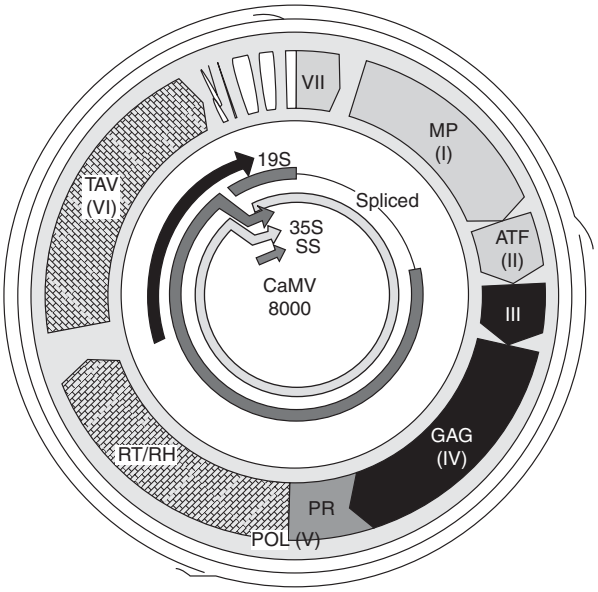

Figure 2 Map of cauliflower mosaic virus. On the outside the open circular double-stranded viral DNA with its overhangs is symbolized. The main circle shows the arrangement of the open reading frames (ORFs). ORF I encodes movement protein (MP or MOV), ORF II aphid transmission factor (ATF), ORF III the VAP, ORF IV the capsid protein precursor (GAG, in analogy to the corresponding protein in retroviruses), ORF V the POL polyprotein consisting of protease (PR), reverse transcriptase (RT), and RNase H (RH), and ORF VI the transactivator/viroplasmin (TAV). On the inside, the primary transcripts and the essential spliced RNAs are shown.

POL Polyprotein, Protease, Reverse Transcriptase/RNase H

CaMV ORF V corresponds to the POL ORF of retroviruses. It produces a polyprotein which is cleaved during virus production into a 15 kDa aspartic proteinase and a 60 kDa reverse transcriptase/RNase H. It is not known whether the RNase H functions as part of the 60 kDa protein or whether it is released by another cleavage reaction. One has to assume that the proteinase also functions as part of the polyprotein, that is, by releasing itself. Members of the family *Caulimoviridae* do not have an integrase and consequently their DNA is not or only accidentally integrated into the host chromatin.

Transactivator of Translation/Viroplasmin

The 62 kDa transactivator of TAV, encoded by ORF VI, has no significant homologies to any other known viral or host genes. It has been implicated in virus assembly, reverse transcription, host range determination, symptom severity, control of polycistronic translation, and seclusion of virus functions and silencing suppression. Perhaps as a consequence of the role of the ORF VI protein in translation, all CaMV proteins including foreign proteins carried by a CaMV vector can be found within the inclusion bodies. A subdomain in its center has been assigned to the translational transactivation and other domains have been found to unspecifically bind single- and double-stranded RNA, respectively. Furthermore, the protein interacts with capsid protein. TAV also has properties of a nuclear shuttle protein and might be involved in viral RNA transport.

Virus Stability

Both, the CaMV inclusion bodies and the virus particles, are very stable. Dissolution of the inclusion bodies to obtain virus particles requires treatment with 1 M urea over a long period. Virus particles aggregate at acidic pH and disintegrate at very high pH (0.1 M NaOH). Virus particles can also be disintegrated by boiling in sodium dodecyl sulfate/dithiothreitol or by treatment with proteinase K and phenol extraction. During these treatments, VAP is released and therefore usually escapes detection as virus component.

Genome Replication

As in retroviruses, replication occurs by production of a terminally redundant RNA by transcription in the nucleus and its reverse transcription in the cytoplasm. Also as in retroviruses, and unlike in hepadnaviruses, a tRNA primer (met-initRNA) is used as the primer for (−)-strand DNA synthesis from the RNA template. The RNA template is digested by RNase H following the reverse transcriptase. However, oligo(G) stretches are resistant to this digestion and remain bound to the (−)-strand DNA where they act as primers for (+)-strand DNA synthesis. The number of (+)-strand synthesis initiation events varies between one and three major events in different members of the family *Caulimoviridae* and even within strains from a particular virus. Minor initiation events also occur. The synthesis of both the strands overshoots, creating short overhangs that can only be repaired by repair exonuclease and ligase after transport into the nucleus. Accordingly, the packaged viral DNA is open circular, while the nuclear one is closed and supercoiled. The latter interacts with histones and forms minichromosomes. Caulimovirus DNA does not integrate into the host chromatin obligatorily. The template for transcription is the supercoiled circular DNA.

Transcription

Transcription in caulimoviruses is unidirectional. All caulimoviruses produce a transcript covering the total genome plus about 180 nt, such that the RNA is terminally

redundant. This RNA is called 35S RNA due to its sedimentation behavior. The terminal redundancy is caused by the polyadenylation signal located on the circular DNA 180 bp downstream of the transcription start site being ignored by the polymerase at its first passage (see below). CaMV-like caulimoviruses produce a second transcript, the 19S RNA, covering ORF VI and encoding the inclusion body protein/translation transactivator.

The 35S promoter of CaMV, FMV, and probably other caulimoviruses is very strong and quasi-constitutive, that is, it is expressed in nearly all types of cells and at all developmental stages. This constitutivity is caused by a number of different enhancer elements, each with some specificity for certain cell types. Some of the corresponding transcription factors have been identified, for example, ASF-1, ASF-2, and CAF recognizing a TGACG motif, a GATA motif, and CA-rich region, respectively.

RNA Processing

Full-length RNA made from the circular DNA template includes a polyadenylation signal. If this is used on the first encounter, a short-stop RNA of 180 nt is formed; if used on the second encounter full-length terminally redundant RNA is formed. The role of the short-stop RNA, if any, is not known.

The CaMV polyadenylation signal consists of an AAUAAA sequence, which determines the cleavage site 13 nt downstream of it. Occasionally cryptic signals are used in addition. In contrast to the animal system, single point mutations in the AAUAAA signal are partially tolerated by the plant system. Polyadenylation enhancers are located upstream of the AAUAAA signal and not downstream as in most animal cases. In CaMV and FMV, these elements are tandem repeats of UAUUUGUA.

In addition to the primary CaMV 35S transcript, alternatively spliced versions of it have been detected. By removing an intron extending from close to the end of the leader to a position within ORF II, an mRNA is created in which ORF III is the first ORF and ORF IV the second. Additional splicing events were found using the same splice acceptor but using donors within ORF I. These led to ORF I–ORF II in-frame fusions, the function of which is not known. Whether the ratio of spliced to unspliced RNA is controlled, for example by nuclear export of unspliced RNA as in human immunodeficiency virus, is not known.

Translation Mechanism

The 35S RNA of caulimoviruses and also its spliced derivatives serve as polycistronic mRNAs for the viral proteins. The ORFs of these viruses closely follow each other, are opened by efficiently recognized start codons, and usually also contain internal start codons. In plant protoplasts and in transgenic plants most of the downstream ORFs are poorly expressed in the absence of TAV interestingly the only ORF that is translated from a monocistronic mRNA. Transactivation activity has been demonstrated for CaMV and FMV, and probably resides also in the corresponding ORFs of the other CaMV-like and PCSV-like caulimoviruses. Transactivation is thought to be based on a reinitiation mechanism.

Another special feature of the caulimovirus (and also the badnavirus) 35S RNAs is their 600–700-nt-long leader, which is rather large for eukaryotic RNAs. These leaders contain several small ORFs and include a large hairpin structure. These are features that usually make an RNA a poor messenger, since initiation factors and/or 40S ribosomes initiate scanning at the cap of an RNA moving in the 3′ direction until an AUG codon is encountered and translation proper begins, whereas translation from AUGs further downstream is precluded. To overcome this problem caulimoviruses employ a shunting mechanism for translation initiation, whereby scanning is initiated at the cap as usual, but the scanning complex bypasses (shunts) most of the leader to reach the first longer ORF. This mechanism is unlike the internal initiation mechanism used by enteroviruses.

Protein Processing

Many of the caulimovirus proteins are processed, that is, in CaMV-like (and by analogy probably the other) caulimoviruses the precapsid protein is cleaved at both ends removing its very acidic termini. This process might be coupled to virus assembly and maturation. The capsid protein is both methylated and glycosylated. The Pol protein is cleaved to yield the aspartic proteinase and reverse transcriptase/RNase H. At least some of these cleavages occur by the action of the viral proteinase. In contrast, the ORF III product is cleaved by a host cysteine proteinase.

Silencing and Silencing Suppression

Another level of expressional control is provided by transcriptional and post-transcriptional silencing, which lead to strong inhibition of transcription and destabilization of the transcript, respectively. Silencing is viewed as a plant defense mechanism directed against viruses and transposons. On the other hand, viruses have developed silencing suppressors to counteract this plant defence strategy. The response of *Brassica napus* to systemic infection with cauliflower mosaic virus that results first in enhancement followed by subsequent suppression of viral gene

expression in parallel with changes in symptom formation can be explained by the battle being waged between silencing suppression and silencing.

Silencing is autocatalytic and systemic, and hence the silencing of CaMV can also lead to the silencing in *trans* of transgenes driven by the CaMV 35S promoter. In a special case, herbicide resistance in oilseed rape conferred by expression of a 35S promoter-driven bialaphos tolerance transgene can be silenced due to the host response to CaMV infection.

Central Nervous System Viral Diseases

R T Johnson and B M Greenberg, Johns Hopkins School of Medicine, Baltimore, MD, USA

© 2008 Elsevier Ltd. All rights reserved.

Introduction

Most viral infections of the nervous system represent serious and potentially life-threatening complications of systemic viral infections. With the possible exception of rabies, viruses are not neurotropic in the literal sense of having a specific affinity for the nervous system. Some viruses frequently invade the nervous system yet seldom cause serious disease; for example, mumps virus may cause meningitis but, even during uncomplicated mumps parotitis, cerebrospinal fluid (CSF) changes in over 50% of patients indicate probable nervous system infection. Other viruses, such as herpes simplex virus, rarely infect the central nervous system (CNS), but when they do, they often cause fatal disease. Thus, both mumps and herpes simplex viruses are regarded as neurotropic; mumps is highly neuroinvasive but has limited neurovirulence; herpes simplex has low neuroinvasiveness but is highly neurovirulent. Such variations are dependent on the structural and functional determinates of nervous system invasion, on the particular neural cells that specific viruses infect, on the effect of this infection on the host cells, and on the immune response or immunopathologic responses to the infection. Several terms are defined as follows:

- Neurotropic: able to infect neural cells.
- Neuronotropic: able to infect neurons in contrast to other nervous system cells.
- Neuroinvasive: able to enter the nervous system.
- Neurovirulent: able to cause neurologic disease.

Anatomic and Physiologic Considerations

Both structural and functional features of the CNS present a unique milieu for viral replication. The blood–brain barrier and the compact structure of the brain and cord

pose formidable barriers to the entry or dissemination of viruses within the nervous system. Yet, the multitude of dense dendritic connections among neurons provide a unique environment for cell-to-cell spread of pathogens. Furthermore, neurons are unique cells with high metabolic rates, intense membrane specialization, and no regenerative capacity. The same barriers that exclude viruses also limit access of immunocompetent cells and antibodies, and the nervous system lacks an intrinsic lymphatic system and has a paucity of phagocytic cells. Thus, the barriers that inhibit virus invasion also deter viral clearance. Therefore, many persistent infections involve the CNS.

The blood–brain barrier was originally conceptualized from the observation that dyes, such as Trypan Blue, stain all tissues except the brain and spinal cord after injection into the systemic circulation. The barrier at the cerebral capillary level consists of tight junctions between the capillary endothelial cells (beyond which most dyes do not pass), a dense basement membrane around the cells and tightly opposed astrocytic footplates. In the choroid plexus, the blood–CSF barrier is structurally different. The capillaries of the plexus are fenestrated, lack a basement membrane, and are surrounded by a loose stroma. Dyes and particles readily pass into the choroid plexus but are prevented from entering the CSF by tight junctions located at the apices of the secretory epithelial cells of the choroid plexus. Tight junctions between the arachnoid cell over the surface of the brain complete the barrier.

There is no comparable barrier between the brain and the spinal fluid. The ependymal cells are not joined by tight junctions and, therefore, there is a free exchange between the extracellular space of the brain and the CSF. However, the intracellular gap between neural cells measures only 10–15 nm, less than the diameter of even the smallest virus, so that free movement of virus particles or inflammatory cells within the extracellular space is relatively restricted.

Neurons have specialized membranes for the transmission and receipt of specific messages; they also have axonal extensions to carry signals to and from distant neuronal populations, motor endplates, and sensory endings. In humans these cytoplasmic extensions may exceed a meter in length. These features are important in viral infections, since different subpopulations of neurons have different receptors usurped by viruses to permit entry into cells. Furthermore, viruses in some cases can be carried by axoplasmic transport systems either into the nervous system or within the nervous system where axonal processes link functionally related neurons.

Antibodies found in the normal CNS are derived entirely from the serum. Antibody levels of immunoglobulin G (IgG) are approximately 0.4% of the serum levels. Since diffusion of macromolecules across the barrier is largely size-dependent, immunoglobulin M (IgM) is present in even lower levels. Complement is largely excluded. There is also no lymphatic system in the usual sense and few phagocytic cells. When inflammation disrupts the blood–brain barrier, antibody molecules leak into the nervous system along with other serum proteins. When a mononuclear inflammatory response is mounted against infection, T lymphocytes usually enter the nervous system first followed by macrophages and B lymphocytes. These B cells from the peripheral circulation move into the perivascular space and can generate immunoglobulins intrathecally.

The postmitotic nature of neurons is one the most important features when considering viral infections of the nervous system. Unlike most organ systems, the fundamental component of the nervous system lacks the ability to regenerate. Thus, by definition, infections that cause cell death (directly or indirectly via the elicited immune response) create irreversible damage. In this setting, neurons have developed various strategies for suppressing viral replication, clearing virus infections, and for creating environments suitable for latent infections.

Pathways of the CNS Invasion

Viruses have been shown to enter the nervous system both along nerves and from the blood. The first experimental studies of viral invasion employed rabies, herpes simplex, or polioviruses, all of which, under experimental circumstances, can penetrate the nervous system along peripheral nerves. The precise mechanisms of neural spread remained a mystery for many years, since it was thought that the axoplasm slowly oozed in an anterograde direction. It was proposed that virus might move in perivascular lymphatics, by ascending infection of the supportive cells within the peripheral nerve, or even by replication in axons, a speculation that is now untenable because of the observed lack of ribosomes or protein synthesis within axons. In the 1960s active anterograde and retrograde axon transport systems were found. Viruses or other particles can be taken up in vesicles at the nerve terminals and transported to the cell body of the sensory or motor neuron (**Figure 1**). This neural route of entry is important in primary viral infections such as rabies and possibly poliomyelitis. Retrograde transport also moves herpes simplex and varicella-zoster viruses from mucous membranes or skin into sensory ganglia at the time of primary infection. Subsequently, anterograde transport carries the reactivated virus from the ganglia to the periphery during exacerbations. Anterograde transport of herpes simplex virus by nerves innervating the dura from the trigeminal ganglia may explain the unique temporal lobe localization of herpes simplex virus encephalitis.

The olfactory spread of virus is a variation of neural spread. In the olfactory mucosa, neural fibers provide a

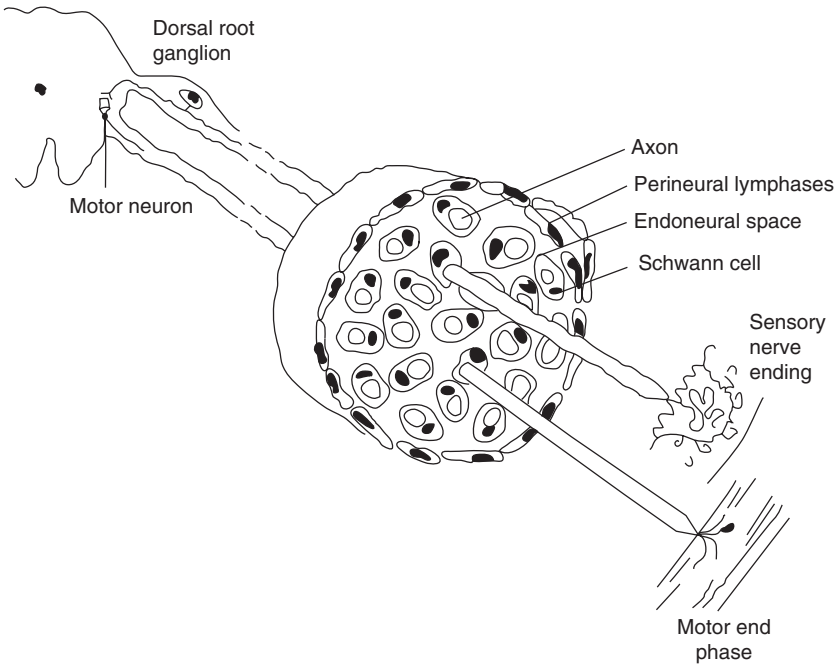

Figure 1 Schematic diagram of possible routes of neural spread of viruses to the nervous system. Reproduced with permission from Johnson RT (1982) *Viral Infections of the Nervous System.* New York: Raven Press.

unique pathway; the apical processes of receptor cells extend beyond the free surface of the epithelium as olfactory rods and the central processes synapse in the olfactory bulb. These are the only nerve cells with processes that link the CNS and ambient environment. Indeed, some colloidal particles placed on the olfactory mucosa can be found in the olfactory bulbs within 1 h. Experimental studies show that viruses can enter through this route, and this may occur in some aerosol infections in humans such as laboratory accidents or rabies virus infections in bat-infested caves. Also, the olfactory pathway has been postulated as a possible route of herpes simplex virus entry into the nervous system as an alternative explanation for the orbital–frontal and medial–temporal lobe localization of herpetic encephalitis. Nevertheless, despite the apparent ease of spread along this route, it appears to be a rare route of natural infection.

In most experimental and natural infections, viruses invade the brain from the blood. Historically, the blood–brain barrier was believed to be impervious to viruses. This belief was based in part on the fact that viruses experimentally inoculated directly into brain cause disease after a brief inoculation period, whereas the incubation period after intravenous inoculation is longer and comparable to that following cutaneous or peritoneal inoculation. The reason for this delay in infection is that virus in the blood is rapidly removed by the reticuloendothelial system; therefore, intravenous inoculation is, in fact, an inoculation primarily of the Kupffer cells of the liver and other reticuloendothelial cells. Therefore, virus must establish a nidus of peripheral replication that can effectively seed a viremia of sufficient magnitude and duration to allow invasion across the blood–brain barrier (**Figure 2**). Thus, some viruses grow in lymphatics and seed into the blood directly via the thoracic duct, others grow in vascular epithelial cells, and others replicate in highly vascular tissue such as muscle.

A persistent viremia can be achieved by several mechanisms. Rate of clearance is dependent upon particle size; small particles such as togaviruses and flaviviruses can maintain high-titer plasma viremias with sufficient rapid replication in peripheral tissue. Other viruses adsorb to red blood cells and thus evade clearance. Many large viruses such as measles and herpes viruses infect white blood cells thus evading clearance and replicating at the same time.

Some viruses enter the nervous system either across the capillary endothelium and others across the choroid plexus. Some viruses infect the capillary endothelial cells and simply grow into the brain while others are able to transit across endothelial cells despite their paucity of endopinocytotic vesicles. Entry in infected leukocytes is a theoretical possibility but leukocyte traffic into the nervous system is limited, although trauma or inflammation due to other causes may predispose the nervous system to infection with viruses that infect white blood cells. Although there are areas of increased blood–brain barrier permeability, no viral infection has been shown to infect these areas selectively. Other viruses, such as mumps

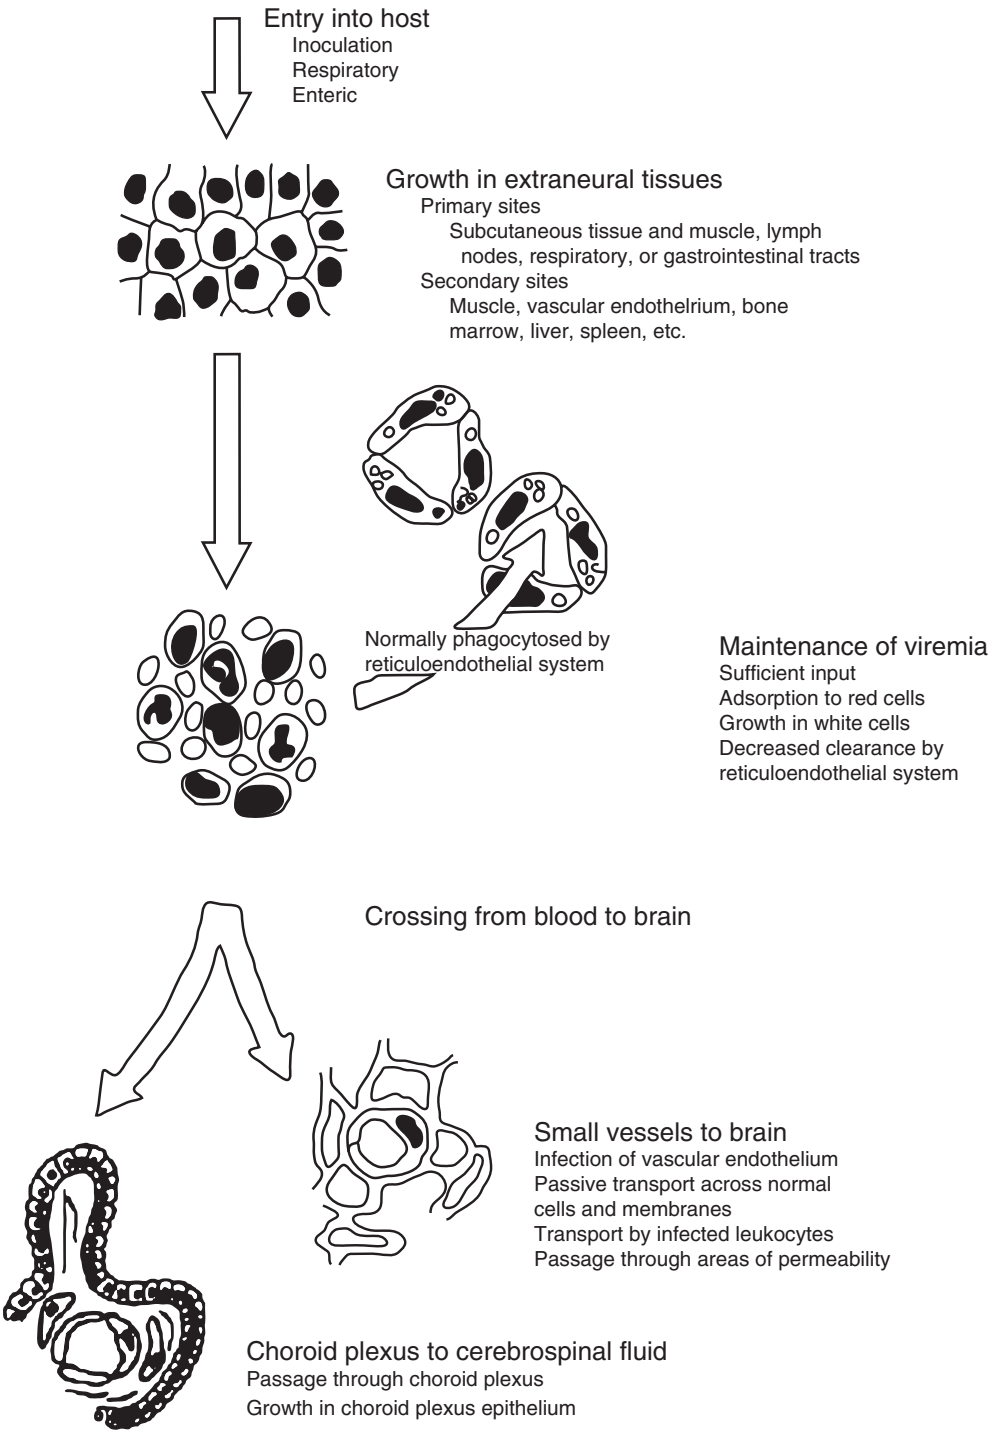

Figure 2 Schematic diagram of steps in hematogenous spread of viruses to the nervous system. Reproduced with permission from Johnson RT (1982) *Viral Infections of the Nervous System*. New York: Raven Press.

virus, grow in choroid plexus epithelium and seed into CSF. Thus, the clearance of particles by the reticuloendothelial system, barriers of nonsusceptible extraneural cells, production of interferon and other nonspecific inhibitors, and the physical barriers of the nervous system itself probably explain why viral infections of the brain are rare, even though systemic infections with the potential pathogens are very common.

Infections of Neural Cells

Once a virus has penetrated into the nervous system it must contact a susceptible cell and spread through the compact neuropil which is a theoretical problem. The fact that some viruses can be neutralized by extracellular antibody even after CNS invasion shows that viruses such as togaviruses and flaviviruses do spread in extracellular space, but this is not true of larger viruses. Conversely, the compact neuropil may facilitate the contiguous cell-to-cell spread of viruses. For example, in subacute sclerosing panencephalitis, a chronic brain infection of humans with measles, extracellular enveloped virus is never seen, and there are enormous titers of extracellular antibody. Apparently, the fusion protein allows measles virus to move from cell to cell through the brain.

Cell-to-cell spread may also involve axoplasmic flow causing infection of functionally linked cells; for example, in poliovirus infections the virus is rapidly spread through the motor system. Some viruses infect only neuronal populations such as rabies, polioviruses, and the arthropod-borne viruses (arboviruses), and some infect selective neuron populations. Other viruses such as herpes simplex virus appear to infect neurons and glial populations with little selectivity.

Infection limited to vascular endothelial cells is found with rickettsial infections but is not recognized in any viral infection of the nervous system. Infection limited to choroid plexus and meningeal cells appears to occur with those viruses that cause benign meningitis. In experimental studies with a number of viruses, widespread lytic infection of ependymal cells can lead to closure or stenosis of the aqueduct of Sylvius and resultant hydrocephalus. Similar aqueductal stenosis and hydrocephalus have been described in children after mumps virus meningitis.

The selective infection of oligodendrocytes has been recognized in nature in the disease progressive multifocal leukoencephalopathy caused in humans by the JC virus and in monkeys by SV-40 virus. In the course of immunosuppression, now seen most frequently with acquired immune deficiency syndrome (AIDS), a selective lytic infection of oligodendrocytes causes multifocal areas of demyelination in the brain. This usually fatal condition has also been seen in patients treated with immunomodulating medical regimens that included natalizumab (a monoclonal antibody against alpha 4 integrin). This drug causes a release of lymphocytes from lymph nodes and prevents the trafficking of lymphocytes across the blood–brain barrier. Thus, this medication may have interfered with the normal immune surveillance of the CNS, leading to the unabated emergence of JC virus within the brain.

With changes in age, the specificity of infection and vulnerability of neural cells may change. For example, bluetongue virus infection of fetal sheep destroys the precursors of neurons and glia of the subependymal plate which leads to hydranencephaly or porencephaly dependent on the age of fetal development, whereas the virus fails to infect the mature postmigratory cells in the late gestational or postnatal animal. Similarly, the external granular cells of the cerebellum in fetal or newborn animals are selectively infected by parvoviruses, and destruction of these mitotic cells leads to the granuloprival cerebellar degeneration seen in both natural and experimental animal infections. Alphaviruses which cause encephalomyelitis have more profound effects in young hosts including mice and humans.

Mechanisms of Cell Damage

Lytic infections of neural cells cause regional destruction of brain or lysis of specific cell populations. Noncytopathic infections of neural cells also occur and lead to persistent infection with no disease or disorders without obvious histological changes. For example, neuroblastoma cells in culture infected with noncytopathic viruses such as rabies can show normal morphology growth rates and protein synthesis, but reduced synthesis of specific neurotransmitters or receptors. These have been termed 'luxury functions', although *in vivo* the ability of neurons to synthesize transmitters or receptors would hardly be considered a luxury. Analogous noncytopathic infection has been demonstrated in mice congenitally infected with lymphocytic choriomeningitis virus. Congenitally infected mice are usually 'runts', but recent studies have shown selective infection of cells of the anterior pituitary which normally generates growth hormone. The animals are actually pituitary dwarfs responsive to growth hormone therapy.

Alternatively, the infected cell may not be damaged by virus replication but destroyed by the immune responses, as seen in adult mice infected with lymphocytic choriomeningitis virus. Indirect cell damage can occur in viral infections that leads to sensitization of the host to neural antigens. This has recently been demonstrated in rats infected with coronaviruses, where the infection of neural cells leads to a cell-mediated autoimmune response to myelin proteins and to subsequent demyelination. In postmeasles encephalomyelitis of humans, autoimmune demyelination appears to occur in the absence of infection of neural cells. Infection of lymphoid tissue leads to disruption of normal immune regulation, and about 1 per 1000 persons develop a symptomatic autoimmune reaction to myelin basic protein.

Other indirect mechanisms of neural cell damage have been postulated to explain the diverse neurological diseases seen in the course of human immunodeficiency virus (HIV) infection. The virus does not appear to cause significant or readily documented infections of

neuronal or glial cells. The primary cells that are infected are macrophages and the microglia of the brain derived from macrophage populations. Possibly viral proteins produced by these cells or cytokines released by these cells interfere with neuronal function or are toxic to neurons or glial cells. For example, tumor necrosis factor, a lymphokine often increased in brains of neurologically affected AIDS patients has been shown *in vitro* to induce demyelination.

Clinical Features

Acute Infections

The varied clinical features of viral infections of the nervous system can be explained in large part by the factors discussed above. Thus, a virus may infect only meningeal or ependymal cells, and cause a clinical syndrome known as viral meningitis or acute aseptic meningitis. This clinical syndrome is characterized by fever, headache, and nuchal rigidity secondary to meningeal irritation but without clinical signs suggesting parenchymal disease. The commonest causes of acutely viral meningitis are enteroviruses and mumps virus.

Encephalitis is a clinical syndrome in which in addition to fever, headache, and stiff neck, there is paralysis, altered mental status, seizures, or other evidence of parenchymal disease of the brain. The commonest causes of severe encephalitis in man are herpes simplex virus and the arboviruses. The former infects neurons and glia and causes diffuse necrotizing encephalitis in the newborn but focal encephalitis in the immune adult presumably because diffuse virus spread is contained by immune responses. Focal signs, hallucinations, behavioral abnormalities, and aphasia are more common with herpes encephalitis because of the localization to temporal lobes. Arboviruses have a propensity to infect neurons, and some flaviviruses tend to infect basal ganglia and brainstem neurons causing movement disorders and sudden respiratory failure. If signs of spinal cord involvement accompanies encephalitis, the term encephalomyelitis is often used. However, the term encephalomyelitis is also used to distinguish an acute postinfectious demyelinating disease of assumed autoimmune origin from acute viral encephalitis. Postinfectious encephalomyelitis (or acute disseminated encephalomyelitis) usually occurs 3–14 days after exanthems (measles, varicella, or rubella) or respiratory infections (mumps, influenza, and others) and clinically is characterized by the abrupt onset of fever, obtundation, seizures, and multifocal neurological signs.

The clinical syndromes of rabies and poliomyelitis are the most distinctive of viral infections because of the selective infection of specific populations of neurons. Polioviruses selectively infect motor neurons which lead to flaccid paralysis. Rabies causes early infection of the limbic system neurons with a relative sparing of cortical neurons which leads to behavioral abnormalities. Rabies infections represent a diabolical adaptation of virus to animal host, causing the animal to remain alert but to lose timidity and develop aggressive behavior to transmit the virus. The advantage of this selectivity is evident considering that strains of rabies that cause the so-called 'dumb' or passive rabies are seldom transmitted in nature.

Slow Infections

Slow infections are characterized by long incubation periods of months to years followed by an afebrile progressive disease. The term was originally coined in veterinary medicine to describe several transmissible diseases in sheep. The prototype slow infections are scrapie, a chronic noninflammatory spongiform encephalopathy due to a transmissible agent in which no nucleic acid has been identified (a prion), and visna, a chronic inflammatory encephalomyelitis caused by a lentivirus. The first slow infection identified in man was 'kuru', a progressive ataxia of a tribal group in New Guinea where the agent, resembling the agent of scrapie, was apparently transmitted by ritual cannibalism. Creutzfeldt–Jakob disease, a subacute dementia with myoclonus, is a worldwide disease due to prion agents. In some cases, transmission is genetic, in others, transmission is by transplants or administration of contaminated growth hormone, but in the vast majority the means of transmission is unknown. In both of these human spongiform encephalopathies, the clinical disease progresses irrevocably to death in about 6 months, but without fever or other clinical or histological findings to suggest infection.

Dementia, a chronic deterioration of cognitive function, can also be caused by several conventional viruses. Subacute sclerosing panencephalitis is a chronic dementing illness caused by measles virus. One per million otherwise healthy children develop this chronic illness at an average of 7 or 8 years after uncomplicated measles. Dementia evolves slowly, associated with myoclonic movements and massive levels of measles antibody in serum and CSF. Children usually die a year or less after infection, but survival may vary from 6 weeks to 6 years. The disease is due to a subacute, slowly progressive diffuse infection of neurons and glial cells. Another viral cause of dementia, HIV, has become a common problem as patients are surviving longer while on highly active antiretroviral therapy.

Clinical symptoms associated with HIV are very diverse (**Figure 2**). This virus now represents the commonest viral infection of the nervous system. From prospective studies of CSF changes, it appears that the majority of people infected with the virus have early invasion of the nervous system, that is, the virus is highly neuroinvasive. However, early during this infection

neurological disease is rare. A presumed autoimmune disorder occasionally causes a demyelinating peripheral neuropathy (Guillian–Barre syndrome); acute meningitis is occasionally seen at the time of seroconversion or during early asymptomatic infection. An asymptomatic pleocytosis is often found. Therefore, the virus is, at this stage, not highly neurovirulent. However, after the onset of immunodeficiency the infection is neurovirulent; at least 50% of the patients develop progressive dementia with cerebral involvement, myelopathies, or painful sensory neuropathies. The pathogenesis of these complications is unknown, but they are thought to be due to some viral protein or lymphokine incited by the virus because of the relative paucity of the virus in the nervous system and its localization to the microglial and macrophage populations.

Tropical spastic paraparesis complicating human T-cell leukemia virus type 1 infections is a recently recognized slow nervous system infection. Less than 1% of the patients infected with this virus develop either acute T-cell leukemia or neurological disease. Since many of those infected are infected by breast milk and the onset of tropical spastic paraparesis is usually in the fourth or fifth decade of life, the incubation period is extraordinarily long. A subacute disease develops with progressive paralysis of the lower extremities associated with impotence, incontinence, and sensory symptoms, but usually minimal sensory findings. Disease progresses slowly until the patients are wheelchair bound, but the disorder remains primarily at the level of the thoracic spinal cord. The involvement of the upper extremities is minimal with hyperreflexia but usually good function, and there is usually little, if any, indication of cerebral involvement. Early pathology found in a biopsy of the spinal cord in a single case showed vasculitis. In late cases, hyalinization of vessels with necrosis and demyelination of spinal cord is found, and findings are most prominent in the thoracic cord. Whether virus replicates in any cells other than T lymphocytes is unknown. These observations lead to the questions of why less than 1:100 who are infected develop disease; why the incubation period is as long as 40 years; why the disease localizes to the thoracic spinal cord; and why over years the disease becomes relatively quiescent despite the fact that there is ongoing high levels of intrathecal antibody synthesis, suggesting that there is still antigenic stimulation by virus within the nervous system.

Identification of viruses or virus-like agents (prions) in a variety of chronic neurological diseases has led to speculation of a viral etiology for multiple sclerosis, Parkinson's disease, amyotrophic lateral sclerosis, Alzheimer's disease, schizophrenia, and other illnesses. Experimental evidence for viruses in these chronic diseases is still tenuous.

Introduction

Maize is the main cereal crop in the world regarding total yield; it is grown on about 120 Mha. Maize has been grown for millennia in Central America. From a plant mainly used as human food, maize is now a main component for feeding animals but is still a major staple food crop in sub-Saharan Africa and America.

Viruses can cause important diseases of maize worldwide. While some viruses are widespread, others are localized. Some maize viruses can be sporadic and devastating causing severe yield losses, others may occur each year but losses are relatively minor. The average yield of maize in several African countries is only about a third of the world's average, and some viral diseases of maize are one of the major factors responsible for this low productivity. When available, resistant or tolerant hybrids provide the most effective means to control maize viruses. A pathogen-derived resistance strategy was developed for some viruses such as maize dwarf mosaic virus (MDMV) and maize streak virus (MSV). The major viruses affecting maize are transmitted by leaf- or planthoppers (16) but four viruses have aphids, two have mites, and one has beetles as vector. Populations of leafhopper and

planthopper vectors can be controlled by systemic insecticides applied as seed dressing or at sowing time. Herbicide eradication of Johnson grass, an overwintering host of some viruses, had a significant impact on disease control. In some cases, crop rotation and selection of planting date result in significant decreases in virus infection.

Maize Virus Diseases

Barley Yellow Dwarf (MAV-PAS-PAV), Cereal Yellow Dwarf (GPV-RPS-RPV), RMV-SGV

All the virus species of the family *Luteoviridae* in this subsection cause similar symptoms (see **Table 1** for a list of relevant virus names). Usually infected cultivars express discoloration of the leaves, reddening and yellowing, but some present no symptoms. More or less red or yellow bands are observed mainly on the borders of the older leaves. Compared to the healthy plants, possible grain yields are lower by 15–20%. Seeds coated with a systemic insecticide have to be used in areas where the disease is frequently encountered. A few maize inbred lines tolerant to barley yellow dwarf virus are available. Maize hybrids are in general tolerant.

Chloris Striate Mosaic Virus

This virus found in 1963 in Australia causes striate mosaic in *Chloris gayana* Kunth and other grass species and in cereals including barley, maize, and oats. It is transmitted by the leafhopper *Nesoclutha pallida* (Evans). Natural hosts are

several grasses, and barley, oats, maize, and wheat. Infected plants develop chlorotic grayish white striation on leaves; notching and curling of leaves may also occur. Maize is occasionally infected but most hybrids are resistant.

Cynodon Chlorotic Streak

Cynodon chlorotic streak virus (CCSV) can cause a serious disease in the Mediterranean region. Symptoms on maize are characterized by the development on the youngest leaves of yellow streaks which become larger and can coalesce to form yellow stripes (**Figure 1(e)**). Finally the whole leaf turns yellow with some parts becoming reddish. If contamination occurs at a young stage, the plants are dwarfed and die early. The virus is transmitted by planthoppers and occurs naturally in Bermuda grass (*Cynodon dactylon* (L.) Pers.) and maize. The level of CCSV infection in maize is directly related to the level of CCSV infection and planthopper vector populations in Bermuda grass. As many as 70–84% virus-infected plants have been observed for some years in southern France. Seed dressing with imidachloprid allowed a good control of the vector population.

High Plains Virus

High Plains virus (HPV), a previously unknown pathogen, was found in 1993 to infect maize in US High Plains states. It has also been found in other countries. The virions are flexible, thread-like particles. Analysis of the nucleic acid shows four bands of double-stranded RNA (dsRNA) after electrophoresis. A great variety of symptoms may be expressed in maize, including spots or flecks along vascular bundles, purpling or reddening of the leaf margins or sectors of the leaf, and stunting. The virus is transmitted obligately by the wheat curl mite *Aceria tosichella* (Keifer) that also transmits wheat streak mosaic virus (WSMV). HPV can be seed transmitted. The host range includes barley, maize, and wheat in addition to several weed species. Three dominant genes for resistance have been identified and mapped in maize, and they provide a high degree of resistance.

Johnson Grass Mosaic Virus

Johnson grass mosaic virus (JGMV) was first reported in Australia in maize and sorghum and later in the US and South America. Johnson grass (*Sorghum halepense* (L.) Pers.), maize, and some other plants of the Poaceae are natural hosts. The virus causes mosaic, mottling, and ringspot symptoms on maize and grass hosts, which is particularly evident on young leaves. Since the symptoms of JGMV and MDMV are very similar, serology or polymerase chain reaction (PCR) may be necessary to distinguish between the two viruses. The type strain from Australia can infect oats, which is not susceptible to the other graminaceous potyviruses. The perennial host Johnson grass allows virus survival between seasons in rhizomes. Resistant or tolerant hybrids provide the best control option.

Maize Chlorotic Dwarf Virus

Confirmed reports of maize chlorotic dwarf virus (MCDV) infection are limited to the US, where the virus was discovered in 1969. The extent of distribution of MCDV in the US is second to that of MDMV. The virus is associated with the occurrence of indigenous Johnson grass (*S. halepense* (L.) Pers.), its overwintering host, and the black-faced leafhopper, *Graminella nigrifrons* (DeLong and Mohr), its principal vector. Symptoms on susceptible maize are shortening of the upper internodes or proportionate stunting of the internodes, chlorotic clearing or banding of the tertiary leaf veins, and red or yellow discoloration of upper leaves. Infected leaves are also more difficult to tear off a plant. On resistant maize, MCDV induces mainly chlorotic clearing or banding of tertiary veins without marked stunting or discoloration. The diagnostic symptom of MCDV infection is vein banding. MCDV's host range is limited to species of the Poaceae. MCDV may complex with MDMV in infections of maize and Johnson grass in the same field or plant and with sugarcane mosaic virus strain MDB in maize. Biological tests for MCDV include transmission by the leafhopper in a semipersistent manner and vascular-puncture inoculation (VPI) to susceptible plants with expression of the diagnostic symptoms of vein clearing or banding of the tertiary leaf veins. Confirmation by serological methods is often necessary. No molecular tests for MCDV have been developed.

Agronomical control of MCDV is possible by early planting of maize to escape peak vector populations and by herbicide eradication of overwintering Johnson grass. However, the latter treatment may result in increased MCDV incidence in susceptible hybrids due to mass migration of viruliferous leafhoppers from dying Johnson grass. Maize inbreds with high levels of tolerance to MCDV have been developed. Virus resistance appears inherited mostly as a dominant to partially dominant trait. Resistant Caribbean germplasm has been identified and the inbred line Oh1VI highly resistant to MCDV has been developed. Commercial hybrids with various degrees of resistance or tolerance and with agronomically satisfactory characteristics are available. The systemic insecticide carbofuran which remains toxic to the leafhopper for up to 55 days after application at planting time is very effective and can control the disease. As a result the economic impact of the virus has decreased and it no longer poses a significant threat to US maize production.

(d) Maize plants infected with Mal de Rio Cuarto virus showing severe dwarfing and leaves distorted and ragged. (e) Yellow stripe and dwarfing on maize infected by cynodon chlorotic streak virus.

Maize Chlorotic Mottle Virus

Maize chlorotic mottle virus (MCMV) was first reported from Peru in 1973, and was later found in central USA, Hawaii, Mexico, and Argentina. Symptoms vary from a mild chlorotic mottling to severe yellowing, necrosis, and plant death depending on the maize variety and plant age when infected. Plants may be stunted with short, malformed, partially filled ears, and male inflorescences may be shortened with sparse spikes. Under natural infection, 10–15% yield reductions can be observed. Maize is the only natural host of MCMV, and the experimental host range is limited to Poaceae. Laboratory transmission of MCMV can be obtained with six species of chrysomelid beetles, but only *Diabrotica* spp., which have a New World distribution and are mostly tropical, are natural vectors. In areas of South America where maize is grown continuously, MCMV spreads from older plants to younger plants via adult and larval beetles. Control would require a halt in continuous cultivation or management of the beetles. Most maize cultivars are susceptible to MCMV but a new variety (N211) is resistant. Transgenic maize shows milder symptoms from MCMV infection. MCMV is sometimes found as part of the corn lethal necrosis complex.

Maize Dwarf Mosaic Virus

MDMV was first reported on corn in 1965 from Ohio, USA. It is considered to be distributed worldwide. Symptoms of MDMV in corn vary with the stage of host development at time of infection, genotype, and virus strain. Initial leaf symptoms are chlorotic spots and short streaks followed by typical mosaic or mottle. When the plants develop, flecks, streaks, and rings appear on new leaves. Ear formation and development are arrested, resulting in losses in grain yield. MDMV is widely adapted to species of the Poaceae infecting over 66% of 293 species tested. Maize and sorghum are important agricultural hosts. More than 15 species of aphids transmit this virus in a nonpersistent manner. MDMV can be mechanically transmitted; it survives by overwintering in the rhizomes of infected Johnson grass. Crop loss due to MDMV ranges from 9% to 72% for susceptible dent corn hybrids. Losses are generally important in seed production or sweet corn hybrid fields.

Many commercial corn MDMV-resistant hybrids are available. A major gene for resistance to MDMV is a dominant gene (*mdm1*) located on chromosome 6. The control of Johnson grass helps to control disease.

Maize Fine Streak Virus

Maize fine streak virus (MFSV) was isolated in 1999, from sweet corn grown in Georgia, USA. Symptoms in the field include fine chlorotic streaks along the major leaf veins, similar to symptoms associated with maize rayado virus (**Figure 1(c)**). Maize is so far the only identified natural host of MFSV. The virus is transmitted by the leafhopper *Graminella nigrifons* (DeLong & Mohr) in a persistent manner. MFSV is readily transmitted mechanically by kernel vascular-puncture inoculation. Maize lines resistant to maize mosaic virus (MMV: Hi31 and Hi34) are also resistant to MFSV.

Maize Indian Fiji-Like Virus

Symptoms include severe plant dwarfing, dark green leaves, enations on the lower leaf surface, and small malformed ears. All of these symptoms are similar to those produced by Mal de Rio Cuarto virus (MRCV) and maize rough dwarf virus (MRDV) on maize. This unreported reovirus was found in southern India, where its incidence ranged from 4% to 61%.

Maize Iranian Mosaic Virus

First observed in the Fars Province of Iran, it is now distributed in other parts of the country. Maize Iranian mosaic virus (MIMV) symptoms consist of long chlorotic lines and stripes along the veins and sheaths, stunting of the plants, and abortion of ears when infected early. MIMV is serologically distinct from others rhabdoviruses infecting Poaceae plants. In polyacrylamide gel electrophoresis, six proteins corresponding to proteins L, G, N, NS, M, and M2 were detected. MIMV is a new virus in the genus *Nucleorhabdovirus* that may be distantly related to MMV. Delphacids are vectors of MIMV. The natural host range includes maize, oat, rice, and wheat. The disease incidence in maize fields can be as high as 80% depending on sowing date and variety. Late planting effectively controls the virus.

Maize Mosaic Virus

MMV causes a serious disease of maize in tropical and subtropical areas of Africa, the Americas, and Australia. It was first reported in 1914 in Hawaii. MMV can occur in mixed infections with maize stripe virus (MSpV). Initial leaf symptoms on sweet corn inoculated with MMV are long stripes, colored light green to yellow, along the midrib (**Figure 1(a)**). These stripes elongate to form distinct, chlorotic stripes between and along the veins extending on the whole leaf. Stripes can appear on sheath and husk. Stunting of plants is common. Mosaic patterns do not occur despite the disease name. Only species of the Poaceae are known to be hosts of MMV. It occurs naturally in itchgrass, maize, and *Setaria vulpiseta* (Lam.) Roem. & Schult. MMV is transmitted in a persistent-propagative manner by the corn planthopper *Peregrinus maidis* (Ashmead), the sole vector. Transmission is by both nymphs and adult males and females. MMV has been shown to be inoculated by vascular puncture of maize kernels (VPI). Several contact and systemic insecticides can control *P. maidis*. Host-plant resistance is likely to be the most effective means of control. Tropically adapted parental inbred lines of maize resistant to MMV have been developed and sweet corn cultivars have been bred and released, both by the University of Hawaii. From Caribbean and Mascarene germ plasm, high resistance was found in line Hi40 and resistance to some levels was found in lines 37–2, A211, and Mp705.

Maize Mottle Chlorotic Stunt Virus

This virus was first reported, in 1937, in East Africa and called maize mottle virus (MMotV). Maize mottle chlorotic stunt virus (MMCSV) is restricted to tropical African countries and the adjacent islands. The virions are spherical, *c.* 40 nm in diameter. MMCSV can be found in mixed infections with maize mosaic and maize streak viruses. Symptoms on maize appear as chlorotic mottling with mild to severe chlorosis of tertiary veins and stunting. Young mottled leaves fail to support themselves in a normal upright position. Tassel abortion can occur in severe cases. Maize is the only known natural host of the virus which is transmitted by several *Cicadulina* spp. in a

persistent manner. Disease control can be achieved by vector control or by growing resistant cultivars, which are now available. Most maize streak virus-resistant cultivars have also moderate to high levels of resistance to MMCSV.

Maize Necrotic Streak Virus

Maize necrotic streak virus (MNeSV) was discovered in 2000 in maize samples from the US state of Arizona. The virus is of little agronomic importance. Virions are isometric, *c.* 32 nm in diameter. MNeSV appears to be a member of the family *Tombusviridae*. Distinctive symptoms of MNeSV infection are initially chlorotic spots and streaks that become spindle shaped. They later coalesce into long chlorotic bands that become translucent and necrotic around the edges. Plant stalks show a chlorosis that becomes necrotic, a symptom especially distinctive for MNeSV. There is no known aerial vector – the virus is transmitted through the soil. Maize lines Oh 1VI OSU23i and Mo17 are highly resistant to MNeSV.

Maize Rayado Fino Virus

Maize rayado fino virus (MRFV) was first described in 1969 in Costa Rica and El Salvador. MRFV is widespread and becoming increasingly important in tropical areas of the Americas. It is the type member of the genus *Marafivirus*, and is the only known indigenous virus of maize in Mesoamerica. Initially, infection causes fine chlorotic dots or stipples, which coalesce into chlorotic stripes at the base and along the veins of young leaves. As the plant grows older, the symptoms become less conspicuous and may disappear when the plant reaches maturity. In locally adapted Central American varieties, the virus incidence varies from 0% to 20%, but may reach 100% in more susceptible foreign or newly developed cultivars. Maize, teosinte, and the perennial *Zea* spp. are the only known natural hosts. In nature, MRFV is transmitted exclusively by the corn leafhopper vector *Dalbulus maidis* (DeLong and Wolcott) in a persistent manner. The natural host range of MRFV may be limited by the ability of the vector to feed on different species. It has been proposed that MRFV, its insect vector, and the maize host co-evolved in a triad in which the parasitic members (insect and virus) displayed highly specialized interactions. It has been suggested that MRFV originated in Mexico or Guatemala, from where it spread in the region.

MRFV is one of the three major components of the corn stunt disease complex. MRFV is endemic in many areas of Central and South America, where the virus and *D. maidis* reach epidemic levels. The use of systemic insecticides does not reduce virus incidence. Crop rotation, mixed plantings, and selection of planting dates result in significant decreases in virus infection. The Guatemalteco variety introduced in Ecuador in 1962 is used as a source of virus tolerance. Production of transgenic plants resistant to MRFV and their evaluation for their susceptibility are in progress in Costa Rica.

Maize Rough Dwarf Virus

This virus was discovered in Europe when corn hybrids were introduced from the US after World War II. In 1949, in Italy, a severe outbreak threatened the maize cultivation, lowering the yield by ~40%. Later, MRDV was reported in several European countries, where it had the potential to be economically damaging. In China, a similar disease was found to be caused by rice black-streaked dwarf virus (RBSDV), not by MRDV. In young field-grown corn, symptoms caused by MRDV are dark green color of leaves, stunting and irregular swellings of veins (enations) along the lower surfaces of leaves and sometimes also of leaf sheaths, ligules, and husks. The enations are rough to the touch, hence the disease name. Plants are stunted with increased girth giving the plant a 'leek' aspect (**Figure 1(b)**). Short chlorotic streaks develop on mature leaves and coalesce into yellowish green stripes parallel to the veins. Later the leaves can turn reddish. Tassels are sterile. The root system is reduced, roots develop swellings, resulting in their frequent splitting. MRDV has a fairly wide experimental host range including only a few species of Poaceae, among which maize is the only one of economic importance. Oats, wheat, and several grasses can be infected naturally. The planthopper *Laodelphax striatellus* (Fallén) is the natural vector and the only known winter host of MRDV. However, in northern Italy, oats were reported as the first overwintering plant. Planthoppers can be controlled either by spraying grasses around the fields with an insecticide in the spring, by seed treatment with imidachlopride, or by row application of an insecticide at sowing time (e.g., carbofuran). Some maize hybrids are less susceptible to MRDV, but the resistance can be overcome if the vector population is very high.

Maize Sterile Stunt Virus

Maize sterile stunt virus (MSSV) was first reported from Australia in 1977. It is a strain of barley yellow striate mosaic virus (BYSMV). The virus causes severe stunting, sterility, purple coloration, and top necrosis in a small number of maize genotypes. MSSV is transmitted in a persistent manner by the delphacid planthopper *Sogatella longifurcifera* Esaki and Ishihara and inefficiently by *Sogatella kolophon* (Kirk) and *P. maidis* (Ashm.). Natural hosts of MSSV are barley, maize, triticale, and wheat.

Maize Streak Virus

Maize streak was first recorded in 1901 in South Africa and is the most widespread and important disease of maize in sub-Saharan Africa and adjacent islands. Maize streak symptoms are characterized by the development of chlorotic spots and streaks in longitudinal lines on leaves. There is a progressive increase in the number and length of streaks that occur on new leaf tissue. The streaks often fuse laterally, resulting in narrow broken chlorotic stripes, which can in some cases cover the entire leaf. In very susceptible maize cultivars, severe chlorosis occurs leading to stunted plant and premature death. MSV is transmitted by several species of leafhoppers in the genus *Cicadulin*a, with *C. mbila* (Naudé) being the most common vector. It transmits MSV in a circulative nonpropagative manner. Streak symptoms have been described in numerous species of wild grasses. Late plantings are generally more severely infected than early ones. The major source of MSV infection on maize is a previously infected maize field. Therefore, planting of maize close to a previous maize field must be avoided. Carbamate insecticides (such as carbofuran) can effectively prevent MSV transmission but prices of chemicals and equipment for spraying are often prohibitive for smallholder farmers. The development of insect resistant plants is under study.

Maize Stripe Virus

MSpV has often been confused with MMV because of their similarity in vector specificity, mode of transmission, symptomatology, and host range. It often occurs in mixed infection with MMV. The virus is commonly found in most parts of the subtropics and the tropics where the vector occurs. MSpV is found to infect maize, sorghum, and itchgrass (*Rottboellia exaltata* L.). It can be transmitted experimentally to barley, oats, rye, and triticale. Initial symptoms on sweet corn are fine chlorotic stipplings and narrow stripes similar to that of MMV. Later, continuous chlorotic stripes develop with varying width and intensity which show a 'brushed out' appearance, and apical bending occurs. Infected plants are often stunted and die prematurely. The virus is transmitted by *P. maidis* (Ashm.), also a vector of MMV, in a persistent-propagative manner. Both nymphs and adults transmit the virus. Control of the maize stripe disease is largely dependent on chemical control of *P. maidis*.

Mal de Rio Cuarto Virus

The Mal de Rio Cuarto was first reported in maize fields of the Rio Cuarto County in Argentina, at the end of the 1960s. MRCV is a major constraint to maize production in Argentina. It spread in the endemic area of the province of Cordoba, but also appeared in the central region. MRCV initially reported as a strain of MRDV but is now considered to be a separate species within the genus *Fijivirus*. In field-infected maize, the symptoms show up within 4–5 weeks. Plants are dwarfed, showing fine chlorotic flecks on secondary and tertiary veins. Stems are usually flattened with shortened internodes and leaves from the upper third may be stiff, distorted, and ragged (**Figure 1(d)**). The root system is fragile, and greatly reduced. The ears are reduced and malformed. Natural dispersion of the virus occurs by the planthopper *Delphacodes kuscheli* Fennah in a propagative manner. Apart from maize, MRCV can infect several monocots, winter small grains (barley, oats, rye, and wheat), spring–summer grains (millet and sorghum), and several spring–summer annual and perennial weeds. The initial inoculum source is its vector that feeds on winter cereals like oat and wheat, where it acquires the virus and migrates to maize when these cereals become senescent. Early sowing of maize helps to prevent high virus infection. Systemic insecticides (carbofuran, imidachlopride) applied as seed coating protect maize seedlings from the vector. Some commercial hybrids with high tolerance levels are now available.

Pennisetum Mosaic Virus

A potyvirus was isolated from whitegrass (*Pennisetum flaccidum* Griseb) in North China, in the early 1980s and was later named pennisetum mosaic virus (PenMV). This virus infects maize and sorghum naturally. Symptoms on maize are not specific when compared to other members of the sugarcane mosaic virus (SCMV) subgroup in the genus *Potyvirus*. The virus is less important, in terms of yield loss, than the other prevalent viruses of the SCMV subgroup.

Rice Black-Streaked Dwarf Virus

The causal agent of characteristic symptoms on maize (stunting and rough white line veins of leaves) was initially identified as MRDV in China in the late 1970s. Subsequently, molecular studies demonstrated that rice black-streaked virus was the cause of the disease. These two viruses are quite similar in host range, serology, morphology, and the genome sequence. Reverse transcription-polymerase chain reaction can discriminate between RBSDV and MRDV. Host range is limited to species in the Poaceae: oats, hordeum, oryza, triticum, and zea. This virus is transmitted by the leafhopper *L. striatellus* in a persistent manner. RBSDV is managed mainly by control of leafhoppers.

Sugarcane Mosaic Virus

SCMV was first detected in sugarcane in 1919 and in maize in 1963, both in the US. SCMV occurs throughout the world. Infected maize plants develop distinct mosaic symptoms which are especially clear on the lower part of

the younger leaves. Very susceptible cultivars react with a strong chlorosis, sometimes together with a red striped pattern. It is often impossible to distinguish SCMV and MDMV infections on the basis of symptoms. In Southern Europe, MDMV is the most prevalent virus. Maize inbred lines resistant to the virus have been described and transgenic maize expressing the coat protein gene of SCMV is also available.

Wheat Streak Mosaic Virus

The symptoms consist of linear arrays of small, yellow-ringed eyespots. On some germplasm, the spots and streaks later form mosaics, or mottle patterns. WSMV is mite transmitted. Three independent genes controlling resistance to WSMV have been identified in maize. Resistance in certain maize lines is not effective against all strains of WSMV. Late planting of corn adjacent to maturing wheat should be avoided.

Maize Diseases Caused by Complex of Pathogens

Corn Lethal Necrosis Complex

This disease is caused by a synergistic interaction between MCMV and certain members of the family *Potyviridae* (MDMV-A, SCMV-MDB, JGMV, and WSMV). Maize plants infected at early stages develop leaf chlorosis followed by necrosis. Plants are stunted, produce small deformed ears, and die prematurely. Only terminal leaves show symptoms with a late infection. Crop losses of up to 90% have been reported.

Corn Stunt Complex

Corn stunt disease complex, also known by the names achaparramiento, maize stunt, and red stunt, is caused by two or more of the following agents: MRFV, corn stunt spiroplasma (CSS), and maize bushy stunt phytoplasma (MBSP). The corn stunt complex pathogens appear to be restricted to the Americas. Early symptoms of CSS consist of yellowish streaks in the youngest leaves. Later, much of the leaf turns purple. Infected plants are stunted and will often have more ears, but the ears are smaller. Maize plants infected with MBSP show stunted growth and reduced grain production, ear proliferation, and greater tillering. The leafhopper vector *D. maidis* (DeLong & Wolcott) can simultaneously transmit CSS, MBS, and MRFV. Although *D. maidis* is the primary vector, other leafhoppers transmit one or more of the corn stunt complex pathogens under experimental conditions.

Glossary

Ambisense A viral nucleic acid that can be 'read' in both directions to be translated into viral encoded proteins.
Capsid Protein envelope of the viral genome (nucleic acid).
Circulative A virus that passes through the intestine of an insect vector into the hemolymph, and eventually reaches the salivary glands of the insect to be injected back into a plant.
Etiology Studies the cause of disease.
Inclusion Virus particles or viral components found in infected plant cells.
Incubation Period of time that a virus needs inside its vector before it can be transmitted to a susceptible host.
ORF Any sequence of DNA or RNA that can be translated into a protein.
Persistent A virus that is not lost by a vector after feeding in a series of healthy plants, without having access to a virus-infected plant (virus source).

Pinwheel A cytoplasmic protein inclusion induced by potyviruses.
Propagative A virus that multiplies in its vector.
Semi-persistent Virus is lost after a vector feeds on a series of virus-free plants.
Single-stranded Viruses consisting of only one strand of viral RNA or DNA.
Transovarial transmission Of a virus from a female insect vector to her progeny.
Transtadial A virus that is retained by an insect vector after each developmental stage until it reaches adulthood.
Virion A mature virus particle (capsid protein, nucleic acid, and any other constituents).
Viroplasm Amorphous aggregation of viral components.

Introduction

Rice (*Oryza sativa* L.) is the second most extensive food crop grown in the world (*c.* 154 million ha) after wheat, and is the main food crop grown in the tropics. Half of the world's population (over 3 billion people) depends on rice, particularly in Asia, where annual per capita rice consumption may be as high as 170 kg in countries such as Vietnam, as compared to 9 kg in the United States. Asia produces almost 90% of all the rice cultivated in the world (136 million ha), mainly China and India, where rice cultivation and domestication seemed to have started over 5000 years ago. Africa cultivates approximately 9 million ha, and Latin America 6.8 million ha of rice. Nigeria and Brazil are the main producers of rice in Africa and Latin America, respectively, with average cultivated areas of 3.8 million ha, each.

Given the history and extensive cultivation of rice around the world, including Europe (565 000 ha) and the United States (1 355 000 ha), it is not surprising to note that this crop has several pest and disease problems of significant socioeconomic importance. Among the various biotic constraints of rice production, viruses constitute an important group of plant pathogens, particularly in Asia. Viral diseases are also considered major constraints to rice production in Africa and Latin America, even though only two viruses are considered pathogens of economic importance outside Asia.

Rice is also affected in the tropics by numerous insect pests, particularly by several species of leafhoppers and planthoppers (Homoptera:Auchenorrhyncha) that cause direct feeding damage and, more important, transmit economically important plant viruses. This article describes the main viral diseases of rice in the world; their causal viruses and vectors; and the different disease management strategies implemented to date.

Rice Dwarf

Rice dwarf was first described in Japan, in 1883. A Japanese rice grower was the first person to demonstrate in 1894, the relation between this disease and the presence of leafhoppers in affected rice fields. Rice dwarf is also known to occur in Korea, China, Nepal, and the Philippines. In 1885, K. Takata reported that the leafhopper *Recilia dorsalis* was 'responsible' for the disease. In 1900, the leafhopper *Nephotettix cincticeps* was thought to be the cause of rice dwarf. In 1899, *N. cincticeps* individuals captured in a disease-free area could not induce disease in healthy rice plants, unless these individuals had been previously allowed to feed on rice dwarf-affected rice plants. Despite this evidence suggesting the existence of an unknown causal agent, it was not until 1960 that the first electron micrographs of an isometric virus *c.* 70 nm in diameter were obtained. The suspected virus was shown in 1966–70, to contain double-stranded (ds) RNA, divided in 12 different segments (4.354–0.828 kb) with a total genome size of 25.13 kb. The causal virus was classified in 1972 as *Rice dwarf virus*, a species of the genus *Phytoreovirus,* in the family *Reoviridae.* The virus replicates in the cytoplasm of infected cells, and the dsRNA genome is encapsidated in super-coiled form.

Rice dwarf virus (RDV) is transmitted by the leafhoppers *N. cincticeps* (main vector in Japan, Korea and China), *Nephotettix nigropictus* (formerly *N. apicalis*; the main vector in Nepal and the Philippines), *Nephotettix virescens,* and *R. dorsalis* (formerly *Inazuma dorsalis*). Few individuals of these species are active or potential vectors, and they acquire the virus by feeding for up to a day on infected plants. The incubation period of the virus in a potential vector ranges from 12 to 25 days ('propagative' virus), and the leafhopper vector remains viruliferous for life ('persistent' mode of transmission). Viruliferous individuals require from a few minutes to half an hour to transmit the virus to a healthy plant, and there is transovarial transmission of RDV to the progeny of viruliferous female vectors. Some nymphs infected through the egg die prematurely. The average lifespan of viruliferous *N. cincticeps* females is 12.1 days, and of virus-free females is 16.6 days. RDV is not mechanically transmissible and it is not transmitted by sexual seed or pollen.

RDV induces stunting and chlorotic specks in infected rice plants. RDV's host range is restricted to the Gramineae, including the genera *Alopecurus, Avena, Echinochloa, Oryza, Panicum, Paspalum, Poa,* and some cultivated species, namely, barley, millet, oats, rye, and wheat. The disease usually appears in the field after transplanting, suggesting an early infection in the seedbed stage. Early infection generally results in severe stunting, shortening of internodes, and small, rosette-like tillers. The root system of diseased plants does not develop well either, and infected plants usually do not produce panicles or seed. Diseased plants remain green

in contrast to virus-free plants, which naturally turn yellow when mature. Virions are found in phloem, cytoplasm, and in cell vacuoles. Viroplasms can be observed in infected cells. Genetic resistance to RDV has been observed in some rice varieties, but current efforts are directed toward the development of genetically modified (transgenic) rice plants possessing resistance to the virus. Complementary cultural practices and other integrated disease management strategies are also recommended.

Rice Black Streaked Dwarf

Rice black streaked dwarf was first reported to affect rice in Japan in the early 1950s, and it also spreads in China and Korea. This disease was shown to be different from rice dwarf, and to be associated with the planthopper *Laodelphax striatellus*. The causal agent was isolated in 1969 and further characterized in 1974 as a spherical virion *c.* 60 nm in diameter, belonging to the reovirus group. Rice black streaked dwarf virus (RBSDV) is currently classified as a member of a species of the genus *Fijivirus*, family *Reoviridae*. It has 10 dsRNA segments coding for the RNA polymerase, core protein, nonstructural components, spikes, major outer shell, and other proteins of unknown function. Three major proteins (130, 120, and 56 kDa) and three minor proteins (148, 65, and 51 kDa) have been detected in RBSDV virions. The 56 kDa protein is the main component of the outer capsid shell. Most of the genome segments are monocistronic, and replication occurs in the cytoplasm of phloem cells. Inclusion bodies of unknown nature are observed in malformed tissue. Some degree of genomic variability among RBSDV isolates has been observed.

RBSDV is transmitted by the delphacid vector *L. striatellus,* and occassionally by *Unkanodes sapporona* and *Unkanodes albifascia*, in a persistent, circulative, and propagative manner. The proportion of active transmitters of *L. striatellus* is about 30%. Shortest acquisition feeding period was 30 min; and incubation periods ranging from 4 to 35 days in the vector *L. striatellus* have been reported. The virus is not transmitted congenitally. *Laodelphax striatellus* breeds on rice, wheat, and barley, but not on maize; whereas *U. sapporona* favors maize, wheat, and barley, but does not breed on rice. Besides rice, RBSDV infects oats, barley, wheat, maize, rye, and species of *Agrostis, Alopecurus, Digitaria, Echinochloa, Eragrostis, Glyceria, Lolium, Panicum,* and *Poa* in the Gramineae. Perpetuation of the virus between seasons occurs through overwintering planthoppers. Main symptoms associated with this disease are: stunting, darkening of leaves, leaf malformation, and waxy swellings along veins of the abaxial leaf surface, which later form dark tumors. Infected plants usually produce excessive tillers.

Resistance to RBSDV has been observed under field conditions. There is at least one dominant gene involved in the resistance to RBSDV, but some modifying genes may also be involved in the outcome of the interaction between the plant genotype and the amount of virus inoculated. Some wild rice species have exhibited moderate resistance to the virus. Cultural practices aimed at reducing vector populations, such as sowing dates that do not coincide with peak populations of the vector, are recommended.

Rice Gall Dwarf

Rice gall dwarf was first observed in Thailand, in the early 1980s. This disease is also present in China, Malaysia, and Thailand. The causal virus belongs to a species in the genus *Phytoreovirus,* family *Reoviridae*. Virions are icosahedral (60–70 nm) and possess 12 dsRNA genome segments and up to seven structural proteins (45–160 kDa). Rice gall dwarf virus (RGDV) is confined to phloem tissues of the plant host. Largest genome segment has 4.4 kb, and the smallest, 0.6 kb. Virions are found in the phloem, cytoplasm, and cell vacuoles in low concentrations, together with viroplasms containing immature virions.

RGDV is transmitted by the leafhoppers *N. nigropictus, R. dorsalis, N. cincticeps, N. malayanus,* and *N. virescens,* in a persistent, circulative, and propagative manner. RGDV is transmitted transovarially, is acquired rapidly from infected rice plants, and has an incubation period of 10–20 days in the insect vector. Main symptoms in rice are stunting, translucent gall formation on the underside of the leaves and on leaf sheaths (enations), and permanent dark green leaves. Infected plants produce few tillers, and form poorly developed panicles. Other grasses susceptible to this virus include oats, barley, rye, wheat, Italian grass (*Lolium* sp.), and *Oryza rufipogon*. Japanese grass (*Alopecurus aequalis*) is an important reservoir of RGDV; and maize also seems to be a host of RGDV in China.

Cultural practices aimed at breaking the cycle of the leafhopper vectors that move from spring to autumn plantings; and the elimination of ratoon plantings from over-wintered rice are recommended.

Rice Ragged Stunt

Rice ragged stunt was first reported from the Philippines and Indonesia in 1976. It is currently distributed in Bangladesh, China, India, Japan, Malaysia, Sri Lanka, Taiwan, and Thailand. The causal virus was isolated in the early 1980s, and shown to belong to a species of the genus *Oryzavirus,* family *Reoviridae*. Rice ragged stunt virus (RRSV) has icosahedral, double-shelled particles (75–80 nm) with conspicuous spikes. Oryzaviruses have a genome of 10 linear dsRNA segments with a total size of

26.6 kb. RRSV particles are composed of five major structural proteins (33–120 kDa) and three nonstructural proteins (31, 63, and 88 kDa). The dsRNA segments contain a single ORF each, except S4, which contains two ORFs. RRSV is serologically related to Echinochloa ragged stunt virus.

RRSV is transmitted by the delphacid planthoppers *Nilaparvata lugens* (brown planthopper) and *N. bakeri*, in a persistent, circulative, and propagative manner. RRSV is not transovarially transmitted. RRSV infects rice and other *Oryza* species, causing stunting, enations, ragged (serrated) leaves, and suppression of reproductive structures. Infected rice plants remain green when healthy plants have senesced. RRSV also infects maize and wheat. Virions are found in phloem enations; and infected cells show the presence of viroplasms and cell wall proliferation.

RRSV persists in rice and in the brown planthopper, and, consequently, continuous rice planting perpetuates the virus and its vectors. Planthoppers migrate from the tropics to temperate areas in the summer time. Resistance to RRSV has been identified in some breeding lines; but molecular breeding techniques have been preferred to genetically modify rice genotypes for resistance to the virus.

Rice Tungro

Tungro means 'degenerate growth' in Ilocano, a Philippine language. Tungro-like symptoms were first observed in the Philippines, Indonesia, Malaysia, and Thailand in the early 1960s, under different names, such as 'mentek', 'penyakit habang', 'penyakit mera', and 'yellow orange leaf'. Severe outbreaks of tungro disease occurred in the late 1960s, following the introduction of early maturing, fertilizer-responsive, and high-yielding rice varieties. The disease has been reported from other Asian countries, namely, India, Bangladesh, and China. Tungro was first associated with the presence of leafhoppers in affected rice fields, but one of the causal agents could only be visualized in 1967, as isometric particles, 30–35 nm in diameter. Between 1967 and 1970, at least four different strains of the tungro 'virus' were identified, and this number increased to eight strains by 1976. In 1978, Indonesian scientists reported the observation of both isometric (30 nm) and bacilliform (35×350 nm) particles in rice plants affected by the 'penyakit habang' disease (tungro) in Indonesia. Severe symptoms were associated with both particles, whereas rice plants infected only by the bacilliform virus showed moderate symptoms. Plants infected only by the isometric virus remained symptomless. The isometric particles were transmitted by the leafhopper *N. virescens*, but the bacilliform virus could not be transmitted in the absence of the isometric virus. This constituted the first demonstration that tungro is a synergistic disease, and that the isometric virus acts as an 'assistor' or 'helper' virus for the bacilliform virus that causes main symptoms associated with tungro disease. In 1979, *N. nigropictus* was also shown to be an occasional vector of the isometric virus, but not of the bacilliform virus. The shortest acquisition feeding for *Nephotettix impicticeps* is 5–30 min, and there is no incubation period. Therefore, the virus does not persist in the vector; and there is no trans-stadial or transovarial passage of the virus in the insect vector.

Rice tungro disease is thus caused by two different viruses: rice tungro spherical virus (RTSV), a positive-sense RNA virus, and rice tungro bacilliform virus (RTBV), a circular dsDNA virus. The nucleotide sequence of rice tungro bacilliform badnavirus (RTBV) DNA was determined in 1991. The circular genome has 8.3 kb and one strand contains four open reading frames (ORFs). One ORF encodes a protein of 24 kDa (P24). The other three ORFs potentially encode proteins of 12, 194, and 46 kDa. Comparative analyses with retroviruses suggested that the 194 kDa polyprotein is proteolytically cleaved to yield the virion coat protein, a protease, and replicase (reverse transcriptase and RNase H), characteristic of retro-elements. The DNA sequence of RTBV suggests that RTBV is a pararetrovirus. RTBV is currently classified as a member of a species of the genus *Badnavirus*, family *Caulimoviridae*.

The 12 433 nucleotide (nt) sequence of RTSV contains a large ORF, capable of encoding a viral polyprotein of 390.3 kDa. Two viral subgenomic RNAs of *c.* 1.2 and 1.4 kb, respectively, were detected in RTSV-infected leaf tissues. There are at least three capsid protein subunit cistrons near the N-terminus of the large ORF. The C-terminal half of the large ORF revealed conserved protein sequence motifs for a viral RNA polymerase, proteinase, and a putative nucleoside triphosphate (NTP)-binding protein. The sequence motifs are arranged in a manner that resembles those of picorna-like viruses. RTSV is the type species of the genus *Waikavirus*, family *Sequiviridae*.

Rice tungro bacilliform virus isolates from Bangladesh, India, Indonesia, Malaysia, and Thailand were compared with the type isolate from the Philippines. Restriction endonuclease maps revealed differences between the isolates, and cross-hybridization showed that they formed two groups, one from the Indian subcontinent and a second one from Southeast Asia.

Diseased leaves become yellow or orange-yellow, and malformed, starting with the tip of the lower leaves. Young infected leaves may show mottling and chlorotic stripes parallel to the veins. Root development is poor and the reproductive stage may be delayed. Affected panicles are usually small and sterile. Symptom expression varies considerably depending on the variety affected and environmental conditions. Yield losses depend upon plant age at the time of infection, and the plant genotype. *Eleusine indica*, *Echinochloa colonum, E. crusgalli, Oryza* spp., *Paspalum* sp.,

Setaria sp., sorghum, and wheat have also shown to be susceptible to tungro disease.

Several sources of resistance to RTSV have been identified at the International Rice Research Institute (IRRI). Promising lines have been identified and some of the superior lines resistant to tungro have been released as varieties. IR20, IR26, and IR30 were the first tungro-resistant cultivars released by IRRI followed by IR28, IR29, IR34, IR36, IR38, and IR40 during the 1970s. Some cultivars resistant to *N. virescens*, such as IR54, IR56, IR60, and IR62, were released in the 1980s, followed by PSBRc4, PSBRc10, PSBRc18, and PSBRc28 during the 1990s. Recently, five tungro-resistant lines showing resistance to RTSV were released as cultivars in Indonesia and the Philippines. Utri Merah, Balimau Putih, Habiganj DW8, and *O. rufipogon* served as donors of resistance genes.

Rice Stripe

Rice stripe is the second oldest viral disease of rice, having been first observed in the 1890s, in Japan. In 1931, the disease was associated with the presence of the leafhopper *L. striatellus*, but its causal agent could not be isolated. The disease continued to spread in Japan in the early 1950s, due to the introduction of new cultural practices (seeding of rice in wheat fields and early plantings) that expanded the temporal availability of young rice plants to the leafhopper vector. Rice stripe eventually emerged in Korea, Taiwan, China, and southwestern regions (Vladivostok) of the former USSR. The causal agent eluded detection until 1975, when Japanese scientists isolated thin (3–8 nm), coiled, filamentous particles of different lengths (2110–510 nm) from rice stripe-affected plants. In 1989, rice stunt virus (RSV) was shown to consist of four ssRNA components, similar to the genome of maize stripe virus (MSpV) isolated in 1981 in the United States. These viruses, together with rice hoja blanca virus (RHBV), isolated in Colombia in 1982, formed the 'rice stripe virus group' in 1988. Further molecular work led to the creation of the genus *Tenuivirus* in 1995. Tenuiviruses consist of up to six segments of linear, negative-sense, and ambisense ssRNA. RSV is believed to have four to five segments, depending on the isolate. Sizes are *c.* 9 kb for RNA 1 (negative polarity); 3.3–3.6 kb for RNA 2 (ambisense), 2.2–2.5 kb for RNA 3 (ambisense); 1.9–2.2 kb for RNA 4 (ambisense); and 1.2 kb for RNA 5 (negative polarity). The viral genome encodes structural (32–35 kDa) and nonstructural proteins (230 kDa), both of which are useful for diagnostic purposes. The nucleocapsid protein is encoded by the 5′ proximal region of the virion-complementary sense strand of RNA 3. Some proteins are translated from subgenomic RNAs.

RSV is transmitted by *L. striatellus*, the 'smaller brown planthopper', *Terthron albovittatum*, *Unkanodes sapporonus,* and *U. albifascia* (formerly *Ribautodelphax albifascia*). The virus multiplies in the insect vector (propagative) and there is transovarial passage of the virus to the progeny. The proportion of active vectors of *L. striatellus* can be as high as 54%. The shortest virus acquisition feeding period may be less than 30 min, and the incubation period in the vector is 5–10 days, although longer incubation periods have been reported for *L. striatellus* (21 days) and *U. albifascia* (26 days). The virus persists in its planthopper vectors for life ('persistent' transmission). RSV is not transmitted manually or through seed. The main hosts of *L. striatellus* are wheat, barley, and Italian rye in spring, and upland rice, *Echinochloa crusgalli,* and *Digitaria* spp. in summer.

Initial symptoms induced by RSV are failure of emerging leaves to unfold normally. Affected leaves may show chlorosis, and chlorotic stripes running parallel to the leaf veins. Affected leaves may eventually develop necrosis and die. In infected, older leaves, a chlorotic mottle may appear. The tillering capacity is often reduced, and panicles may fail to produce seed. RSV also infects at least 35 other species of plants in the Gramineae, including oats, barley, rye, sorghum, wheat, and maize.

All the Japanese paddy rice cultivars tested as seedlings proved susceptible, whereas most Japanese upland rice cultivars are highly resistant or immune. Outside Japan, most *indica* rice cultivars were resistant, but *japonica* rice cultivars were susceptible. Resistance in Japanese upland varieties was found to be controlled by two complementary dominant genes (St_1 and St_2). Multiple alleles of the latter gene may be responsible for the resistance associated with *indica* cultivars. Partial dominant resistance has been identified, linked to another dominant gene (St_3). Resistance to the virus is not necessarily linked to resistance to the vector. Transgenic rice cultivars (coat protein mediated resistance) possessing resistance to RSV have already been developed.

Rice Grassy Stunt

Rice grassy stunt was first observed in 1963 in the Philippines, where the characteristic stunting was initially referred to as 'yellow dwarf' or 'rice rosette'. This disease is now present in China, India, Indonesia, Japan, Malaysia, Sri Lanka, Taiwan, and Thailand. The association of this disease with the brown planthopper, *N. lugens,* was made in 1964. The causal agent of rice grassy stunt was isolated in the early 1980s, as a member of a distinct species of the genus *Tenuivirus*. Hence, rice grassy stunt virus (RGSV) shares most of its physicochemical characteristics with RSV. However, RGSV has an additional (sixth) ssRNA segment (ambisense), and its RNA 3 (3.1 kb) and RNA 4 (2.9 kb) are different from the corresponding segments of other tenuiviruses. RGSV

RNA 1 (9.8 kb), 2 (4.1 kb), 5 (2.7 kb), and 6 (2.6 kb) are homologous to RNAs 1, 2, 3, and 4, respectively, of other tenuiviruses. Both the capsid and non-structural proteins of RSV and RGSV are serologically related. A tentative tenuivirus, rice wilted stunt virus, originally reported in 1981 from Taiwan, is often considered a synonym of RGSV.

RGSV is transmitted by the planthoppers *Nilaparvata bakeri, N. lugens*, and *N. muiri,* in a persistent manner. RGSV multiplies in the vector, but it is not transmitted congenitally. Main symptoms consist of severe stunting, excessive tillering, erect growth, and short, narrow chlorotic leaves. Young leaves may show mottling and/or stripes. Inclusions are present in infected cells. Other hosts of RGSV include: *E. colonum, Cynodon dactylon, Cyperus rotundus, Leersia hexandra*, and *Monochoria* sp.

Genetic resistance to RGSV has been identified in some rice varieties. A single dominant gene conferring resistance to RGSV was identified in *Oryza nivara*. Some sources of RGSV resistance are susceptible to the planthopper vectors.

Rice Hoja Blanca

Rice hoja blanca ('white leaf') was first observed in the Cauca Valley of Colombia, South America, in 1935. By 1940, the disease was present in most rice-producing regions of Colombia. The disease was detected in Panama in 1952, in Cuba in 1954, in Venezuela in 1956, in Costa Rica in 1958, in El Salvador in 1959, in Guatemala in 1960, and in Nicaragua, Honduras, and the Dominican Republic in 1966. In South America, rice hoja blanca also occurs in Ecuador and Peru. The virus was detected in southern United States in the late 1950s, but it is not a problem there. Until the end of the twentieth century, hoja blanca was the only known viral disease of rice in the Americas.

The etiology of rice hoja blanca remained elusive until 1983, when virus-like particles isolated from infected rice plants in Colombia, were shown to be similar to those described in Japan for RSV. The causal virus was finally characterized as a member of the rice stripe virus group created in 1988, which also include MSpV. In 1995, these viruses became species of the genus *Tenuivirus*. The main physicochemical characteristics of these viruses have been described above, but RHBV virions consist of four species of ssRNA, with a total genome of 17.6 kb. RNA 1 is 9.8 kb and encodes the viral polymerase. RNA 2 (3.5 kb) has the capacity to code for two proteins in an ambisense manner, and RNA 3 (2.3 kb) encodes two proteins in an ambisense manner, including the capsid protein (35 kDa). RNA 4 (1.9 kb) has the same basic arrangement as RNAs 2 and 3, and codes for a nonstructural protein (23 kDa). Echinochloa hoja blanca virus (EHBV) was initially considered a strain of *Rice hoja blanca virus*, because it coexists with this virus in most affected rice fields, but it is now considered a distinct, serologically related tenuivirus.

RHBV is transmitted in a persistent, circulative, and propagative manner by the planthopper *Tagosodes orizicolus* (previously *Sogatodes oryzicola*). The virus also infects the insect vector and passes transovarially to the progeny of viruliferous females (80–95% efficiency). However, only 5–15% of the wild *T. orizicolus* population has the ability to transmit the virus in nature. Incubation periods of 6–36 days have been reported for RHBV in its planthopper vector. *Tagosodes cubanus*, the planthopper vector of EHBV, has been reported to transmit RHBV from rice to *E. colonum* but not from rice to rice, or from *Echinochloa* to rice, unless the viruliferous insects are forced to feed on the test plants. Colonies containing over 90% active vectors can be developed by crossing known male and female vectors. If left unattended, these colonies revert to their natural 5–15% of active vectors, suggesting that viruliferous individuals are at a biological disadvantage with respect to nontransmitters. The acquisition feeding period observed for at least 50% of the potential vectors to transmit RHBV is 15 min, with an optimum of 1 h. The incubation period is 6–9 days for individuals who acquire the virus transovarially, but may be up to 36 days for individuals acquiring the virus as nymphs or adults (males usually have a shorter life span and must acquire the virus transovarially). Nonviruliferous *T. orizicolus* females lay more eggs than viruliferous females, which suggested a deleterious effect of RHBV in its insect vector.

RHBV induces small chlorotic spots at the base of infected leaves, which then show longitudinal chlorotic stripes. The following leaves may be completely chlorotic (hence the name 'white leaf'). Plants affected at an early stage are usually stunted, and may eventually die. Malformation of grains or sterility of the panicle can be observed in systemically infected rice plants that reach the reproductive stage. RHBV has been shown to infect *Digitaria* spp., *Leptochloa* spp., oats, barley, rye, and wheat. Massive screenings of rice cultivars took place in Cuba, Venezuela, and Colombia in the late 1950s and early 1960s. Most commercial long-grain rice varieties are susceptible. Resistance to RHBV was identified in short-grain *japonica* varieties and hybrids with *indica* types. These hybrids have been used to develop resistant rice cultivars, but their level of resistance ultimately depends on virus pressure. Some varieties possessing high levels of RHBV resistance have been developed in recent years in Colombia, which seem to be the result of combining different mechanisms of resistance, not necessarily against the virus. Transgenic plants that show moderate levels of resistance to the causal virus have been developed. RHBV epidemics are cyclic, often separated by several

years of low disease incidence. The deleterious effect of the virus in viruliferous females may account for this cyclical phenomenon.

Rice Yellow Stunt

Rice yellow stunt (previously known as 'rice transitory yellowing') was first reported from southern Taiwan in 1960. The disease was initially believed to be caused by the lack of aeration in paddy fields. The characteristic foliar yellowing, stunting, and root rot were once blamed for the destruction of over 2000 ha of rice in the 1960s. In 1965, a virus was first suspected as the causal agent, and the leafhopper *N. nigropictus* (previously *N. apicalis*) was implicated as the vector. The name 'transitory yellowing' was given to this disease because affected rice plants often recovered from the yellowing symptoms at later stages of growth. The causal virus was isolated in 1986 and shown to be a bullet-shaped rhabdovirus approximately 190×95 nm. *Rice yellow stunt virus* is currently characterized as a species of the genus *Nucleorhabdovirus*, family *Rhabdoviridae*. Nucleorhabdoviruses multiply in the nucleus of infected cells, forming large granular inclusions. Virus maturation occurs at the inner nuclear envelope, where rice yellow stunt viruses (RYSVs) acquire their lipid envelope. The virus contains a single molecule of negative-sense ssRNA about 13.5 kb in size. A modular organization of the genome shows three highly conserved blocks, encoding structural and nonstructural proteins, membrane proteins, movement protein, and the polymerase.

RYSV is transmitted by the leafhoppers *N. nigropictus*, *N. cincticeps,* and *N. virescens* in a persistent and propagative manner. The virus does not pass congenitally to the progeny. Warm winters and continuous rice plantings increase virus incidence. *Japonica* varieties are more susceptible to RYSV than *indica* types. Highly resistant rice varieties have been selected since the early 1960s to manage this disease.

Rice Yellow Mottle

Rice yellow mottle was first observed in 1966 in Kenya and is currently the most important viral disease of rice in sub-Saharan Africa. The disease also affects rice in Madagascar. Yield losses ranging from 25% to 100% are not uncommon in West Africa. The causal agent was described in 1974 as an isometric virus about 30 nm in diameter, possessing positive-sense ssRNA (1.4×10^6 M). The RNA has 4450 nt organized into four ORFs, three of which overlap (except ORF 1). ORF4 codes for the 26 kDa capsid protein. This protein is required for cell-to-cell and long-distance movement. Rice yellow mottle virus (RYMV) is currently classified as a member of the species *Rice yellow mottle virus* in the unassigned genus *Sobemovirus*.

RYMV is transmitted by chrysomelid beetles (Coleoptera): *Sesselia pusilla, Chaetocnema pulla, C. dicladispa, Trichispa sericea, Dicladispa (Hispa) viridicyanea,* and *D. gestroi*, in a semi-persistent manner. The virus is lost when beetles molt; it does not multiply in the vector and is not congenitally transmitted. RYMV is transmitted by mechanical means but is not seed-borne. Rice yellow mottle disease is characterized by stunting, crinkling, mottling, yellow streaks, malformation of panicles, reduced tilllering, and sterility. RYMV also infects other *Oryza* species, and the grasses *Acroceras zizanioides, Dinebra retroflexa, Eragrostis aethipica, E. ciliaris, E. namaquensis, E. tenella, Echinochloa colona, Ischaemum rugosum, Panicum repens, P. subalbidum, Phleum arenarium, Sacciolepsis africana,* and *Setaria longiseta*.

Most African rice cultivars are highly susceptible to RYMV. Two types of resistance have been identified in *Oryza*: polygenic resistance in *O. sativa*, *japonica*, which slows down virus dissemination; and monogenic resistance in *Oryza glaberrima,* which prevents infection. Transgenic rice plants showing 'enhanced' resistance to RYMV have also been developed. The epidemiology of RYMV is poorly understood, specially regarding the identification of primary inoculum sources, and propagation of the virus in the field. Resistance-breaking isolates of RYMV have been recently detected in West and Central Africa.

Rice Stripe Necrosis

Rice stripe necrosis first emerged in Ivory Coast, West Africa, in 1977. The disease induces chlorotic striping, malformation, and necrosis of leaves, besides stunting and reduced tillering. The causal virus was shown to consist of rod-shaped virions of two predominant lengths (110–160 and 270–380 nm), and 20 nm wide. The virus can be mechanically transmitted to *Chenopodium amaranticolor* (local lesions), but is not seed-borne. The virus was transmitted through contaminated soil, which led to the identification of the fungus *Polymyxa graminis* as the vector. The causal virus, rice stripe necrosis virus (RSNV), was tentatively classified as a member of the genus *Furovirus*. However, its relatively low incidence and economic importance, when compared to rice yellow mottle virus, relegated RSNV to the condition of a minor pathogen. In the meantime, RSNV slowly disseminated into the main rice-growing areas of West Africa, where farmers and scientists alike mistook the disease for a soil or physiological problem. It was not until 1991, when a new disease of

rice emerged in the Eastern Plains of Colombia, South America, that research conducted at CIAT, Palmira, Colombia, demonstrated that the new disease was in fact 'rice stripe necrosis', probably introduced from West Africa in contaminated rice seed. The Colombian isolate of RSNV had rod-shaped particles with a bi-modal length of 260 and 360 nm, and a particle width of 20 nm. These particles were observed in the cytoplasm of infected rice cells, affecting mainly mitochondria and the endoplasmic reticulum.

The virus was isolated as four components of ssRNA (6.3, 4.6, 2.7, and 1.8 kb), and a capsid protein subunit of 22.5 kDa. At least two distinct replication-associated domains of RSNV RNA1 show sequence identities of >78% with the corresponding domains of Beet necrotic yellow vein virus (BNYVV-RNA 1). As in the case of BNYVV, the RNAs of RSNV terminate in a 3′-poly(A) tail. RSNV's particle length, number of RNA segments, polyadenylation of the RNAs 3′-end, and partial homology to BNYVV suggest that RSNV is a species of the genus *Benyvirus*. Partial sequence obtained from the Colombian isolate's RNA 1 segment also showed a 51% similarity to the corresponding region of BNYVV, member of the type species of the genus *Benyvirus*. The vector of the Colombian RSNV isolate was molecularly characterized as a type II isolate of the fungus *P. graminis*.

Since the 1970s, when RSNV was first reported from West Africa, it was evident that rice varieties reacted differentially to RSNV. Some IRAT lines (8, 9, and 13) showed low virus incidences or escaped disease. Screening of the main rice varieties grown in Colombia showed that most of these cultivars were susceptible. Some breeding lines and some Asian varieties exhibited moderate resistance levels. *Oryza glaberrima*, a related species planted for human consumption in West Africa, was observed to possess a high level of resistance to RSNV in that region and in Colombia. The disease seems to spread more rapidly in mechanized and irrigated rice plantings, but the main virus-vector dissemination mechanism is undoubtedly the use of seed produced in affected fields, where the fungus and the virus persist for many years. Rice stripe necrosis is currently found throughout West Africa, and in four neighboring countries of Latin America: Colombia, Ecuador, Panama, and Costa Rica.

Rice Necrosis Mosaic

Rice necrosis mosaic was first observed in Japan in 1959. The causal virus was observed in 1968 to have filamentous particles of two different lengths (275 and 550 nm) and 13 nm in width. Rice necrosis mosaic virus (RNMV) is currently classified as a member of the species *Rice necrosis mosaic virus* of the genus *Bymovirus,* family *Potyviridae*. Virions contain two molecules of positive-sense ssRNA. RNA 1 is 7.5–8.0 kb, and RNA 2 is 3.5–4.0 kb, and both RNAs are polyadenylated at their 3′-ends. The capsid protein is located in the 3′-proximal region of RNA 1. Virions have a single capsid protein subunit of *c.* 33 kDa. As other species in the family *Potyviridae*, RNMV induces cylindrical (pinwheels) inclusions in the cytoplasm of infected cells.

RNMV is transmitted by mechanical means and through soil by the vector fungus *P. graminis*. The main symptoms are initial mottling of the lower leaves, which gives rise to streaks and irregular foliar patches. Affected leaves turn yellow. Although susceptible rice plants are not markedly stunted, the number of tillers is usually reduced. Necrotic lesions can appear on leaf sheaths and the base of culms. Grain production is significantly reduced in diseased plants. The virus seems to be limited to *O. sativa*.

Viruses transmitted by *P. graminis* are generally disseminated through contamination of agricultural tools and machinery; irrigation water; and seed contaminated with soil particles containing viruliferous fungal propagules (cystosori). These propagules can remain viable in contaminated soils for over 10 years. Soil used in seedbeds should be kept free of the vector. Resistance to this disease has been identified in some rice varieties.

Glossary

Guttation Phenomenon linked to the natural movement of the fluid from the apoplastic areas to the leaf surface through stomata under conditions that allow gutate to form.
Pathotype A pathotype is a virus strains that exhibits a differential interaction with the host, usually increased virulence.
Pyramiding genes A combination of different resistance genes introduced in one line or cultivar.
Strain A virus isolate called strain exhibits specific interactions in front of several plant species. A strain may also be charaterized by particular properties of the viral particles.

Introduction

Most of the viruses that infect barley also infect wheat. Of the 57 viruses infecting wheat and or barley (**Table 1**), ten have been discovered less than 30 years ago and new strains or pathotypes are regularly reported. A few apparently nonpathogenic viruses belonging to the genera *Metavirus*, *Pseudovirus*, and *Endornavirus* have been characterized but are not described here. Only the most damaging viruses and some emerging viruses are described.

Agropyron Mosaic Virus

This virus of low agronomical importance on wheat is believed to be transmitted by the cereal rust mite *Abacarus hystrix* (Nalepa). In USA, agropyron mosaic virus (AgMV) may occur in wheat fields infected with wheat streak mosaic virus (WSMV). In the presence of the two viruses, a yield loss of 85% has been estimated.

Arabis Mosaic Virus

In Switzerland, arabis mosaic virus (ArMV) has been detected in fields of winter barley. Partial stunting, without yellowing, can occasionally be observed. Barley infection is achieved by the nematode *Xiphinema diversicaudatum* (Micoletzky).

Aubian Wheat Mosaic Virus

This emergent virus was observed in some winter wheat fields from northern and southern France. A similar virus is present in the UK. The rod-shaped particles of this virus are detected by enzyme-linked immunosorbent assay (ELISA). *Polymyxa graminis* cystosori are detected in the roots of infected plants but aubian wheat mosaic virus (AWMV) is not serologically related to the *Polymyxa*-transmitted viruses already known. The only known natural hosts of this virus belong to the genus *Triticum*. AWMV is mechanically transmitted to wheat and to some eudicots but mosaic symptoms were observed only on wheat. All the cultivars of bread and durum wheat inoculated were infected. In wheat fields, yellow patches of diseased plants are observed from the beginning of the year till heading stage. Most of the cultivars are slightly stunted showing variable mosaic symptoms. Nucleic acid sequences of the genome and natural transmission of the virus are under investigation.

Barley Stripe Mosaic Virus

This virus is no longer a global agronomical problem to barley. In the past, up to 60% yield loss has been reported. Pollen transmission of barley stripe mosaic virus (BSMV) is the main way of contamination. Immunological control of the seeds allows growing virus-free cultivars. BSMV is less frequently found on wheat. Its recent detection in Turkey means this virus should be monitored closely. With its tripartite genome and the high seed transmission, BSMV remains a model for studies of virus/plant interactions.

Barley Yellow Streak Mosaic Virus

This virus has been detected in several US states and Canada. The agronomical importance of barley yellow streak mosaic virus (BaYSMV) has not been evaluated. Nearly all plants in a field may be infected resulting in yield loss up to 100%. Infected plants are stunted and show chlorotic streaks and stripes parallel to the leaf veins. Virus particles are filamentous *c.* 64 nm in diameter and of varying lengths between 127 and 4000 nm. Particles have an outer lipid-like envelope. From purified particles, a dominant protein of ~32 Da and several single-stranded RNA (ssRNA) species of ~13–11 kbp have been isolated. This unassigned virus which resembles some insect and animal viruses probably belongs to a new genus.

[l]Unassigned virus.

BaYSMV is transmitted by the brown wheat mite *Petrobia latens* and is retained in eggs of mites which are the overwintering reservoir. No resistant barley cultivars are known.

Barley Yellow Striate Mosaic Virus

The distribution of this virus was first described in the Mediterranean areas. Recently, barley yellow striate mosaic virus (BYSMV) has been detected in East European countries. More than 10% yield loss in susceptible cultivars of durum wheat is suspected. Symptoms consist of leaf chlorotic striations, dwarfing, and excess tillering, and heads may be confined in the boot. Awns are short or broken and show mosaic. Wheat and barley plants die in spring in the case of an early infection in the autumn. BYSMV is transmitted in a persistent manner mainly by the planthopper *Laodelphax striatellus* (Fallén). The virus can be transmitted transovarially. Limited molecular tools have been used to compare BYSMV with other serologically related viruses (digitaria striate virus, maize sterile stunt virus, northern cereal mosaic virus (NCMV), wheat rosette stunt virus (WRSV)). Small grain species and several grasses are hosts of BYSMV. Durum wheat is generally more susceptible to BYSMV than bread wheat. Genetic basis of susceptibility/tolerance in wheat is under study.

Brazilian Wheat Spike Virus

This virus found in Brazil seems to be of low incidence on wheat crops. Young leaves of infected plants are entirely chlorotic, older leaves show bright stripes. Spikes of affected plants are pale yellow to whitish, containing empty grains. Particle morphology and cytology indicate that Brazilian wheat spike virus (BWSpV) could be a tenuivirus.

Brome Mosaic Virus

Brome mosaic virus (BMV) disease has been reported on wheat and triticale. Infected plants show yellow streak and stunting. The virus is present in the guttation fluid of the leaves. Beetles are considered to be the main vectors. Mechanical inoculation by animal and machinery traffic probably also occur.

Bymoviruses of Barley

Barley Yellow Mosaic Virus, Barley Mild Mosaic Virus

Bymoviruses have bipartite ssRNA genomes and each segment (RNA1 and RNA2) carries a single open reading frame (ORF) which encodes a polyprotein. The coat protein (CP) gene is located at the C-terminus of the RNA1.

Barley yellow mosaic virus (BaYMV) and barley mild mosaic virus (BaMMV) are major pathogens of winter barley in Europe and East Asia. Yellow discolored patches of different sizes are often the first sign of field infection in early spring. First symptoms are chlorotic or pale green spots and streaks along the leaf veins and can be observed in December or after snow break in February or March. Generally, the third leaves show as rolled young leaves. The bymoviruses of barley significantly reduce height and number of fertile tillers and losses caused by these viruses vary from 10% to 90%. When temperature rises, the new leaves remain green but show distinct pale green streaks. BaYMV and BaMMV can be found, either separately or together. In general, high yield reductions can be anticipated when the winter is very severe (**Figures 1** and **2**).

Different biological or/and serological variants of BaYMV, BaMMV, and wheat spindle streak mosaic virus (WSSMV) have been reported in Europe. In Europe, the resistant genes *rym4* and *rym5* have been overcome by

Figure 1 Symptoms of barley yellow mosaic virus pathotype 2 (BaYMV 2) in winter barley.

Figure 2 Symptoms of barley mild mosaic virus Sillery pathotype (BaMMV-Sil) in barley.

BaYMV 2 and BaMMV Sillery strain (BaMMV-Sil). In France, the presence of several pathotypes of BaYMV and BaMMV able to overcome at least seven of 15 known genes has been reported. These pathotypes, in slow progression, do not pose an agronomic problem for the moment. In Japan, seven strains of BaYMV and two strains of BaMMV have been described on the basis of pathogenicity toward barley cultivars. A Korean strain of BaMMV (BaMMV-Kor) differing biologically and serologically from the Japanese and European isolates and several biological variants of BaYMV in China have also been recognized.

The vector of BaYMV/BaMMV is *P. graminis* Ledingham, a soil organism belonging to the family Plasmodiophoraceae.

The only effective means of controlling these viruses is through the use of resistant cultivars. Resistant genes have been described and localized in the barley genome. Some of them confer complete immunity against BaYMV and/or BaMMV while others only delay the appearance of symptoms. Pyramiding genes have been introduced in barley cultivars and other genes are studied in various *Hordeum* species.

Bymoviruses of Wheat

Wheat Spindle Streak Mosaic Virus, Wheat Yellow Mosaic Virus

WSSMV and wheat yellow mosaic virus (WYMV) were reported in America/Europe and Asia, respectively. These two viruses are major pathogens of bread and durum wheat, rye, and triticale (**Figure 3**). In the case of WSSMV, it was demonstrated that its genome associated to viral CP is internalized by *P. graminis*. In France, a new serotype (sII) of the WSSMV has been reported. Depending on the wheat cultivars, WSSMV resistance is controlled by a single dominant gene or by two pairs of alleles, which show complementary effects.

Figure 3 Symptoms of wheat spindle streak mosaic virus in winter bread wheat.

Furoviruses

Chinese Wheat Mosaic Virus, Soil-Borne Cereal Mosaic Virus, Soil-Borne Wheat Mosaic Virus

Several wheat furoviruses infecting cereal species have been described in the worldwide: soil-borne wheat mosaic virus (SBWMV) in wheat, rye, and barley; soil-borne cereal mosaic virus (SBCMV) in wheat and rye (**Figure 4**); and Chinese wheat mosaic virus (CWMV) in wheat. These viruses are transmitted by *P. graminis*. SBWMV, the type member of the genus *Furovirus*, occurs mostly on winter wheat in America, Europe, Asia, and Africa. Based on genomic organization and biological characteristics, it was proposed that the American SBWMV, CWMV, European SBCMV, and Japanese SBWMV are four strains of the same virus species. SBWMV is internalized by *P. graminis* in the form of viral RNAs associated to movement proteins. Genomes of these viruses are divided into two ssRNA species that are individually encapsidated. The furoviruses of wheat often causes a 'rosetting' disease, meaning that the plants are severely stunted. The number of tillers and kernel weight are also reduced. The disease usually results in a 10–30% yield loss, but may cause up to 80% yield loss in seriously infested fields. Resistance to SBCMV is controlled by a single locus *Sbm* on 5DL chromosome. Recently a bulk segregant analysis demonstrated that the SBWMV resistance gene was also on chromosome 5DL. The relationship between the two loci is being investigated. This resistance limits the movement of the viruses from the roots to leaves.

Soil-borne wheat mosaic virus Marne strain (SBWMV-Mar) was isolated from barley cv. Esterel in France (Marne department). This furovirus, in contrast to common French isolates of SBCMV, is mechanically transmitted to barley and to oats. Nucleotide and amino acid sequence analyses revealed that the French virus infecting barley is closely related to a Japanese isolate of SBWMV (SBWMV-JT), which was originally isolated from barley.

Figure 4 Symptoms of soil-borne cereal mosaic virus in winter wheat.

High Plains Virus

This virus, discovered in USA in 1993, has been identified in two other continents. High Plains virus (HPV) is similar or identical to wheat spot mosaic virus described since 1952. Severe symptoms are shown by wheat plants when infected by HPV. The host range of HPV is large including barley, maize, and many grasses. The virus is transmitted obligatorily by the mite *Aceria tritici* (Shevtchenko) that also transmits WSMV. Two sources of resistance to WSMV *RonL* and *Wsm1* are not effective on HPV.

Indian Peanut Clump Virus

Found in five states of India and in Pakistan, Indian peanut clump virus (IPCV) is one of the few viruses infecting both Poaceae and Eudicot species. Several Poaceae species are important reservoirs of this virus which induces a severe disease in peanut. Like barley and maize, wheat is severely affected by IPCV. Early infected plants are dark green, stunted, and generally die. Spikes of late infected plants are malformed and produce shriveled seeds. IPCV is transmitted by the soil-borne vector *P. graminis* Ledingham and at a low level by wheat seeds. Peanut clump virus from West Africa is closely related to IPCV. Its agronomical importance on wheat and barley is unknown.

Iranian Wheat Stripe Virus

The agronomical importance of this virus was not estimated but is probably not high in the Fars Province of Iran where it was discovered. Chlorosis, whitening, and striping are observed in infected plants which are dwarfed. Iranian wheat stripe virus (IWSV) is transmitted in a persistent-propagative manner by the planthopper *Unkanodes tanasijevici* (Dlabola). From the comparison of genomic nucleic acid sequences, it has been suggested that a common ancestor between IWSV and RHBV/EHBV tenuiviruses may exist in the New World.

Maize Streak Virus – B Strain

Three strains of MSV have been distinguished on the basis of nucleic acid sequences. Strain A is associated to maize. Strain B (MSV-B) has been characterized in wheat, barley, and grasses in South Africa and in Tasmania. MSV-B is more aggressive on wheat and barley than on maize. Recombinants between strain A (from maize) and strain B have been characterized. Agronomical importance and epidemiology of strain B have to be investigated.

Northern Cereal Mosaic Virus

Several viruses such as WRSV from China, cereal mosaic virus, and winter wheat Russian mosaic virus (WWRMV) from east Russia are probably isolates or strains of the NCMV described in Japan. On winter wheat associated with conditions of high viral inocula in the autumn, yield losses may reach 80%. The infected wheat plants show stunting and prolific tillers. The leaves develop longitudinal yellow and green stripes. Plants infected at the seedling stage die during winter. When infection occurs later, the plant develops thickened stems and foliage. Grains are frequently shriveled. The virus is transmitted in a persistent-propagative manner mainly by *L. striatellus*. Small grains and several grasses are natural hosts of NCMV. Maize has been reported to be resistant to NCMV. Late sowing in autumn and eradication of volunteer plants are recommended.

Particle size, antigenic properties, and vector specificity of these cytorhabdoviruses are very similar or identical. Cereal pseudorosette virus (CPV) is transmitted also by *L. striatellus*. Since its particles are shorter than those of NCMV, CPV is considered a distinct species.

Triticum Mosaic Virus

This virus, discovered in 2006 in Kansas, has been found in areas where WSMV and HPV are present. The gene RonL giving resistance to WSMV is not efficient on triticum mosaic virus (TriMV). The Wsm1 source of resistance is active on TriMV at 19 °C but not at 25 °C. Symptoms induced by TriMV are similar to those of WSMV. In the future, serological diagnosis may become useful to distinguish TriMV from other viruses commoly found in wheat.

Wheat American Striate Mosaic Virus

Reported from Canada and the north-central regions of US, this virus has a limited importance because it is usually present only on the borders of wheat fields. Wheat American striate mosaic virus (WASMV) has a relatively narrow natural host range including barley and maize. Fine chlorotic parallel streaks, brown necrotic streaking of culms and glumes are relatively good indicators of WASMV infection. Susceptible cultivars are stunted and most ears are sterile. *Endria inimica* (Say), the main leafhopper vector, transmits WASMV in a persistent-propagative manner. Early planting favors autumn infection. Several cultivars such as TAM107 are tolerant.

Wheat Dwarf Virus

In continental areas of Europe and its borders, this virus may be very severe on winter wheat, durum wheat, triticale, rye, and barley. Two strains of wheat dwarf virus (WDV) have been characterized. Overall nucleic acid sequences of the wheat-adapted strain (WDV-W) which does not infect barley showed 16% divergence with the barley-adapted strain (WDV-B) which does not infect wheat. The monoclonal antibody MAB 3C10 developed in Germany detects only WDV-B. The two strains have several common hosts. In winter wheat, the leaves show large yellowing bands, the plants are stunted, and an excess of tillering is frequent in contrast to infection by yellow dwarf viruses (YDVs). In winter, barley plants are dwarfed, leaves are shortened, and start yellowing. As in wheat, early infected plants die. *Psammotettix* is the only known leafhopper vector of this virus. Both nymphs and adults of *Psammotettix alienus* (Dahlbom) transmit WDV in a persistent-circulative manner. Only local populations of *P. alienus* carry the viral inoculum to new crops. Depending on the climatic conditions, one, two, or three vector generations may be observed during the warm active periods. In autumn, flying insects are not seen when the maximum temperature is below 10 °C. *Psammotettix alienus* survives the winter in the egg stage on several Poaceae species. Fallows, regrowths, and volunteers play a major role in the constitution of the autumn viral inoculum. Herbicide sprays and tillage of fallows and of preceding susceptible crops reduce the size of *P. alienus* populations. Sowing as late as possible is also recommended. Insecticide-dressed seed offers good protection. Depending on the evolution of *P. alienus* populations, protection of crops can be achieved using one or two pyrethroid sprays.

Wheat Eqlid Mosaic Virus

This emergent virus found in the Fars Province of Iran is transmitted by the root aphid *Forda marginata* (Koch). It has been suggested that wheat Eqlid mosaic virus (WEqMV) should be included in a new genus of the family *Potyviridae*.

Wheat Streak Mosaic Virus

Agronomical importance of this virus is high mainly in European continental areas where analysis of the genome sequence suggested that this virus probably originated in the Fertile Crescent. WSMV-infected plants show mosaic symptoms and develop a rosette appearance. Symptoms on winter wheat usually appear only in spring at temperatures above 10 °C. Infected plants are stunted with sterile heads. Yield losses can be as high as 100%. WSMV is transmitted by the wheat curl mite (WCM) *Aceria tosichella* (Keifer). The virus is acquired during nymphal stages and is retained up to several weeks even following molting. Prevailing winds play an important role in long-distance dispersion of mites. Seed transmission of WSMV in wheat was estimated from 0.5% to 1.5%. The host range of WSMV is very wide including maize. Prevention of the infection of WSMV in winter wheat in the autumn is achieved by elimination of volunteers 2 weeks before planting.

Wsm1 is a gene of *Thinopyrum intermedium* translocated in wheat. Other partial amphiploids (Zhong1, Zhong 2) are resistant to WSMV and WCM. Recently, two wheat origins from Iran (Adl Cross and 4004) have been reported to carry two distinct genes providing complete resistance to WSMV symptoms. Five genes of resistance to WCM detected in *Aegilops* have been transferred to wheat. Introduction of WSMV replicase (NIa) or CP gene into transgenic wheat confers virus resistance (**Figure 5**).

Wheat Yellow Head Virus

This virus detected in USA is of limited agronomical importance. The infected plants show yellow heads and mosaic symptoms of flag leaves. Its vector is not known but wheat yellow head virus (WYHV) can be transmitted by vascular puncture inoculation to maize and to *Nicotiana clevelandii* plants. In infected plants, a major protein of 32–34 kDa is detected. Analysis of the amino acid sequences of this protein demonstrated that WYHV is closely related to rice hoja blanca virus, a tenuivirus.

Wheat Yellow Leaf Virus

Agronomical importance of this virus, detected in Japan, China, and Italy, is limited. The virus causes diffuse chlorotic flecks or interveinal chlorosis and severe yellowing. All small grain crops are susceptible to wheat yellow leaf virus (WYLV). In Japan, the weed *Agropyron*

Figure 5 Symptoms of wheat streak mosaic virus in winter wheat.

tsukushiense (Ohwi) is probably an important reservoir of the virus. *Rhopalosiphum maidis* (Fitch) and *Rhopalosiphum padi* (L.) transmit WYLV in a semi-persistent manner. Resistant Chinese cultivars have been reported.

Yellow Dwarf Viruses

Barley Yellow Dwarf-MAV, -PAS, -PAV; Cereal Yellow Dwarf-GPV, -RPS, -RPV; RMV; SGV

Different viruses of the family *Luteoviridae* infecting Poaceae (barley yellow dwarf-MAV, -PAS, -PAV; cereal yellow dwarf-GPV, -RPS, -RPV) and two other viruses not assigned to a genus are collectively called YDs. The distribution of these viruses is dependent on environmental conditions. BYDV-PAV is probably the most widespread. In fields mainly infected by BYDV-PAV, yield reduction from 5% to 20% and nearly 40% have been reported in susceptible wheat and barley cultivars, respectively. Symptoms in infected fields occur in patches. Yellowing (mostly in barley) or reddening (mostly in wheat) are characteristic of YDV infection. These symptoms appear at the two- to three-leaf stage in barley and often after heading in wheat. YDVs are transmitted in a circulative-persistent manner by one or several aphid species. The capsid of YDVs includes a CP and a read-through protein, both needed for aphid transmission.

In temperate areas, YDV vectors have two main flight periods. At the beginning of autumn, winged aphids leave summer hosts (ripening maize, perennial grasses, regrowths, and volunteers). These aphids are attracted to low plant density areas in young winter cereal fields. Depending on the temperature, one to several cycles of virus infection occur before aphids are killed by low temperatures. In oceanic and in other warm areas, low concentration of apterous aphids is maintained during winter. In spring, aphids leave their hosts and infect spring crops and then maize crops. Perennial grasses maintain a low but permanent reservoir of YDVs and aphids.

Risk assessment systems have been developed. In Australia, forecasts of vector incidence are based on the temperature and rainfall in late summer/early autumn. In France, a decision-support system based on temperature-driven simulations of aphid populations was proposed. In UK, a computer-based decision-support system associating the number of aphids found in suction traps and the numbers of foci of YDV infection per unit area of crop was developed. Using these systems, a risk index allows rationalization of foliar pesticide usage (usually synthetic pyrethroids). Treating seeds with an aphicide is necessary in some areas when early sowing of susceptible cultivars is decided or when the pressure of YDV inocula is known to be regularly high. Imidacloprid (nicotinic agonist) or fipronil (chloride channel agonist) gives a good protection during several weeks.

Only minor sources of resistance are known in wheat. Several sources of tolerance have been detected in other Triticinae genera. Several lines derived from crosses between wheat and *Thinopyrum* sp. are very tolerant to YDVs. The basis for *Thinopyrum*-derived resistance to CYDV-RPV is associated to resistance via inhibition of viral systemic infection.

In barley, a major gene of resistance mapped to chromosome 3H, Ryd2, has been introduced into present-day cultivars. The level of protection conferred by this gene varies according to strains of BYDV-PAV and has a low efficiency for CYDV-RPV. Recently, a new major gene Ryd3 mapped to chromosome 6 has been characterized. In resistant plants, these genes tend to increase seed yield compared to healthy controls.

Recent data on the mechanism and genetics of transmission by aphids and evidence of the glycosylation of virus CP open new avenues to control these viruses in the future.

Chandipura Virus

S Basak, University of California, San Diego, CA, USA
D Chattopadhyay, University of Calcutta, Kolkata, India

© 2008 Elsevier Ltd. All rights reserved.

Introduction

Vesicular stomatitis has been known for more than a century as a disease that causes severe mouth lesions in cattle, with ruptured vesicles in the gum or tongue and reddish ulcerations. The first report of vesicular stomatitis described the prevalence of the disease in South Africa as early as in 1897, whereas reports of infected horses with symptoms of vesicular stomatitis in the New World date back to an outbreak in the United States in 1916. In spite of multiple outbreaks of the disease in domestic animals that resulted in huge economic loss in different parts of the world, it was only in 1942 that the causative agent was identified as a virus and named vesicular stomatitis virus (Indiana serotype). In the subsequent year, the New Jersey serotype of vesicular stomatitis virus was isolated.

Chandipura virus (CPHV) closely resembles vesicular stomatitis virus but it was readily distinguished by its ability to infect humans. CHPV was first isolated in 1965 in Nagpur, India, from serum samples collected from two febrile patients. This virus isolate was shown to produce cytopathic effects when inoculated into cells in culture. Subsequently, CHPV was isolated from the serum of an encephalopathy patient in 1980 to further confirm its existence and its ability to propagate in the human population. Subsequent serological studies established the existence of this virus in many parts of India in both humans and in a variety of animals.

Taxonomy and Classification

Vesiculoviruses are assigned to the genus *Vesiculovirus* in the family *Rhabdoviridae*, order *Mononegavirales*. Vesiculoviruses are enveloped and contain a nonsegmented, single (mono) strand of genomic RNA of negative sense. Virions display bullet-shaped morphology, which is typical of viruses included in the family *Rhabdoviridae* (rhabdo in Greek means rod-shaped) (**Figure 1(a)**). Other genera of the family *Rhabdoviridae* include *Lyssavirus*, *Ephemerovirus*, *Novirhabdovirus, Cytorhabdovirus*, and *Nucleorhabdovirus*, and these include viruses that are important pathogens of ruminants, fish and plants, and human pathogens such as rabies virus. *Vesicular stomatitis Indiana virus* (VSIV), *Vesicular stomatitis New Jersey virus* (VSNJV), and *Chandipura virus* (CPHV) have been formally recognized as distinct species within the genus *Vesiculovirus*. Virus species that have been classified in the genus *Vesiculovirus* are presented in **Table 1**. Other viruses that have been placed tentatively in the genus *Vesiculovirus* include important viruses such as spring viremia of carp virus, Tupaia virus, and Calchaqui virus.

Viral Epidemiology

Although CHPV was first isolated in 1965, it was only in 2003 that the first evidence for its association in human epidemic was obtained during acute encephalitis outbreaks. One outbreak took place in the state of Andhra Pradesh and affected 329 children, resulting in 183 deaths. Simultaneously, another encephalitis outbreak was reported in the state of Maharashtra, resulting in about 400 encephalitis cases with 115 deaths. Subsequently, another outbreak of encephalitis associated with CHPV infection was reported in 2004 in the eastern state of Gujarat with a fatality rate of more than 75%. These recent outbreaks indicate the emergence of CHPV as a deadly human pathogen in the Indian subcontinent. Phylogenetic analysis has indicated

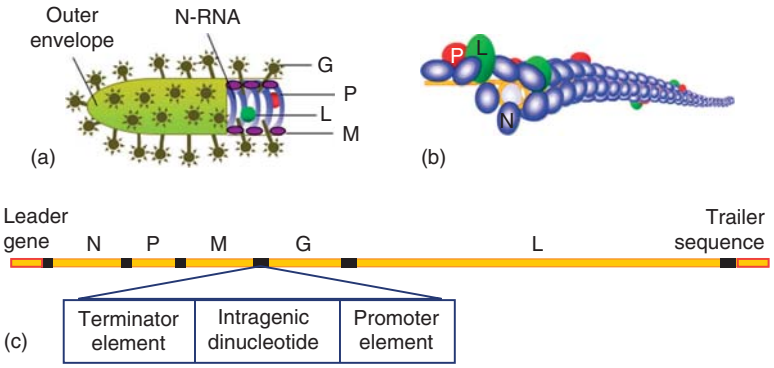

Figure 1 Vesiculoviruses: a general overview. A general overview of the vesiculoviruses with particular reference to Chandipura virus (a) Schematic presentation of bullet-shaped CHPV. Outer membrane envelope and relative organization of N-RNA nucleocapsid, glycoprotein G, phosphoprotein P, large protein L, and matrix protein M within virion structure have been indicated; (b) Nucleocapsid protein enwrapped genome RNA along with associated phosphoprotein P and large protein L forms a helical structure; (c) CHPV genome RNA encoding leader gene, five protein-coding genes, and gene junctions. Relative arrangement of the *cis*-acting elements within the gene junction has been indicated.

Maraba virus	MARAV	Brazil, 1984; *Am. J. Trop. Hyg.* 1984 Sep; 33(5): 999–1006	Sandflies
Carajas virus	CJSV	Brazil, 1984; *Am. J. Trop. Hyg.* 1984 Sep; 33(5): 999–1006	Sandflies

circulation in the population during these recent epidemics of multiple strains of CHPV which are subtly different from the original Nagpur strain.

The symptoms of CHPV encephalitis include high fever, generalized convulsions, vomiting, diarrhea, decerebrate posture leading to coma, neurological deficit, and acute encephalitis. During the outbreaks Chandipura encephalitis affected children below 15 years of age and resulted in a high mortality rate. Electron microscopy, complementation fixation and neutralization tests, as well as molecular biological techniques, were performed to examine the existence of Chandipura virus in the sera obtained from patients. The presence of anti-CHPV IgM antibodies and viral RNA was confirmed in the serum to implicate CHPV as an important etiological agent in the outbreak. Subjects infected with CHPV were shown to have an elevated level of cytokines in the blood that is thought to result in the damage to the central nervous system, and CHPV antigen and RNA was found in the brain tissue of the infected patients.

The prevalence of anti-CHPV antibodies in animal sera indicates that domestic animals might serve as a natural reservoir for this pathogen. Indeed, the presence of neutralizing antibodies to Chandipura virus was confirmed in 30.6% of pig, 14.3% of cattle, 17.9% of buffalo, 9.3% of goat, and 7.7% of sheep serum samples collected from the epidemic affected areas. The sandfly has been long recognized as a potential vector for the transmission of CHPV. The virus was isolated from a pool of 253 sandflies of the genus *Phlebotomus* in 1969. Transovarial transmission has

also been established in *Phlebotomus papatasi*. However, investigations carried out in the outbreak-hit areas suggest the involvement of sandflies of the genus *Sergentomyia* in the transmission of the pathogen.

Chandipura Virus Structure and Composition

At the molecular level, VSIV is the most extensively studied member of the family *Rhabdoviridae*. However, research on VSNJV and CHPV has also allowed us to gain further molecular insights into vesiculovirus' replication. The recent association with epidemics have emphasized the necessity to develop better understanding of the mechanism of Chandipura virus pathogenesis. Below, we summarize our current knowledge on the structure and replication of CHPV at the molecular level.

The CHPV virion is a bullet-shaped particle that is ~150 nm long and ~60 nm wide with a ~10 nm distinct surface projection. It has two compartments, the outer envelope and the inner nucleocapsid structure. The helical nucleocapsid is composed of a 11 119-nucleotide (nt) single-stranded genome RNA that is tightly wrapped with ~1200 molecules of nucleocapsid protein N (mol. wt. 50 kDa). In addition, ~50 molecules of large protein L (mol. wt. 241 kDa) and ~500 molecules of phosphoprotein P (mol. wt. 32.5 kDa) remain associated with the N-RNA complex. The envelope is a membranous structure that surrounds the nucleocapsid and contains an embedded transmembrane glycoprotein G that protrudes externally from the membrane surface. The matrix protein M lies at the inner side of the membrane and tethers the nucleocapsid to the envelope (**Figures 1(a)** and **1(b)**).

Genetic Makeup and Gene Structure

Vesiculoviruses exemplify one of the simplest genome architectures among the *Mononegavirales*. The entire CHPV genome has been sequenced and comparison with other vesiculoviruses has confirmed similar genetic makeup among vesiculoviruses. The Chandipura virus RNA genome comprises a 49-nt long leader sequence (l), followed by five transcriptional units coding for viral polypeptides separated by intergenic, nontranscribed spacer regions, and a short nontranscribed trailer sequence (t) arranged in the order 3′ l-N-P-M-G-L-t 5′ (**Figure 1(c)**). The CHPV gene junctions encompass a 23-nt long sequence that is highly conserved among different vesiculoviruses; this conserved sequence is comprised of a 11-nt gene end signal that regulates transcription termination and polyadenylation of viral mRNA, a 2 nt nontranscribed spacer region, and a 10 nt conserved promoter element that has been implicated in the transcription initiation. Comparative sequence analysis has indicated CHPV to be evolutionarily equidistant from the New World vesiculoviruses VSIV and VSNJV and closely related to the Asian vesiculovirus Isfahan.

Replication Cycle

The vesiculovirus replication cycle can be divided into nine discrete steps, namely: (1) adsorption of the virus particle; (2) viral entry into the host cell via receptor-mediated endocytosis; (3) membrane fusion and release of the core RNP into the cytosol from endosomal vesicles; (4) transcription of the genome by viral polymerase; (5) translation of viral mRNA; (6) post-translational modifications of viral proteins; (7) replication of viral genome; (8) assembly of progeny particles; and finally, (9) budding of the mature virion (**Figure 2**). The entire vesiculovirus replication cycle is cytosolic. Genomic RNA enwrapped with nuleocapsid protein N acts as a template during transcription to produce short leader RNA (l) and five monocistronic capped and polyadenylated viral mRNAs. Viral RNA-dependent RNA polymerase (RdRp) is composed of large protein L, which is the catalytic subunit and phosphoprotein P that acts as a regulatory subunit. Translation of viral mRNA results in the accumulation of viral polypeptides within the infected cell to prepare for the onset of genome replication. During replication, the same polymerase copies the entire genomic template into an exact polycistronic complement that acts as replication intermediate to produce multiple copies of negative-sense genome upon further cycles of replication. Subsequently, progeny of negative-sense genomic material is either packaged within the mature virion or subjected to further transcription, often referred to as secondary transcription. Notably, virus-specific genomic analogs always remain encapsidated by N protein; it is believed that the N-mediated enwrapment of the genomic RNA protects RNA from cellular RNases (**Figure 2**).

Viral Invasion

The receptor utilized by Chandipura virus to invade into the host cell has not yet been characterized. However, studies on VSIV have provided valuable information on the entry mechanism used by vesiculoviruses, in general. Consistent with its broad host range, the receptor utilized by VSIV is thought to be phosphatidyl serine, a ubiquitously present membrane lipid. Subsequent to the attachment, clathrin-mediated endocytosis triggers entry of the virus particle into the host cell through the endosomal pathway, which is then followed by G protein-mediated fusion of the virus particle with the endosomal membrane and release of the core nucleocapsid into the host cytoplasm.

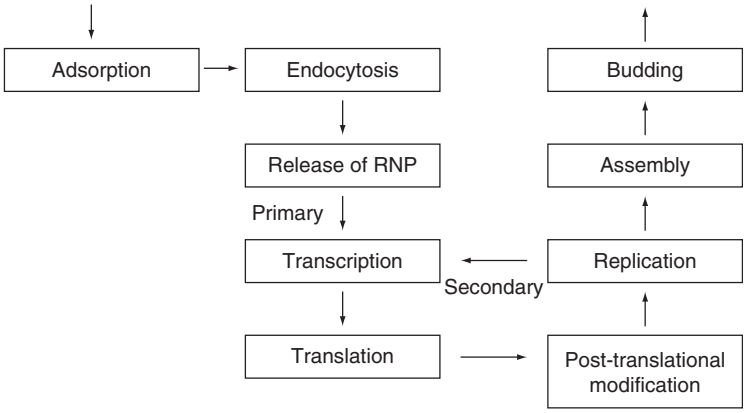

Figure 2 Vesiculovirus replication cycle. Graphical presentation of nine steps of the vesiculovirus replication cycle with particular reference to Chandipura virus. Transcription from the nucleocapsid particle released from the infecting virion, also referred to as primary transcription, as well as transcription from nucleocapsid particles synthesized *de novo* within infected cells, also referred to as secondary transcription, have been indicated in the figure.

Role of Glycoprotein G

Glycoprotein G is the sole spike protein that has been implicated in adsorption as well as budding of Chandipura virus. Studies on CHPV G protein expressed from a cloned DNA have revealed the presence of an N-terminal cleavable signal peptide, an N-terminal ectodomain with two N-linked glycosylation sites, a membrane anchor domain, and a cytosolic domain at the C-terminus. It has been proposed that a low pH-induced conformational change in G protein within the endosomal environment subsequent to viral entry results in membrane fusion to release core nucleocapsid particle into the host cytoplasm. The ectodomain of glycoprotein G mediates critical steps in membrane fusion. It is interesting to note that almost all the mutations in the G protein sequences identified in epidemic-associated virus strains were within this ectodomain.

Role of Matrix Protein M

Matrix protein M glues the core nucleocapsid particle to the outer membrane within the mature virion. The highly basic N-terminal domain of the M protein is primarily responsible for membrane association, although additional domains have been proposed to contribute in membrane binding.

Chandipura virus makes use of the fact that host mRNA is synthesized in the nucleus, whereas viral mRNA synthesis occurs in the cytoplasm to promote preferential translation of viral mRNAs. To achieve this, CHPV utilizes M protein to inhibit nuclear export of host mRNAs and thus channel host machinery towards translating viral mRNAs. Furthermore, M proteins of both VSIV and CHPV have been shown to shut off RNA polymerase I- and II-mediated transcription within infected cells. Not surprisingly, M protein alone was shown to account for cytotoxicity in virus-infected cells.

Gene Expression

Sequential and Polar Transcription

Vesiculovirus gene expression illustrates two distinct well-conserved characteristics; namely sequential and polar transcription. Vesiculovirus mRNAs are synthesized in an obligatory sequential manner after polymerase entry at a single site at the 3′ end of the genome, that is, at the beginning of leader RNA. Also, measurement of molar ratios of different VSIV mRNAs indicated that their abundance decreases with increasing distance from the polymerase entry site in the order $N > P > M > G > L$. To explain this polar and sequential mRNA synthesis, a stop–start model has been postulated for vesiculovirus transcription (**Figure 3**). In this model, subsequent to the entry into the N-RNA template, viral RdRp sequentially transcribes the genome with progressive attenuation at each gene boundary, which results in decreasing amounts of transcripts for genes that are distant from the entry site. Each termination event may cause the polymerase to fall off the template or may allow for re-initiation at the downstream promoter. Therefore, transcription of the downstream genes depends on the termination of the upstream gene transcription and re-initiation processes. Genomic RNA enwrapped with N protein into a nucleocapsid structure and not the naked viral RNA is recognized by the polymerase as a template for RNA synthesis. *In vitro* transcription reconstitution as well as *in vivo* studies have suggested that the proposed mechanism for vesiculovirus transcription is mostly conserved in CHPV system (**Figure 3**(**a**)).

Viral RdRp

CHPV RdRp is composed of the L and P proteins. Catalytic activities for RNA polymerization, capping, and polyadenylation reside within the L protein. The entire ORF

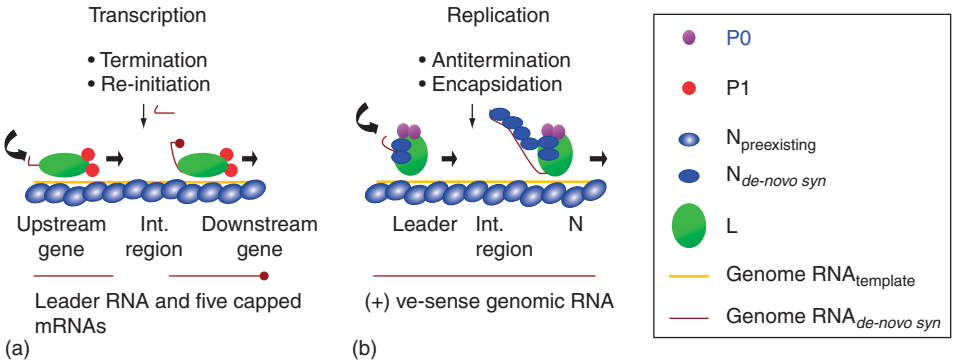

Figure 3 Vesiculovirus gene expression. Schematic diagram to depict Chandipura virus gene expression. (a) Stop–start model to describe vesiculovirus transcription, where, polymerase terminates and re-initiates at each gene junction to sequentially synthesize leader RNA and five mRNAs. (b) Viral replication that is characterized by the antitermination at each gene junction with concomitant encapsidation of the nascent replication product by nucleocapsid protein N. A role for unphosphorylated P protein (P0) has been postulated during replication.

encoding the CHPV L gene has been sequenced. The L protein exhibits a distinct structural module similar to that of a right hand, with palm, thumb, and finger domains. The palm domain structure is particularly conserved among almost all known RdRps. However, L protein only in association with the phosphorylated form of the P protein, and not L alone, acts as viral transcriptase.

Phosphoprotein P in Transcription

The P protein is packaged within the mature virion particle and remains associated with the viral nucleocapsid. Subsequent to the release of core nucleocapsid into host cytoplasm, the P protein plays an essential role in viral transcription. The P protein through its C-terminal domain interacts with both N-RNA template and the L protein, thus assembling transcriptase complex on the genomic template. The P protein utilizes its N-terminal acidic domain to interact with and activate polymerase function during transcription, similar to the activation mediated by classical eukaryotic transcription activators. The CHPV P protein exists in the virus-infected cells in two distinct states; the unphosphorylated form has been designated as P0, while its phosphorylated counterpart is referred to as P1. Phosphorylation of P at a distinct site is required for P to act as a transcriptional activator. Further investigations identified casein kinase II (CKII) as the host kinase responsible for phosphorylating P at specific residues. Biochemical and mutational analysis identified ser62 in the CHPV P protein as a single phosphorylation site both *in vitro* and *in vivo*.

How does phosphorylation regulate P protein function as a transcriptional activator? Studies on CHPV have revealed that the phosphorylated P protein forms a dimer. The N-terminal 46 amino acids were implicated in the dimerization of phosphorylated protein. It has been proposed that the unphosphorylated P protein exists as a monomer, whereas, dimerization upon phosphorylation enables P to act as a transcriptional activator. However, the unphosphorylated form of CHPV P protein has also been shown to form a dimer in a concentration-dependent manner. Recent structural analysis also indicated that a central domain that is conserved among different vesiculoviruses mediates dimer assembly of the VSIV-P protein in its unphosphorylated form. Therefore, dimerization alone is inadequate to explain transcriptional activation by phosphorylated P. Interestingly, phosphorylation at ser62 residue has been shown to promote a major conformational change in the P protein that exposes the N-terminal coiled-coil motif on the surface of protein tertiary structure. In light of the available information, it seems possible that the central domain assembles P into a dimer, whereas, additional interactions mediated through the N-terminal domain may stabilize such a dimer assembly. Conformational changes within the N-terminal domain of P upon phosphorylation and net negative charge attributed by the incorporated phosphate have been proposed to facilitate precise polymerase (L) contact by P1, resulting in optimal transcription.

mRNA Modification by Viral Transcriptase

One unique feature of vesiculovirus gene expression is the utilization of a single protein (L) for mRNA synthesis, 5′ end modification, and 3′ end polyadenylation of the mRNA. With the exception of leader RNA, all other viral transcripts possess a 5′ end cap structure, similar to that observed in cellular mRNAs. Although certain host factors have been postulated to participate in the capping reaction, primary enzymatic activity that mediates viral mRNA capping resides within the L protein. Viral transcriptase is also involved in the polyadenylation of viral mRNA. Polymerase slippage during transcription termination at the U7 tract present in the gene boundaries

results in addition of a poly(A) tail at the 3′ end of viral mRNAs. However, our current knowledge of mRNA modifications mostly relies upon contemporary studies that have been conducted in the VSIV system, due to the lack of a recombinant CHPV L protein expression system.

Replication of the Genome RNA

Transcription–Replication Switch

During transcription, the viral polymerase obeys the termination signals present at the gene boundaries to produce discrete viral mRNAs, whereas the same polymerase antiterminates at the gene boundaries during the replication phase to produce a positive-sense polycistronic complement of the entire genome. Subsequent rounds of replication that utilize the positive-sense replication intermediate as template produce many more copies of the progeny, negative-sense genomic RNA, which, after packaging buds out as a mature virion (**Figure 2**). The switch in polymerase function that allows it to ignore termination signals during replication is known as the transcription–replication switch. Although the same L protein is involved in RNA polymerization during both transcription and replication the phosphorylation state of the regulatory subunit P is proposed to be different in these two processes.

Role of Unphosphorylated P Protein

Recent studies in both CHPV and VSIV systems have indicated a role for unphosphorylated P protein in transcription–replication switch. A tripartite complex composed of a phosphorylation-defective mutant of P, N, and L was shown to efficiently synthesize VSIV replication product *in vitro*. It was postulated that the formation of L–N–P0 complex enables L protein to recognize promoter elements for replication and suppress the transcription termination signal present at the gene boundaries during VSIV replication. Similarly, *in vivo* analysis revealed that the N-terminal phosphorylation of P protein, although necessary for transcription, was dispensable for CHPV or VSIV replication. Indeed, a preexisting pool of phosphorylation-defective mutant of CHPV P protein (Ser62Ala) was shown to boost viral replication with a two-log increase in the virus yield upon subsequent infection with the wild-type virus. Therefore, the form of P protein (P1) engaged in transcription appears to be distinct from the form (P0) that has been implicated in replication.

However, another intriguing observation connected the proposed role of P0 in viral replication with the events on the nascent leader RNA chain. In an *in vitro* RNA-binding assay, it has been shown that P protein in its unphosphorylated form binds to leader RNA, whereas, CKII-mediated phosphorylation abrogated its RNA-binding ability. Leader RNA–P0 interaction was observed to be distinct from the N-mediated encapsidation. Similar phosphoregulation of RNA-binding ability of P protein has also been reported for rinderpest virus, a paramyxovirus. Accordingly, a refined model has been proposed to explain Chandipura virus genome replication. In this proposal, recruitment on the nascent leader chain brings P0 to the vicinity of the transcribing polymerase to promote P0 association with the polymerase. Such P0–L interaction alters the polymerase conformation in a manner that enables read-through at the gene boundaries. Nonetheless, progressive encapsidation of nascent viral RNA by CHPV N has been proposed to maintain processivity of such a replicase complex (L–P0) to allow for the synthesis of ∼11.1 kb positive-sense genome (**Figure 3(b)**). Curiously, recent analysis identified a conserved Glu64Asp mutation in the CKII consensus site within the N-terminal region of P protein in all epidemic isolates. In the light of the proposed function of P0 in viral replication, functional consequences of such mutations need to be further explored.

Genome Encapsidation and Assembly

Genome Encapsidation

Viral replication intermediates or replication products always remain encapsidated by N protein within infected cells and enjoy protection from cellular RNases. Consistently, vesiculovirus replication critically relies upon *de novo* synthesis of N protein. However, N protein is prone to aggregation and this aggregated form is unable to appropriately encapsidate viral RNA. Phosphoprotein P, by virtue of its N-specific chaperone-like activity, prevents self-aggregation of N protein and maintains it in an encapsidation-competent state. *Cis*-acting elements present within the first 20 nucleotides from the 5′ end of the positive-sense anti-genome and also at the 5′ half of the trailer region of the negative-sense genome, have been implicated in the initiation of encapsidation. CHPV N protein, in its monomeric form, possesses intrinsic RNA-binding specificity and is able to recognize *cis*-elements present in the genome RNA. However, this RNA-binding specificity has been shown to be compromised upon homooligomerization of N protein. Accordingly, a model has been proposed to provide mechanistic insight into the encapsidation process. In this model, monomer N initiates encapsidation by recognizing specific sequence element present in the nascent viral RNA. Subsequently, N–N interactions allow oligomer N to continue the elongation phase of the encapsidation process to enwrap diverse RNA sequences into the nucleocapsid structure. It is believed that the ensuing encapsidation of nascent RNA by N protein may also facilitate antitermination during replication by opposing polymerase pausing at the gene boundaries. Nevertheless, the major role of

N protein in viral replication cycle remains to protect viral RNA from cellular RNases and present genomic RNA in a specialized helical form that is recognized by viral polymerase.

Assembly and Budding

Progeny genomic RNA molecules enwrapped in the nucleocapsid structures associate with matrix protein M and are subjected to further M-mediated condensation. Subsequently, M protein participates in recruiting mature nucleocapsid particles to the membrane during assembly and budding in a manner that is dependent on the cellular ubiquitin–proteasome system, at least in the VSIV system. *De novo*-synthesized G protein is organized in the plasma membrane of virus-infected cells into microdomains that serve as assembly sites for the viral components.

Concluding Remarks

Our current understanding of the discrete steps of the CHPV replication cycle relies on the studies being conducted on the CHPV as well as on other vesiculoviruses. Remarkable similarities between CHPV and VSIV in genetic makeup, gene structure, polypeptide composition as well as function allow the postulation of a generalized model to describe vesiculovirus transcription at the molecular detail. While the proposed mechanism for CHPV replication that involves RNA binding by the phosphoprotein needs to be tested in the VSIV system, existence of distinct mechanisms in different serotypes of vesiculoviruses is possible. Nevertheless, information obtained from the molecular analysis of the epidemic-associated strains in conjunction with the large body of information that is available on N–P, N–leader RNA, or P0–leader RNA interactions should be utilized to further understand CHPV pathogenesis. While retaining general academic interest to understand RNA synthesis in rhabdoviruses, future CHPV research should also focus on development of the potential antiviral therapeutic interventions that will allow for specific inhibition of virus multiplication.

Glossary

Hyphal anastomosis The union of a hypha with another resulting in cytoplasmic exchange.
Mycoviruses Viruses that infect and multiply in fungi.
Viruses with multipartite genomes The essential genome is divided among several genomic segments (segmented genome) that are either separately encapsidated in identical capsids (multicomponent viruses, i.e., chrysoviruses) or jointly enclosed in a single particle (e.g., reoviruses).

Introduction

The discovery in the late 1960s and early 1970s of polyhedral virus particles in many of the industrial strains of *Penicillium chrysogenum* used for penicillin production generated considerable interest in the study of *Penicillium* viruses. It was surmised then that virus infection might be responsible for the instability of some of these strains. *Penicillium chrysogenum virus* (PcV), the type species of the genus *Chrysovirus*, was one of the first mycoviruses to be extensively studied at the biochemical, biophysical, and ultrastructural levels. Although the results of these earlier studies on PcV properties were mostly in agreement, they differed in their explanation of the nature of genome

complexity. Although PcV and the related *Penicillium* viruses penicillium brevicompactum virus (PbV) and penicillium cyaneo-fulvum virus (Pc-fV) have similar isometric particles, 35–40 nm in diameter, and are serologically related, there was confusion as to whether they contain three or four double-stranded RNA (dsRNA) segments. Because none of these viruses was characterized at the molecular level until recently, these three *Penicillium* viruses were originally grouped under the genus *Chrysovirus* and provisionally placed in the family *Partitiviridae* with the assumption that their genomes are bipartite, with dsRNA1 encoding the RNA-dependent RNA polymerase (RdRp) and dsRNA2 encoding the major capsid protein (CP). The additional dsRNAs (dsRNAs 3 and/or 4), like those of some partitiviruses, were presumed to be defective or satellite dsRNAs. The classification of the genus *Chrysovirus* was recently reconsidered because the complete nucleotide sequence and genome organization of each of the four monocistronic dsRNA segments associated with PcV virions and with the chrysovirus Helminthosporium victoriae 145S virus were recently reported. Based on the consistent simultaneous presence of their four dsRNA segments, the existence of extended regions of highly conserved terminal sequences at both ends of all four segments, sequence comparisons and phylogenetic analysis, it became clear that PcV and related viruses should not be classified with the family *Partitiviridae*. This led to the creation of the new family *Chrysoviridae* to accommodate the isometric dsRNA mycoviruses with multipartite genomes. The name *Chryso* is derived from the specific epithet of *Penicillium chrysogenum*, the fungal host of the type species.

Virion Properties

The buoyant densities of virions of members in the family *Chrysoviridae* are in the range of 1.34–1.39 g cm^{-3} and their sedimentation coefficients $S_{20,w}$ (in Svedberg units) are in the range of 145S to 150S. Generally, each virion contains only one of the four genomic dsRNA segments. However, purified preparations of PcV and Pc-fV can contain minor distinctly sedimenting components that include empty particles and replication intermediates.

Chrysovirus particles possess virion-associated RNA-dependent RNA polymerase (RdRp) activity, which catalyzes the synthesis of single-stranded RNA (ssRNA) copies of the (+) strand of each of the genomic dsRNA molecules. The *in vitro* transcription reaction occurs by a conservative mechanism, whereby the released ssRNA represents the newly synthesized plus strand.

Genome Organization

The virions of members of the family *Chrysoviridae* contain four unrelated linear, separately encapsidated, monocistronic dsRNA segments (2.4–3.6 kbp in size; **Table 1**). the largest segment, dsRNA1, codes for the RdRp and

dsRNA2 codes for the major CP. The dsRNA segments 3 and 4 code for proteins of unknown function. The genomic structure of PcV, the type species of the genus *Chrysovirus*, comprising four dsRNA segments, is schematically represented in **Figure 1**. The earlier conflicting reports on whether PcV contains three or four segments were recently explained when studies on cDNA cloning and sequencing of the viral dsRNAs were completed. Although the dsRNA extracted from purified virions is resolved into three bands by agarose gel electrophoresis (**Figure 2**, lane EB), northern hybridization analysis using cloned cDNA probes representing the four dsRNA segments shows clearly that each of the four segment has unique sequences (**Figure 2**). Because dsRNAs 3 and 4 differ in size by only 74 bp (**Table 1**), they co-migrate when separated by agarose gel electrophoresis. Previous studies on sequencing analysis and *in vitro* coupled transcription–translation assays showed that each of the four dsRNAs is monocistronic, as each dsRNA contains a single major open reading frame (ORF) and each is translated into a single major product of the size predicted from its deduced amino acid sequence. Thus, the fact that PcV virions contain four distinct dsRNA segments has clearly been established.

Unlike PcV, dsRNAs 3 and 4 from other chrysoviruses, helminthosporium victoriae 145SV (Hv145SV), amasya cherry disease associated chrysovirus (ACDACV) and cherry chlorotic rusty spot associated chrysovirus (CCRSACV) are clearly resolved from each other when purified dsRNA preparations are subjected to agarose gel electrophoresis. As shown in **Table 1**, dsRNAs 3 and 4 from these viruses are significantly different in size. Assignment of numbers 1–4 to PcV dsRNAs was made according to their decreasing size. Following the same criterion used for PcV, the dsRNAs associated with Hv145SV, CCSRACV, and ACDACV were accordingly assigned the numbers 1–4. Sequence comparisons, however, indicated that dsRNAs 3 of Hv145SV, CCSRACV, and ACDACV are in fact the counterparts of PcV dsRNA4 rather than dsRNA3. Likewise, dsRNA4 of these three chrysoviruses are the counterparts of PcV dsRNA3. Since PcV was the first chrysovirus to be characterized at the molecular level and to avoid confusion, the protein designations P3 and P4 as used for PcV will be adopted and referred to as

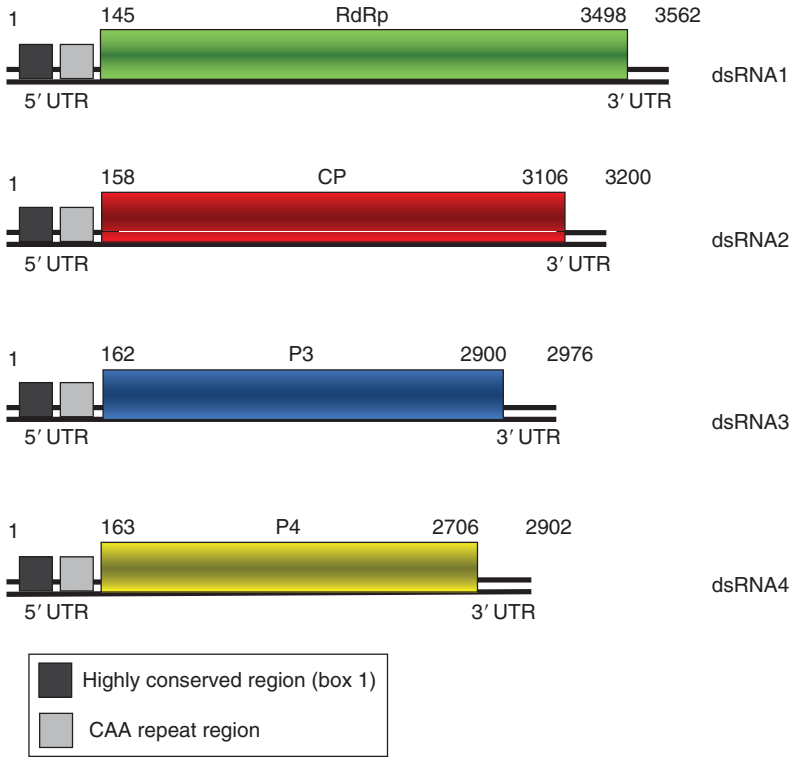

Figure 1 Genome organization of penicillium chrysogenum virus (PcV), the type species of the genus *Chrysovirus*. The genome consists of four dsRNA segments; each is monocistronic. The RdRp ORF (nt positions 145–3498 on dsRNA1), the CP ORF (nt positions 158–3106 on dsRNA2), the p3 ORF (nt positions 162–2900 on dsRNA3), and the p4 ORF (nt positions 163–2706 on dsRNA4) are represented by rectangular boxes. chryso-P3 and chryso-P4. Thus, whereas the chryso-P3 protein represents the gene product of PcV dsRNA3, it comprises the corresponding gene product of Hv145SV dsRNA4, and so on.

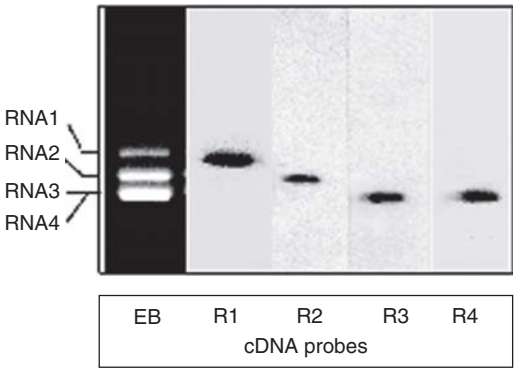

Figure 2 Northern hybridization analysis of PcV dsRNA segments. Virion dsRNAs were separated on a 1.5% agarose gel, transferred onto Hybond-N$^+$ membrane and hybridized with ^{32}P-labeled probes prepared by random-primer labeling of cloned cDNA to PcV dsRNA1 (R1), dsRNA2 (R2), dsRNA3 (R3), and dsRNA4 (R4). EB, ethidium bromide-stained virion dsRNAs separated on a 1.5% agarose gel. Reproduced from Jiang D and Ghabrial SA (2004) Molecular characterization of penicillium chrysogenum virus: Reconsideration of the taxonomy of the genus chrysovirus. *Journal of General Virology* 85: 2111–2121, with permission from Society for General Microbiology.

Except for CCRSACV and ACDACV dsRNAs, the 5′ UTRs of chrysovirus dsRNAs are relatively long, between 140 and 400 nucleotides in length. In addition to the strictly conserved 5′- and 3′-termini, a 40–75 nt region with high sequence identity is present in the 5′ UTR of all four dsRNAs (box 1; **Figure 3**). A second region of strong sequence similarity is present immediately downstream from 'box 1' (**Figure 3**). This consists of a stretch of 30–50 nt containing a reiteration of the sequence 'CAA'. The $(CAA)_n$ repeats are similar to the enhancer elements present at the 5′ UTRs of tobamoviruses. Although the 5′ UTR of CCRSACV and ACDACV contain the 'CAA' repeat region upstream of the translation initiation codon, the 'box 1' region is significantly shortened. Furthermore, these viruses do not share with PcV and Hv145SV the strictly conserved terminal 8 and 7 nucleotides, respectively at the 5′ and 3′ ends (**Table 2**). The discrepancies in the length and features of the 5′ and 3′ UTRs of CCRSACV and ACDACV dsRNAs compared to those of PcV and Hv145SV could be due to the cloning procedure used, which may not have allowed for the exact termini to be cloned. This, however, seems unlikely because of the strong similarities of the termini and internal sequences of the 5′ and 3′ UTRs of all four CCRSACV and ACDACV dsRNA segments. Alternatively, the divergence in the features of the 5′ and 3′ UTRs of ACDACV and CCRSACV may be because

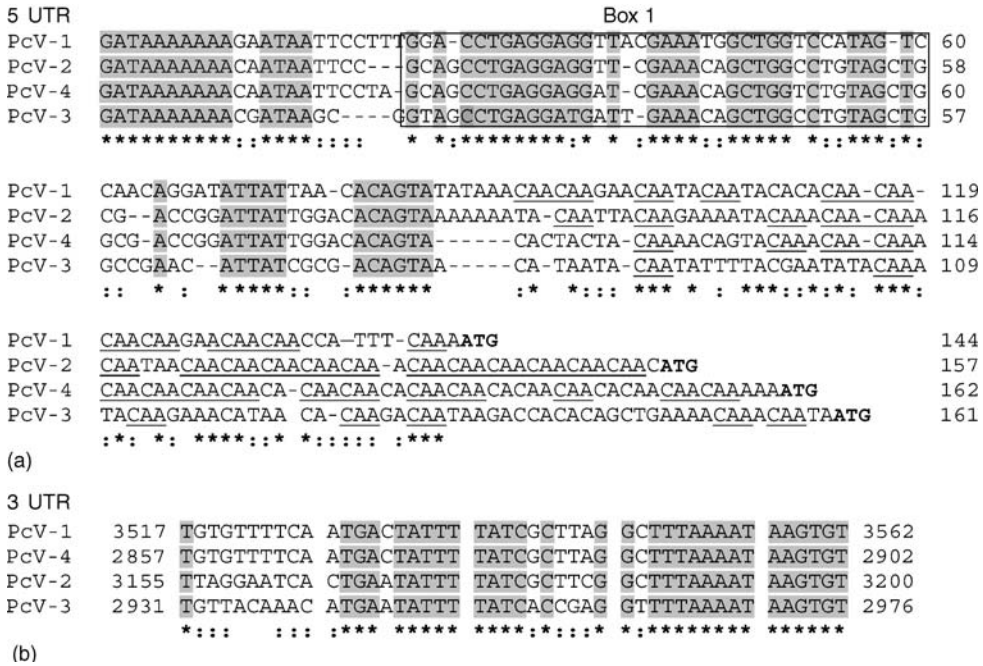

Figure 3 Comparison of the 5′ and 3′ UTRs of the four dsRNA segments of PcV. Multiple sequence alignments were obtained using CLUSTAL X (and some manual adjustments) with the nucleotide sequences of the 5′ UTR (a) and the 3′ UTR (b). The (CAA) repeats are underlined in (a). Asterisks signify identical bases at the indicated position (shaded) and colons specify that three out of four bases are identical at the indicated positions. Genome Expression and Replication

Chrysovirus dsRNA1s Code for RdRp

The largest dsRNA segment (dsRNA1) of the chrysoviruses so far sequenced contains a single large ORF coding for RdRp. The calculated molecular mass of chrysovirus RdRps ranges from 122 to 129 kDa (**Table 1**). These values are consistent with those estimated by SDS-PAGE of the *in vitro* translation products of full-length transcripts derived from cDNAs to dsRNA1s of PcV and Hv145SV. Examination of the deduced amino acid sequence of the RdRp ORF reveals the presence of the eight conserved motifs characteristic of RdRps of dsRNA viruses of simple eukaryotes (**Figure 4**). A comparison of the conserved motifs of chrysovirus RdRps with those of totiviruses and partitiviruses reveals that the RdRps of chrysoviruses are more closely related to those of totiviruses than to those of partitiviruses (**Figure 4**). This conclusion is also supported by published results of phylogenetic analysis of RdRp conserved motifs and flanking sequences of chrysoviruses and viruses in the families *Totiviridae* and *Partitiviridae* (see section on 'Evolutionary relationships').

Chrysovirus dsRNA2s Code for CP

The second largest dsRNA segment (dsRNA2) of chrysoviruses so far sequenced contains a single large ORF coding for CP. The calculated molecular mass of chrysovirus CPs ranges from 100 to 112 kDa (**Table 1**). The predicted size of PcV CP (109 kDa) is similar to that estimated by SDS-PAGE of purified PcV virions as well as that determined for the *in vitro* translation product of full-length transcript of dsRNA2 cDNA. Direct evidence that PcV dsRNA2 encodes CP was provided by amino acid sequencing of a tryptic peptide derived from a gradient-purified PcV capsid.

Chryso-P3 Shares a 'Phytoreo S7 Domain' with Core Proteins of Phytoreoviruses

PcV dsRNA3 codes for its chryso-P3 protein, whereas Hv145SV, ACDACV, and CCRSACV dsRNA4s encode the corresponding chryso-P3s. Although the function of chryso-P3 is not known, sequence analysis and database searches offer some clues. ProDom database searches reveal that chryso-P3 sequences share a 'phytoreo S7 domain' with a family consisting of several phytoreovirus P7 proteins known to be viral core proteins with nucleic acid binding activities. The consensus for the three chrysoviruses is [X(V/I)V(M/L)P(A/M)G(C/H)GK(T/S)T-(L/I)]. Phytoreovirus P7 proteins bind to their corresponding P1 (transcriptase/replicase) proteins, which bind to the genomic dsRNAs. It is of interest, in this regard, that the N-terminal regions of all chryso-P3s (encompassing the amino acids within positions 1–500) share significant sequence similarity with comparable N-terminal regions of the putative RdRps encoded by chrysovirus dsRNA1s. A multiple alignment of a portion of the N-terminal region sequences of chrysovirus P3s and RdRps is shown in **Table 3** to demonstrate the level of similarity among the N-terminal sequences of these proteins. The regions in the dsRNA1-encoded proteins with high similarity to chryso-P3 occur upstream of the eight highly conserved motifs characteristic of RdRps of dsRNA viruses of simple eukaryotes. The significance of this sequence similarity to the function of chryso-P3 is not known for certain, but one may speculate that the N-terminal region of these proteins may play a role in viral RNA binding and packaging.

Figure 4 Comparison of the conserved motifs of RdRps of selected isometric dsRNA viruses. Numbers 1–8 refer to the eight conserved motifs characteristic of RdRps of dsRNA mycoviruses. The amino acid positions corresponding to conserved motifs 1 and 2 for the RdRps of viruses in the family *Partitiviridae* are not well defined and, therefore, they are not presented. Multiple sequence alignments were obtained using the CLUSTAL X program with RdRp amino acid sequences of the following viruses. Upper set: viruses in the family *Totiviridae*: sphaeropsis sapinea RNA virus 1 (SsRV-1), SsRV-2, helminthosporium victoriae 190S virus (Hv190SV), and ustilago maydis virus H1 (UmV-H1). Middle set: viruses in the family *Chrysoviridae*: Hv145SV PcV and CCRSACV. Lower set: viruses in the family *Partitiviridae*: fusarium poae virus 1 (FpV1), rhizoctonia solani virus-717 (RhsV-717), atkinsonella hypoxylon virus 1 (AhV1), heterobasidion annosum virus (HaV), beet cryptic virus 3 (BCV3), and fusarium solani virus 1 (FsV1). Asterisks signify identical residues (shaded) at the indicated positions; colons signify highly conserved amino acid residue within a column; numbers in parentheses correspond to the number of amino acid residues separating the motifs.

Chryso-P4 is Virion Associated as a Minor Protein

Present evidence, based on amino acid sequencing of a tryptic peptide derived from gradient-purified PcV virions, strongly supports the conclusion that PcV chryso-P4 is virion-associated as a minor protein. The chryso-P4 encoded by chrysoviruses contains the motif PGDGXCXXHX. This motif (I), along with motifs II (with a conserved K), III, and IV (with a conserved H), form the conserved core of the ovarian tumor gene-like superfamily of predicted cysteine proteases. Multiple alignments showed that motifs I–IV are also present in other viruses including AbV-1, a tentative member of the family *Chrysoviridae*. Whether the RNAs of these viruses indeed code for the predicted proteases remains to be investigated.

Replication of Chrysoviruses

There is very limited information on how chrysoviruses replicate their dsRNAs. The virion-associated RdRp catalyzes *in vitro* end-to-end transcription of each dsRNA to produce mRNA by a conservative mechanism. Purified virions containing both ssRNA and dsRNA have been isolated from *Penicillium* spp. infected with PcV or Pc-fV, which may represent replication intermediates.

Virion Structure

Virions are isometric, nonenveloped, 35–40 nm in diameter (**Figure 5**). The capsid structure of PcV was recently determined at relatively moderate resolutions (~2.5 nm) using cryotransmission electron microscopy combined with three-dimensional image reconstruction. The outer surfaces of full particles of PcV, viewed along a five-, three-, and twofold axis of symmetry are shown in **Figure 6**. The capsid comprises 60 protein subunit monomers arranged on a $T = 1$ icosahedral lattice. The outer diameter of the capsid is 406 Å and the average thickness of the capsid shell is 44 Å. At this low to moderate resolution, some features are distinguished on the relatively smooth

topography of full and empty particles. The $T=1$ full capsid is formed by 12 slightly outward protruding pentamers making an underlying cavity. The pentamers are rather complex; on the outer surface, they are formed by five connected, elongated, ellipsoid-like structures surrounded by another five smaller similar structures that are neither connected to each other, nor intercalated with inner ellipsoid-like structures. No holes are evident in the shell. The outer surface of the empty capsid is essentially identical to that of the full capsid except for the presence of five pores around the inner, elongated, ellipsoid-like structures at the fivefold axis, and three small pores around the threefold axis (not shown). There are significant differences between empty and full capsids on the inner surface around the five- and threefold positions, suggesting conformational changes. Although conformational changes have been characterized in related cores, the structural changes that are observed between empty and full PcV particles are considered unique.

The PcV capsid with its genuine $T=1$ lattice is the exception among dsRNA viruses whose capsids have '$T=2$' layers, which is the typical architecture for dsRNA viruses. PcV has the largest coat protein making a $T=1$ shell. Examination of the PcV coat protein sequence reveals a possible relationship with the canonical $T=2$ layers. Sequence analysis indeed suggests that the PcV capsid subunit falls into two similar domains that are likely to build a similar fold. Even though they are covalently linked, this unusual building unit could resemble the regular 120-subunit capsid. In this situation, PcV capsid might be considered a pseudo-($T=2$) structure. The coat protein of the chrysoviruses Hv145SV and CCRSACV share some of the repeated segments only in their amino-terminal half. The structures of the Hv145SV and CCRSACV capsids have yet to be elucidated.

Biological Properties

There are no known natural vectors for the recognized chrysoviruses PcV, PbV, Pc-fV, and Hv145SV. They are transmitted intracellularly during cell division and sporogenesis (vertical transmission), and following hyphal anastomosis (cell fusion) between compatible fungal strains (horizontal transmission).

Unlike the *Penicillium* chrysoviruses, which are associated with latent infections of their hosts, all other known chrysoviruses occur in mixed infections with other mycoviruses (or possibly plant viruses) and are associated with disease phenotypes of their hosts. The chrysovirus Hv145SV, which together with the totivirus Hv190SV coinfect the plant pathogenic fungus *Helminthosporium* (*Cochliobolus*) *victoriae*, is associated with a debilitating disease of the fungal host. The role of Hv145SV in disease development, however, is not yet clear.

ACDACV and CCRSACV are associated with two diseases of cherry, the Amasya cherry disease (ACD) and

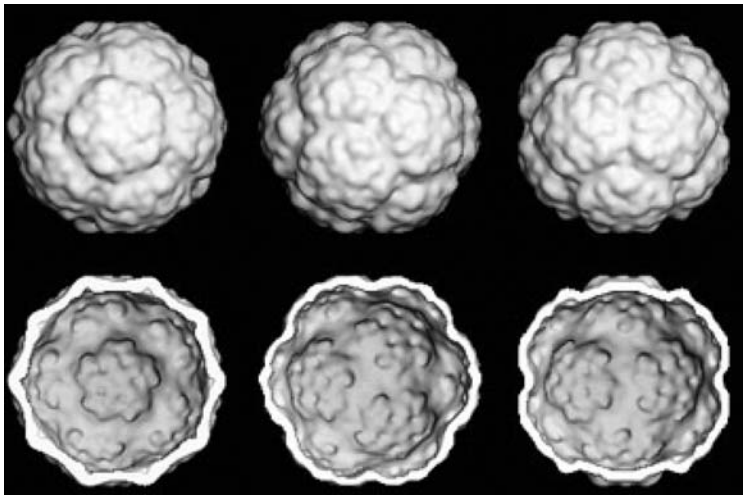

Figure 6 Three-dimensional structures of full PcV capsids. Surface-shaded representations of the outer surfaces of full PcV capsids viewed along a five-, three-, and twofold (left to right, upper row) axis of icosahedral symmetry. Models with the front half of the protein shell removed viewed along the five-, three-, and twofold axis are shown (left to right, lower row). Courtesy of R. J. Castón.

cherry chlorotic rusty spot (CCRS) disease. Both ACD and CCRS diseases are associated with a complex pattern of virus-like dsRNAs. Symptomatologically, both diseases are indistinguishable, a conclusion that was further supported by similar PAGE profiles for their associated dsRNAs. Furthermore, the sequences of at least six of these dsRNAs are essentially identical. Four of the ACD- and CCRS-associated dsRNAs comprise the genomic dsRNAs of the chrysoviruses ACDACV and CCRSACV, respectively. The etiology of these two cherry diseases is unknown and it has yet to be determined whether the dsRNAs associated with the diseases represent the genomes of plant or fungal viruses. In addition to the chrysovirus dsRNAs, the mixture of dsRNAs associated with the disease also contain a partitivirus and and larger dsRNAs with similar sizes to totiviruses. Whether the chrysoviruses alone or in combination with other dsRNA viruses play a role in disease development has yet to be elucidated.

The tentative chrysovirus AbV-1, also designated La France isometric virus (LFIV) induces a serious disease of cultivated mushroom (named La France disease). The AbV1 virions, isolated from diseased fruit bodies and mycelia, are isometric 34–36 nm in diameter and co-purify with nine dsRNA segments (referred to as disease-associated dsRNAs). The sizes of the dsRNA segments vary from 3.6 to 0.78 kbp, at least three of which are believed to be satellites. AbV1 represents a multiparticle system in which the various particle classes appear to have similar densities. Interestingly, phylogenetic analysis of RdRp conserved motifs of AbV1, encoded by dsRNA segment L1, and other dsRNA mycoviruses showed that AbV1 is closely related to the multipartite chrysoviruses. Although there is convincing evidence that infection with AbV-1 alone is essential and sufficient for induction of the La France disease, another mushroom virus, the mushroom bacilliform virus (MBV), the type species of the family *Barnaviridae*, is commonly found in mixed infections with AbV1 in diseased mushrooms. MBV is apparently not essential for disease development since no obvious phenotypic changes were observed in an *Agaricus* culture singly infected by MBV. However, synergistic interactions between AbV1 and MBV in doubly infected mushrooms cannot be ruled out.

Evolutionary Relationships among Chrysoviruses

The *Penicillium* chrysoviruses PcV, Pc-fV, and PbV are serologically related and have similar biochemical and biophysical properties. Although molecular data is only available for PcV, the three viruses could be considered as strains of the same virus for all practical purposes. The fact that these closely related viruses occur in different fungal species suggested that transmission by means other than hyphal anastomosis may occur in nature, since hyphal fusion between different fungal species is doubtful. Horizontal transmission of fungal viruses in nature, however, has yet to be demonstrated, and in the case of viruses of *Penicillium* species may not need to occur since the viruses replicate in parallel with their hosts and are carried intracellularly during the vegetative growth of the host (vertical transmission). Furthermore, the viruses are

efficiently disseminated via the asexual spores (conidia) of *Penicillium* species. It seems feasible, however, that virus infection arose early in the phylogeny of *P. brevi-compactum, P. chrysogenurn*, and *P. cyaneo-fulvum* before they diverged and that the resident virus remained associated with them during their subsequent evolution.

BLAST searches of PcV RdRp amino acid sequence showed that it has significantly high sequence similarity (40% identity and 57% aa sequence similarity) to the RdRps encoded by the chrysoviruses Hv145SV, ACDACV, and CCRSACV. High similarities (BLAST hits of $e^{-}16$ or lower) were also found to the RdRps of the tentative chrysovirus agaricus bisporus virus 1 (AbV-1) as well as to the totivirus ustilago maydis virus H1 (UmV-H1) and the giardiavirus trichomonas vaginalis virus (TVV). Still high similarity hits can be obtained with the RdRps of several members of the family *Totiviridae*. Interestingly, no significant hits were evident with any of the viruses in the family *Partitiviridae,* another validation for the removal of chrysoviruses from the family *Partitiviridae* and their placement in the newly created family *Chrysoviridae*. The conclusion that chrysovirus RdRps are more closely related to those of totiviruses than to those of partitiviruses is consistent with the results shown in **Figure 4**, where the RdRp conserved motifs of members of the three families are compared. Phylogenetic analysis (**Figure 7**), based on the complete nucleotide sequences of the RdRps of members of the three families, provides further confirmation to this conclusion.

BLAST searches of the deduced amino acid sequence of dsRNA2 ORF showed significant high similarity hits ($3e^{-}62$) to Hv145SV CP (29% identity and 50% amino acid sequence similarity) and ACDACV and CCRSACV CPs (24% identity and 46% similarity). It is interesting that the region of high sequence similarity between the CPs of these chrysoviruses is limited to the N-terminal half of the proteins (aa 19–560 of PcV CP; data not shown). This finding may have implications when considering the structural organization of chrysovirus capsids.

Future Perspectives

Functions of Chryso-P3 and Chryso-P4

Present evidence suggests that both chryso-P3 and chryso-P4 are virion associated and that they may play a role in RNA transcription, RNA binding, and packaging. Because infectivity assays are not amenable for chrysoviruses, no direct evidence is currently available in support of the conclusion that chrysovirus segments 3 and 4 and their gene products are essential for virus infection and replication. However, based on the consistent co-presence of the four dsRNA segments, the existence of extended regions of highly conserved terminal sequences at both ends of all four segments, sequence comparisons and phylogenetic analysis, it is abundantly clear that the structural features of chrysoviruses are typical of RNA viruses with multipartite and multicomponent genomes. The dsRNA pattern of PcV virions isolated from different strains of *Penicillium chrysogenum* has remained unchanged throughout the years since PcV was first isolated. This is also true for other chrysoviruses isolated from different *Penicillium* species and from various strains of *Helminthosporium victoriae*. The co-presence of all four segments in different fungal species and strains harboring chrysoviruses and the stability of the dsRNA patterns support the contention that all four segments are essential for infection and that none is defective or satellite in nature.

An alternative approach to infectivity assays that should be applicable to chrysoviruses is to transform virus-free fungal isolates with full-length cDNA clones of viral dsRNAs. In a recent preliminary study involving transformation of virus-free *H. victoriae* protoplasts with individual as well as different combinations of full-length cDNAs of the four dsRNAs of Hv145SV, productive yield of ssRNA transcripts corresponding to all four dsRNA segments was only generated in transformants containing DNA copies of all four dsRNAs. Although dsRNA synthesis was not launched in these transformants, the results suggest that dsRNA segments 3 and 4 and their gene products are necessary for accumulation and stability of the viral transcripts.

Etiology of the CCRS Disease and Potential Occurrence of Plant Chrysoviruses

The etiology of the CCRS disease remains a mystery. Although there is circumstantial evidence for a fungal etiology for the disease, no fungal pathogen was ever isolated from diseased trees. Although it is true that no plant chrysoviruses have been identified to date, there is no reason to exclude this possibility. As a matter of fact, it is not yet determined whether the partitivirus cherry chlorotic rusty spot associated partitivirus (CCRSAPV), which is co-isolated along with CCRSACV from diseased cherry trees, is a plant or a fungal partitivirus. Phylogenetic analysis based on RdRp conserved motifs placed CCRSAPV in a cluster with a mixture of plant and fungal partitiviruses. This finding raised the interesting possibility of horizontal transfer of members of the family *Partitiviridae* between fungi and plants. This possibility is reasonable because some of the viruses in this phylogenetic cluster have fungal hosts that are pathogenic to plants. As more chrysoviruses from a wider range of fungal (and possibly plant) hosts are isolated and characterized, the reality of plant chrysoviruses may become apparent as well as the need to reconsider the taxonomy of the family *Chrysoviridae*.

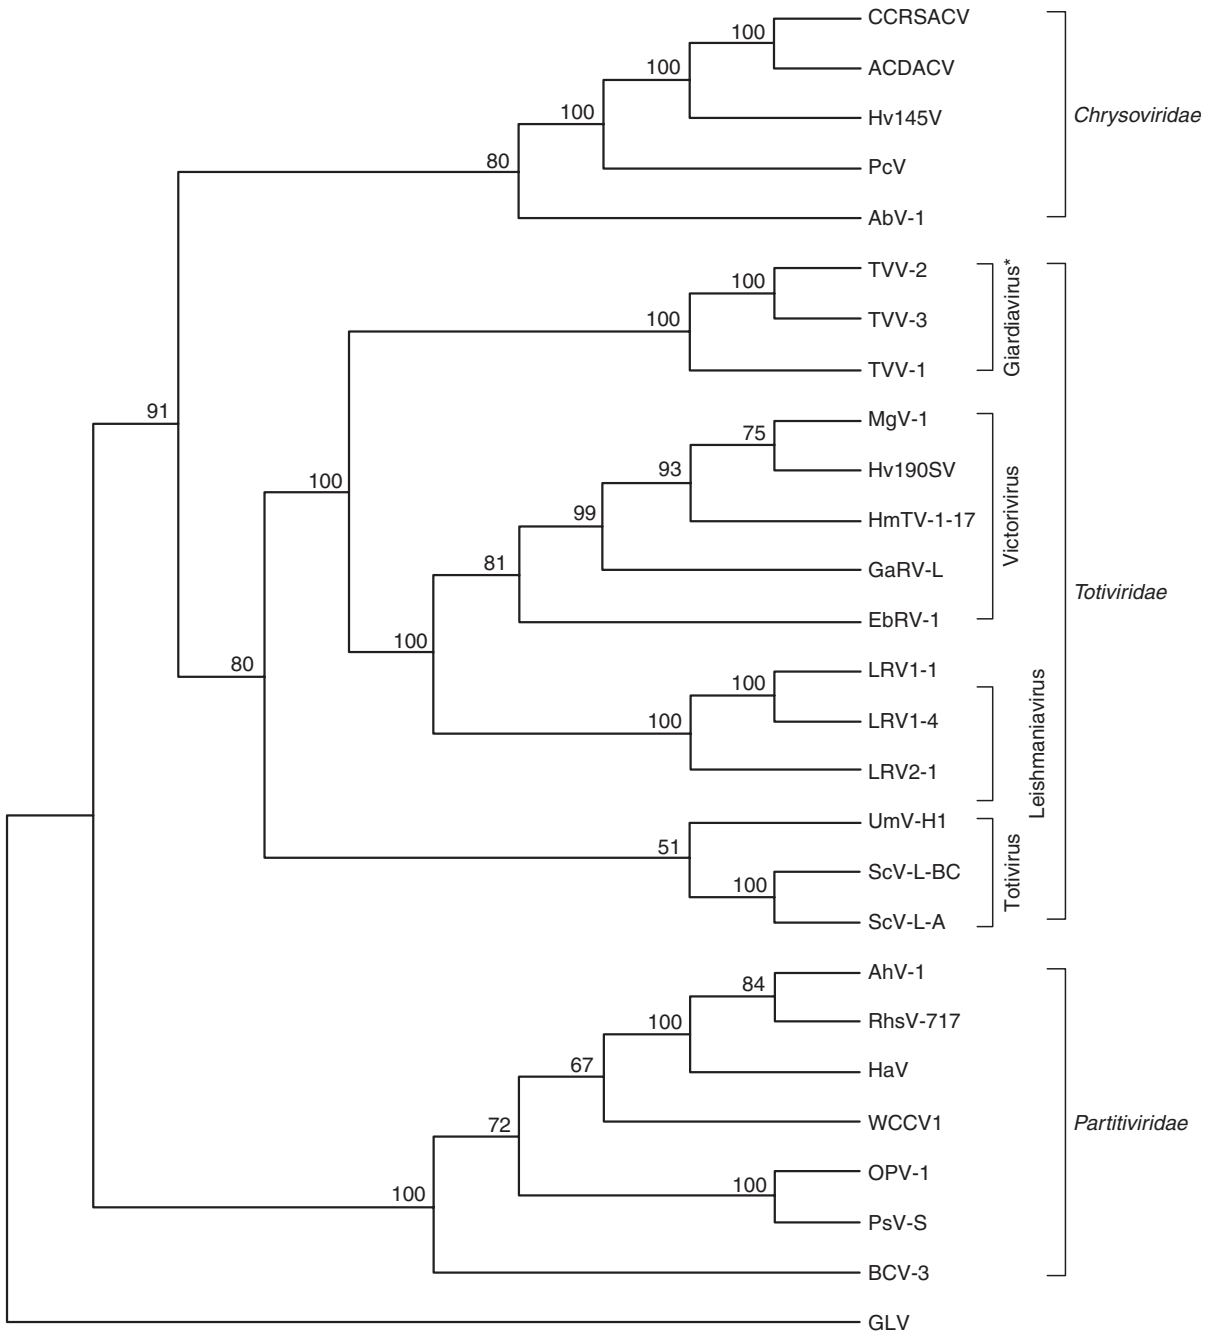

Figure 7 Neighbor-joining phylogenetic tree constructed based on the complete amino acid sequences of RdRps of selected isometric dsRNA viruses. The RdRp sequences were derived from aligned deduced amino acid sequences of members of the families *Chrysoviridae*, *Partitiviridae*, and *Totiviridae* using the program CLUSTAL X. See **Table 1** for names and abbreviations of chrysoviruses. The following viruses in the family *Totiviridae* were included in the phylogenetic analysis (abbreviations in parenthesis): trichomonas vaginalis virus-1 (TVV-1), TVV-2, and TVV-3, magnaporthe grisea virus 1 (MgV-1), helminthosporium victoriae 190S virus (Hv190SV), Helicobasidium mompa *totivirus 1-17* (HmTV-1-17) gremmeniella abietina RNA virus L (GaRV-L), eimeria brunetti RNA virus 1 (EbRV-1), leishmania RNA virus 1-1 (LRV1-1), LRV1-4, LRV2-1, ustilago maydis virus H1 (UmV-H1), saccharomyces cerevisiae virus L-A (ScV-L-A), and ScV-L-BC. The following viruses in the family *Partitiviridae* were included: atkinsonella hypoxylon virus 1 (AhV-1), rhizoctonia solani virus-717 (RhsV-717), heterobasidion annosum virus (HaV), white clover cryptic virus 1 (WCCV-1), ophiostoma partitivirus 1 (OPV-1), penicillium stoloniferum virus S (PsV-S), and beet cryptic virus 3 (BCV-3). The phylogenetic tree was generated using the program PAUP*. Bootstrap numbers out of 1000 replicates are indicated at the nodes. The tree was rooted with the RdRp of Giardia lamblia virus, the type species of the genus *Giardiavirus* in the family *Totiviridae*, which was included as an outgroup. * Note that TVV-1, TVV-2, and TVV-3 are tentative members of the genus *Giardiavirus*.

Circoviruses

A Mankertz, Robert Koch-Institut, Berlin, Germany

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Apoptosis Programmed self-induced cell death.
Botryoid Grape-like appearance.
Bursa of Fabricius Specialized organ in birds, that is necessary for B-cell development.
Chimera Virus created from two or more different genetic sources.
Koch's postulates Four criteria that must be fulfilled in order to establish a causal relationship between an agent and a disease.
Mono/polycistronic mRNA mRNA is termed polycistronic when it contains the genetic information to translate more than one protein, monocistronic if only one protein is encoded.
Phylogenetic tree Depicts the evolutionary interrelationships among species that are believed to have a common ancestor.
Rolling-circle replication (RCR) Mechanism of replication which takes its name from the characteristic appearance of the replicating DNA molecules, a special feature of RCR is the uncoupling of the synthesis of the two DNA strands.

Circovirus Taxonomy

Circoviruses contain a covalently closed circular single-stranded DNA (ssDNA) genome with sizes between 1759 and 2319 nt. The circular nature of their genomes, which are the smallest possessed by animal viruses, has led to the family being termed *Circoviridae*. Differences in organization of the viral genomes and capsid morphology led to their classification into two different genera.

Chicken anemia virus is the only species member of the genus *Gyrovirus*, while the genus *Circovirus* currently comprises *Porcine circovirus type 1* and *Porcine circovirus type 2*, *Psittacine beak and feather disease virus*, *Pigeon circovirus*, *Canary circovirus*, and *Goose circovirus*. Duck circovirus (DuCV), finch circovirus (FiCV), and gull circovirus (GuCV) are members of tentative species in the genus, while the circoviruses of raven (RaCV) and starling (StCV) have been discovered only recently and are therefore not yet included in the taxonomic classification.

The reported size range for the chicken anemia virus (CAV) virion is 19.1–26.5 nm, the genome is of (−) polarity, and the open reading frames (ORFs) are overlapping. Only one mRNA molecule is produced from a promoter/enhancer region; it encodes three partially overlapping ORFs. CAV shows homology to the newly identified ssDNA viruses in humans, torque teno virus (TTV) and the related torque teno mini virus (TTMV), which are members of the unassigned genus *Anellovirus*. The noncoding regions of CAV and TTV are G/C-rich and show a low level of nucleotide homology. In addition, CAV and TTV specify structural proteins that contain two amino acid motifs with putative roles in rolling-circle replication (RCR) and nonstructural proteins that exhibit protein phosphatase activity. CAV and TTV are separately classified, since their sequence homology is limited and only one mRNA is produced from CAV, while splicing has been detected in TTV and TTMV. Phylogenetic investigation of the family *Circoviridae*

revealed that CAV has no close relationship to the genus *Circovirus* (**Figure 1**).

Members of the genus *Circovirus* differ in several aspects from CAV, because they display a smaller particle size (12–20.7 nm, **Figure 2**), their ambisense genomes (**Figure 3**) are divergently transcribed, and splicing has been reported. The viruses of the genus *Circovirus* show homology in genome organization and protein sequences and function to the plant-infecting viruses of the family *Nanoviridae* and *Geminiviridae*.

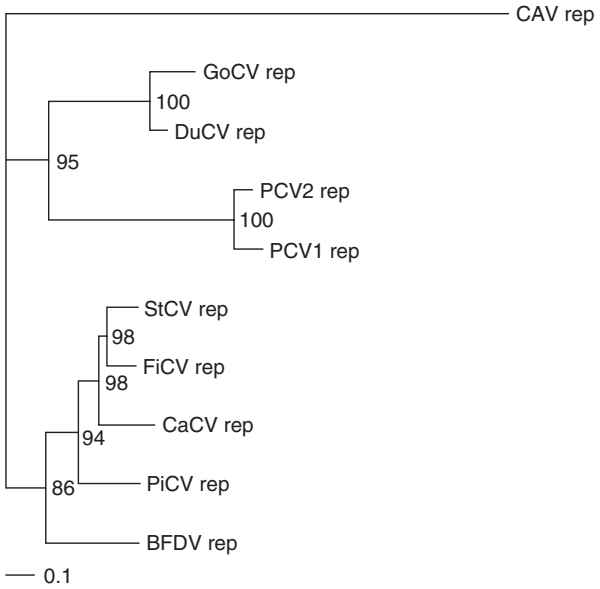

Figure 1 Phylogenetic tree of members of the family *Circoviridae*. The amino acid sequences of the Rep proteins of the members of the genus *Circovirus* (GoCV, DuCV, BFDV, PiCV, StCV, FiCV, CaCV, PCV1, PCV2) and of the only member of the genus *Gyrovirus* (CAV) were compared. Analysis was performed using the MacVector program package by analyzing 100 data sets.

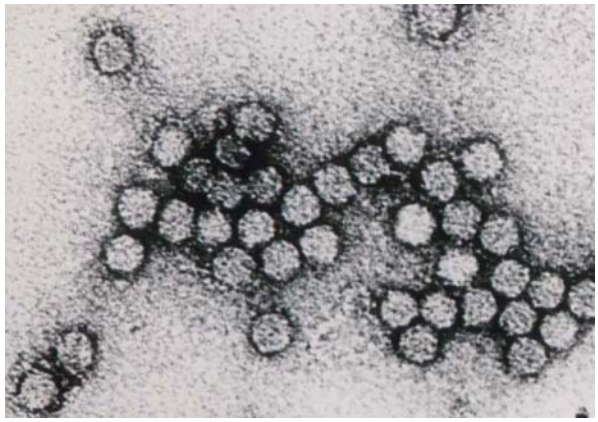

Figure 2 Electron microscope picture of particles of PCV1. PCV1 particles in an immunoaggregation with a PCV1 hyperimmuneserum (180 000-fold magnification, negative contrasting with 1% UAc).

Virion Structure

The size for the CAV virion has been reported as 19.1–26.5 nm and 12–20.7 nm for circoviruses (**Figure 2**).

The virions of CAV, porcine circovirus type 1 (PCV1) and porcine circovirus type 2 (PCV2), are each comprised of one structural protein, for which sizes of 50 (CAV), 30 (PCV1), and 30 kDa (PCV2) have been estimated, respectively. Psittacine beak and feather disease virus (PBFDV) is reported to contain three proteins (26, 24, and 16 kDa). The protein composition of the other avian circoviruses is not known, but putative structural proteins have been identified by homology searches. All capsid proteins have a basic N-terminal region containing several arginine residues, which is expected to interact with the packaged DNA. Virions do not possess an envelope. Investigation of the structures of CAV, PCV1, and PCV2 revealed that all have an icosahedral $T=1$ structure containing 60 capsid protein molecules arranged in 12 pentamer clustered units. PCV2 and BFDV show similar capsid structures with flat pentameric morphological units, whereas chicken anemia virus displayed protruding pentagonal trumpet-shaped units.

Pathogenesis of Circoviruses

Circoviruses and Gyroviruses Induce Diseases

Circoviruses are supposed to be host specific or to have narrow host ranges. The fecal–oral route of transmission is likely, but vertical transmission has been reported in some cases. With the exception of PCV1, all known circoviruses are pathogens, which cause immune suppression and damage in the lymphoreticular tissues.

CAV infections occur mainly in young chicken. The main targets of CAV replication are cells in the bone marrow (hemocytoblasts) and precursor lymphocytes in the thymus. Characteristic symptoms are aplastic anemia and hemorrhagic lesions, watery blood, pale bone marrow, lymphoid depletion, atrophy of thymus and bursa, and swollen and discolored liver. Since macrophages recovered from infected birds produce less interleukin 1 (IL-1) and the pathogenicity of co-infecting viruses such as Marek's disease virus, infectious bursal disease virus, and Newcastle disease virus are enhanced, immune suppression is thought to play a role in CAV-induced pathogenesis.

Another intensively studied circoviral disease is psittacine beak and feather disease (PBFD). PBFD is the most common disease in cockatoos and parrots and is typically detected in young birds. Deformation of beak, claws, and

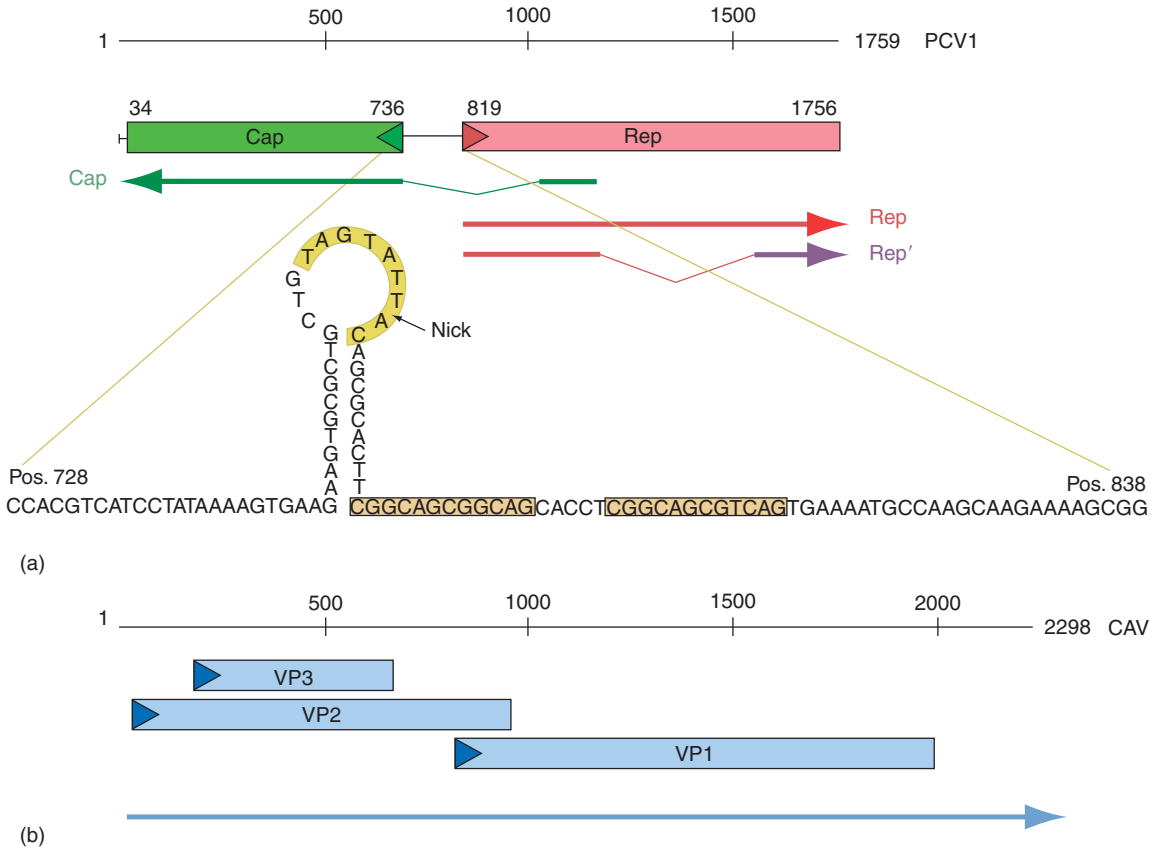

Figure 3 Genomic organization of PCV1 member of the type species of the genus *Circovirus* and CAV member of the type species of the genus *Gyrovirus*. ORFs are shown in open boxes, the direction of transcription is indicated by triangles. Transcripts are indicated by arrows, splice processes by dotted lines. (a) PCV1, the species type of the genus *Circovirus*, is shown. The ambisense genomic organization is outlined, that is, both strands of the replicative form are coding for proteins. Therefore, the two major genes Rep and Cap are divergently transcribed. Between the start points of Rep and Cap, the origin of viral replication is located. This element is drawn to a larger scale, displaying its characteristic features, a putative hairpin, and adjacently located repeats. An arrow indicates the position where Rep and Rep′ restrict the replicative intermediate to initiate the replication.(b) CAV is a member of the type species of the genus *Gyrovirus*. Its genome is of the 'negative-sense' type, that is, the viral strand does not encode genetic information, it has to be converted into a dsDNA version, from which one polycistronic mRNA is produced. Splice processes have not been observed.

feathers, lethargy, depression, weight loss, and severe anemia are the most prominent symptoms.

Young pigeon disease syndrome (YPDS) is a multifactorial disease in which PiCV is assumed to induce immunosuppression in young birds, which suffer from ill-thrift, lethargy, anorexia, and poor race performance. Depletion of splenic and bursal lymphocytes was seen and bacterial agents as *Escherichia coli* and *Klebsiella pneumoniae* were isolated more frequently from PiCV-infected birds. Inclusion bodies were present in various organs, especially the bursa of Fabricius.

In CaCV-infected neonatal canary birds, a condition known as 'black spot' has been reported. It is associated with abdominal enlargement, gall bladder congestion, failure to thrive, dullness, anorexia, lethargy, and feather disorder. Histological changes as lymphofollicular hyperplasia, lymphoid necrosis, cellular depletion, and cystic atrophy are observed in the thymus and the bursa of Fabricius. A general feature of circovirus infection is the formation of globular or botryoid, basophilic inclusion bodies in the cytoplasm, in which the virus may form paracrystalline arrays.

PCV1 and PCV2 seem to be restricted to pigs. PCV2 is the etiological agent of a new disease in swine, the so-called post-weaning multisystemic wasting syndrome (PMWS), and may be involved in several other porcine circoviral diseases (PCVDs) like porcine dermatitis and nephropathy syndrome (PDNS) or porcine respiratory disease complex. PMWS was first recognized in Canada in 1991. Since then it has been described as a major economic concern in virtually all pig-producing areas of the world. PMWS primarily occurs in pigs between 60 and

80 days old. Maternal antibodies confer titer-dependent protection against PCV2 infection – higher titers are generally protective, but low titers are not. PMWS is characterized by wasting, respiratory signs, enlargement of superficial inguinal lymph nodes, diarrhea, paleness of the skin or icterus, but the clinical signs are often variable. The most consistent feature of PMWS is a generalized depletion of lymphocytes. Secondary infections with opportunistic organisms are common. This indicates that the immune system is involved in the pathogenesis of PMWS. On affected farms, mortality may reach up to 40%, but it can be reduced, if special management plans are implemented. In the first attempts, experimental reproduction of the disease according to Koch's postulates has led to an amazing variety of results, since no symptoms were seen as well as histopathological lesions or a full-blown PMWS. The symptoms of the disease were aggravated when piglets were infected in which the immune system had been stimulated either by a prior vaccination or by a co-infection with porcine parvovirus (PPV) or porcine reproductive and respiratory syndrome virus (PRRSV). These and other findings indicate that PMWS is a multifactorial disease, in which not only factors such as the status of the immune system and genetic predisposition but also practical aspects such as nutrition and vaccination policy may influence the onset of the disease and the severity of the symptoms.

Diagnosis of Circoviral Diseases

In general, diagnosis of circoviral diseases is based on detection of the virus by culture, polymerase chain reaction (PCR), immunohistochemistry or *in situ* hybridization, or detection of antibodies against the circovirus by serology. PBFD can also be diagnosed on the basis of feathering abnormalities. PCV2 is a ubiquitous virus and also prevalent in healthy pigs; therefore, diagnosis of PMWS must concurrently meet three criteria: (1) the presence of compatible clinical signs, (2) the presence of moderate to severe characteristic microscopic lymphoid lesions, and (3) the presence of moderate to high amount of PCV2 within these lesions.

PCV1 and PCV2

A striking difference is seen in the pathogenicity of PCV1 and PCV2. No disease is attributed to PCV1, while PCV2 is the etiological agent of PMWS, a new emerging disease of swine. What may be the molecular basis for this distinct feature? The genomes of the two strains are highly conserved, especially the origin of replication (80% sequence homology) and the Rep gene (82%). Exchange of replication factors between PCV1 and PCV2 did not reveal differences, since the Rep protein of PCV1 (Rep/PCV1) replicated its cognate origin as well as the heterotype origin of PCV2 (and vice versa), suggesting that pathogenesis may not be linked to the replication factors. A higher degree of sequence deviation is found in the Cap genes with less than 62% homology between PCV1 and PCV2. Chimeras of PCV1 and PCV2 have been produced and tested for their potential to induce PMWS and to stimulate the immune answer. The chimera PCV2/1, containing the PCV1 capsid gene cloned into the backbone of the pathogenic PCV2 genome, was compared to a chimera PCV1/2, containing the PCV2 capsid gene in the nonpathogenic PCV1 genome. Both variants displayed similar growth characteristics *in vitro*. Gross lesions significant for PMWS were not observed, but PCV1/2 induces protective immunity to wild-type PCV2 challenge in pigs, indicating that it may be an effective vaccine candidate. ORF3 is comprised by the rep gene and may also contribute to the pathogenesis of PCV2, because its sequence differs significantly in PCV1 and PCV2 and induction of apoptosis has been reported.

Interaction with the Immune System

PCV2 provides a valuable model for gaining insight into how ssDNA viruses interact with the host immune system and for understanding their pathogenesis. PCV2 is intriguing in its ability to persist in macrophages and dendritic cells without replication although its infectivity is retained. When natural interferon (IFN)-producing cells responded to an inducer of cytokine synthesis, their co-stimulatory function, which induces myeloid dendritic cell maturation, was clearly impaired in case of a concurrent PCV2 infection. Stimulation of the porcine immune system with IFN-α and IFN-γ causes increased replication of PCV2 *in vivo*, while no changes were observed in IL-1-, IL-6-, tumor necrosis factor alpha (TNF-α)-, or IL-10-treated cells. With the circumstantial evidence compiled over the last years, one may assume that PMWS can be considered as an acquired immunodeficiency syndrome of pigs although direct evidence for this hypothesis is still missing.

Molecular Biology of Circoviruses

Genome Organization of Circoviruses

The genomes of all circoviruses are composed from a circular ssDNA molecule with a size between 1759 and 2319 nt and therefore display the smallest genomes possessed by mammalian viruses. Nevertheless, members of the genera *Circovirus* and *Gyrovirus* show remarkable differences in their genome organization.

The genomes of CAV isolates are either 2298 or 2319 nt in size. Part of the noncoding region of the genome is

G–C-rich and able to form putative hairpin structures. The three genes are encoded by the viral (–)strand, therefore CAV has a negative-sense genome organization. One major polycistronic mRNA (2.0 kbp) is transcribed from the circular double-stranded (ds) replication form (RF), which is produced after infection. The nontranscribed region of the genome contains transcription initiation and termination signals and a tandemly arranged array of four or five 19 nt repeats with which promoter–enhancer activity is associated. Within this sequence, estrogen response element consensus half-sites were found, resembling the arrangement that can be recognized by the nuclear receptor superfamily. Since expression from the CAV promoter was significantly increased with estrogen treatment, members of the nuclear receptor superfamily may provide a mechanism to regulate CAV activity.

The hypothesis that the circular ssDNA genome replicates using the RCR mechanism is supported by the presence of the conserved nonanucleotide motif within the CAV genome, at which RCR is initiated in other circular ssDNA replicons, but it is not located at the apex of a putative hairpin. The presence of two amino acid motifs typical for enzymes involved in RCR within VP1 also suggests that this structural protein possesses DNA replication function, while its basic N-terminus implies that this protein is involved in capsid formation, too. This would be highly unlike the genus *Circovirus*, where two distinctly encoded proteins perform the two most elementary functions of replication and packaging of the genome. Coding regions of the avian and porcine circoviruses are arranged divergently resulting in an ambisense genome organization and creating two intergenic regions, a larger one between the 5′ ends of the two major ORFs rep and cap and a shorter one between their 3′ ends. In case of PCV1 and PCV2, the non-coding regions between the ATGs of the rep and cap gene comprise the origin of viral genome replication. Similar genomic structures are found in members of the families *Geminiviridae* and *Nanoviridae*.

Viral ORFs and Proteins

Synthesis of three virus proteins is directed from the CAV genome. VP1 (52 kDa) is encoded by ORF1 and may combine the function of a structural protein as well as the initiator of replication. VP2 (26 kDa) is a protein phosphatase encoded by ORF2. VP2 protein phosphatase activity is required for efficient replication. It may also have a role as a scaffolding protein during virion assembly. Co-expression of both VP1 and VP2 is necessary for the induction of neutralizing antibodies. VP3 is a 14 kDa virulence factor known to induce apoptosis in transformed cell lines and has been called 'apoptin'.

Two major ORFs are encoded by the genomes of PCV1 and PCV2, encoding the viral functions for replication (Rep and Rep′) and a structural protein (Cap). A similar genomic structure is seen in the avian circoviruses. Several smaller ORFs have been found by computer analyses, but with the exception of ORF3 of PCV, which seems to be involved in pathogenesis and apoptosis, their expression has not been studied yet. The largest ORF of the ambisense organized circoviruses is located on the viral plus-strand (V1). It encodes the Rep protein (312 or 314 aa). Three motifs conserved in enzymes mediating replication in the RCR mode and a dNTP-binding domain have been identified. Both Rep proteins reside in the nucleus of infected cells. Phylogenetic analyses suggest that circovirus Rep proteins may have evolved by a recombination event between the Rep protein of nanoviruses and an RNA-binding protein encoded by picorna-like viruses or a helicase of prokaryotic origin. The second largest ORF of all circoviruses is located on the complementary strand (C1) and encodes the major structural protein Cap protein (234 aa), which displays a basic N-terminus rich in arginine residues. This suggests that this region is involved in binding to viral DNA. Some avian circoviruses use alternative start codons for Cap translation. After expression in bacteria and insect cells, Cap of PCV assembled into virus-like particles when viewed by electron microscopy. Cap has been shown to reside mostly in the nucleoli, but shuttling to the cytoplasm occurs during the infectious cycle. ORF3 is encoded counterclockwisely by ORF1. It encodes a protein that is not essential for PCV replication but has been reported to induce apoptosis.

Transcription of PCV

The promoter of the cap gene of PCV has been mapped to a fragment at 1168–1428, that is, P_{cap} is located within the rep gene. P_{cap} is not regulated by virus-encoded proteins. The cap transcript starts at nucleotide 1238 with an untranslated leader sequence of 119 nt (1238 to 1120) joined to exon 2 of the ORF1 transcript at nucleotide 737, immediately adjacent to the start point of translation. Processing of this RNA has presumably evolved to avoid synthesis of another protein initiated at an internal start codon in the intron. The start of the rep transcript of PCV1 has been mapped to nucleotide 767 ± 10. The promoter of the rep gene, P_{rep}, is comprised within a fragment, nucleotides 640–796. P_{rep} overlaps the intergenic region and the origin of replication. P_{rep} is repressed by the Rep protein by binding to hexamers H1 and H2; these elements are involved in initation of replication, too. Mapping the rep mRNA revealed synthesis of several transcripts in PCV1 and PCV2. A full-length transcript directs synthesis of the Rep protein (312 aa, 35.6 kDa). In a spliced transcript,

removal of an intron (nucleotides 1176 to 1558) results in synthesis of a truncated protein, which has been termed Rep′. Rep′ is truncated to 168 aa (19.2 kDa) and, due to a frameshift, the last 49 aa are expressed in a different reading frame. Comparison of the ratio of Rep and Rep′ transcript with a real-time PCR discriminating between the two transcripts indicated a variation of the ratio of the two transcripts in correlation to time. Replication of PCV is dependent on expression of both proteins. Splicing of Rep proteins is a well-known feature in other small ssDNA viruses (e.g., *Mastrevirus*), but, in contrast to PCV, one Rep protein is sufficient for replication of these viruses.

Replication of Circoviruses

Although the main target for viral replication still remains unknown, PCV2 was seen *in vivo* in a variety of cell types including hepatocytes, enterocytes, epithelial and endothelial cells, lymphocytes, smooth muscle cells, and fibroblasts. This broad range of cells that support PCV2 infection indicates that PCV2 does not enter the cell via a rarely expressed receptor. When binding of PCV2 to monocytic cells was investigated, it became evident that surface proteins and glycosaminoglycans heparan sulfate and chondroitin sulfate B are attachment receptors for PCV2. This result is supported by the finding that the heparan sulfate binding motif (XBBXBX; B = basic amino acid, X = neutral/hydrophobic amino acid) is present on the PCV2 capsid protein. PCV2 enters the cells predominantly via clathrin-mediated endocytosis and requires an acidic environment for infection.

Replication of PCV has been studied in detail. PCVs are supposed to replicate their genomes using a circular, ds RF intermediate, which is produced by host cell DNA polymerases during the S phase of cell division. The origin of replication of PCV has been mapped to a fragment comprising the intergenic region between the start points of the two major ORFs (**Figure 3**).

Replication of these fragments cloned into a vector was observed after co-transfection of porcine kidney cells with plasmids expressing the rep gene. By sequence alignment, analogous elements can be identified for all other circoviruses with the exception of CAV. The origin of replication is characterized by a potential stem–loop structure with a nonamer (5′-TAGTATTAC; **Figure 3**) in its apex. Mutagenesis of the nonamer resulted in inactivation of PCV replication. Adjacent to the nonamer, short repeats are located, which serve as the binding site for the rep gene products. Nonamer, stem–loop, and adjacent short repeats are conserved in all other circoviruses, in the families *Nanoviridae* and *Geminiviridae*, and, although to a lesser extent, in many replicons replicating via RCR. The conserved elements in the *cis*-acting origin of replication as well as RCR signatures in the *trans*-acting Rep protein amino acid (aa) sequence (see below) indicate an RCR-like replication mechanism for the circoviruses.

Functional Analyses of PCV-Encoded Proteins

Truncation of the rep gene as well as site-directed mutagenesis of the four conserved motifs abrogated replication of PCV, indicating that the rep gene products are indispensable. The roles of Rep and Rep′ of PCV have been analyzed in detail.

Binding to DNA. Rep and Rep′ bind *in vitro* to fragments of the origin of replication containing the stem–loop structure plus the conserved nonamer and the four hexamer (H) repeats (5′-CGGCAG; H1 to H4). Proteins bind either the two inner (H1/H2) or the two outer (H3/H4) hexamers. A minimal binding site (MBS) has been identified for Rep and Rep′ protein using truncated substrates: the Rep MBS was mapped to the right leg of the stem–loop plus the two inner hexamer repeats H1/H2, while the MBS of Rep′ was composed of only the two hexamer repeats H1/H2. Gel shift assays also revealed presence of several complexes, indicating that variable amount of proteins may be bound.

Replication. The covalently closed, ssDNA genome of PCV replicates via a dsDNA replicative intermediate. The replication occurs by RCR whereby a single-stranded break is introduced by Rep or Rep′ leading to a free 3′-hydroxyl group serving as a primer for subsequent DNA synthesis. Replication does occur when Rep plus Rep′ protein are expressed in the cells, indicating that both proteins are essential for replication from the PCV origin. This is in contrast to other ssDNA viruses, for example, AAV2 or members of the genus *Mastrevirus*, in which spliced Rep proteins are produced, but are not essential for viral replication. Rep and Rep′ cleave the viral strand between nucleotides 7 and 8 *in vitro* within the conserved nonanucleotide located at the apex of a putative stem–loop structure. In addition, Rep and Rep′ join viral ssDNA fragments, implying that these proteins also play a role in the termination of virus DNA replication. This joining activity is strictly dependent on preceding substrate cleavage and the close proximity of origin fragments accomplished by base pairing of the stem–loop structure. This dual 'nicking/joining' activity associated with Rep and Rep′ are pivotal events underlying the RCR-based replication of porcine circoviruses in mammalian cells. Although presence of the palindrome plus a single H sequence is sufficient for PCV replication, a tandem repeat arrangement is more stable. Within the H sequence, selected nucleotides at specific positions are critical for Rep-associated protein recognition and for viral DNA replication.

Repression of the Rep gene promoter P_{rep}. When the influence of virus-encoded proteins upon P_{rep} was investigated, it

became apparent that P_{rep} is repressed by its own gene product Rep but not by Rep′ or Cap. This finding illustrates that Rep protein initiates replication and controls its own transcription by binding to hexamers H1/H2. Interestingly, Rep′ also binds to H1/H2, but this does not result in repression of P_{rep} activity. Since mutagenesis of H1/H2 decreases but does not inactivate P_{rep} transcription, features other than binding of Rep may be necessary for repression of P_{rep}, for example, interaction of Rep protein with transcription factors. P_{cap} is not regulated by Cap, Rep, and Rep′.

Interaction. Studies investigating the interaction of PCV-encoded proteins are bemusing, because the results were depending on the system used for expression. While two hybrid analysis in bacteria revealed interaction of Rep and Cap, this was not observed in yeast cells, suggesting that post-translational modifications of Rep and Cap may significantly modulate their function. Rep and Rep′ have been observed to interact in yeast cells and this observation was reproduced by immunoprecipitation in mammalian cells, the natural target of PCV.

Localization. Rep and Rep′ protein co-localize in the nucleoplasm of infected cells, but no signal was seen in the nucleoli. The localization did not change during the infection cycle. Rep and Rep′ carry three potential nuclear localization signals (NLSs) in their identical N-termini. Proteins mutated in their NLSs demonstrated that NLS1 and NLS2 mediate the nuclear import, whereas NLS3 enhances the nuclear accumulation of the replication proteins. In contrast to Rep and Rep′, the localization of the Cap protein was restricted to the nucleoli in plasmid-transfected cells. In PCV-infected cells, Cap was localized in the nucleoli in an early stage, while it was seen later on in the nucleoplasm and the cytoplasm. This signifies that Cap is shuttling between distinct cellular compartments during the infection cycle. Since Rep, Rep′, and Cap are all located in the nucleus, this points out that DNA replication and encapsidation of the circular closed ssDNA probably occur in the nucleus and not in cytoplasmic compartments. The biological function of the early localization of Cap to the nucleoli remains unclear. Nucleolar localization has been described for proteins of many DNA and RNA viruses and it has been proposed that virus proteins enter the nucleoli to support viral transcription or influence the cell cycle.

Conclusion

Although the family *Circoviridae* comprises only a relatively small number of viruses, the increasing number of publications demonstrates rising interest. This may not only be related to the fact that circoviruses induce severe multifactorial diseases, which compromise and unbalance the immune system, but also to the fact that the apparent simplicity of the circovirus genome contrasts highly with the complex and poorly understood pathogenesis. Hopefully, this will induce many question-solving studies, enabling us to improve our understanding of these intriguing viruses in the future.

Glossary

Cross-protection Prevention of the symptomatic phase of a disease by prior inoculation with a mild or nonsymptomatic isolate of the same virus.
Defective RNA Subviral RNA molecules lacking parts of the genome while maintaining the signals enabling their synthesis by the viral replication system.
Genome The complete genetic information encoded in the RNA of the virus, including both translated and nontranslated sequences.
Subgenomic RNA Shorter than full-length genomic RNA molecules produced during the replication process sometimes to allow translation of open reading frames (ORFs).
Transgenic pathogen-derived resistance Plants genetically transformed to harbor viral or other pathogen-derived sequences expected to confer resistance against related virus isolates.

History

Over the last 70 years citrus tristeza virus (CTV) has killed, or rendered unproductive, millions of trees throughout most of the world's citrus-growing areas and hence it is rightfully considered as the most important virus of citrus, the world's largest fruit crop, hence the name 'tristeza' which means 'sadness' in Spanish and Portuguese. However, as with many other disease agents, the actual damages of CTV infections and their timings varied considerably at different periods and geographical regions. The origins of CTV infections remain unknown; the virus however existed for centuries in Asia as an unidentified disease agent, but growers in these areas adapted citrus varieties and rootstock combinations with resistance or tolerance to CTV infections. Out of Asia, citrus production moved to the Mediterranean region, primarily through the introduction of fruit and propagation of seed which does not transmit CTV to the resulting plantings; hence, the new cultivation areas starting from seed sources remained free of the virus for centuries. However, the improvement in maritime transportation, allowing long-distance transport of rooted citrus plants, led to the outbreak of the deadly citrus root rot disease caused by *Phytophthora* sp., which was managed by adapting the more tolerant sour orange rootstock. The considerable horticultural advantages offered by this rootstock coincided with the large-scale expansion of plantings throughout the Mediterranean and American countries, and as a result citrus production in many areas was almost entirely based on a single rootstock. Consequently, this decision had grave effects when CTV pandemics swept throughout the world, causing 'quick decline' (death) of trees on this rootstock. Although the CTV problems were first noticed in South Africa and Australia where by the end of the nineteenth century the growers had found that sour orange was an unsuitable rootstock, it was only in the 1930s that the extent of this deadly disease problem manifested itself first in Argentina and shortly later in Brazil and California, with the death of millions of trees.

The virus-like nature of the tristeza-related diseases was demonstrated experimentally by graft and aphid transmission of the disease agent in 1946; however, description of CTV properties began with the seminal findings of Kitajima *et al.* of thread-like particles (TLPs) associated with tristeza-infected trees. These unusually long and thin particles presented a challenging problem for isolation (purification), which was an essential step toward virus characterization. Development of effective purification methods and biophysical characterization of TLP and similar viruses led to their assignment to the closteroviruses, a group of elongated viruses. The association of infectivity with the TLP-enriched preparations was demonstrated first by Garnsey and co-workers; however, the unequivocal completion of Koch's postulates for TLPs was completed only in 2001 with the mechanical infection of citrus plants with TLPs obtained from RNA transcripts of an infectious CTV cDNA clone amplified through serial passaging in *Nicotiana benthamiana* protoplasts.

Developments of TLP purification methods paved the way to antibody preparations and to improved CTV diagnosis by enzyme-linked immunosorbent assay (ELISA), which revealed considerable serological identity among CTV isolates. Later, RNA extracts from CTV-enriched particle preparations were used for molecular cloning of DNA molecules, which when used as probes demonstrated considerable genomic variation among CTV isolates. Nucleic acid probes also demonstrated that plants infected with CTV contained many defective RNAs (dRNAs) in addition to the normal genomic and

subgenomic RNAs. Infected plants also contain unusually large amounts of dsRNAs corresponding to the genomic and subgenomic RNAs and the dRNAs. Because of the ease of purifying these abundant dsRNAs, they often have been the template of choice for producing cDNAs. The advent of cDNA cloning of CTV led to the sequencing of its genome and to description of dRNAs.

Taxonomy and Classification

CTV belongs to the genus *Closterovirus,* family *Closteroviridae*. The family *Closteroviridae* contains more than 30 plant viruses with flexuous, filamentous virions, with either mono- or bipartite (one tripartite) single-stranded positive-sense RNA genomes. A recent revision of the taxonomy of the *Closteroviridae* based on vector transmission and phylogenetic relationships using three proteins highly conserved among members of this family (a helicase, an RNA-dependent RNA polymerase, and a homolog of the HSP70 proteins) led to the demarcation of three genera: the genus *Closterovirus* including CTV and other aphid-borne viruses with monopartite genomes; the genus *Ampelovirus* comprising viruses with monopartite genomes transmitted by mealybugs; and the genus *Crinivirus* that includes whitefly-borne viruses with bipartite or tripartite genomes. Viruses of this family are all phloem-limited viruses. Among the hallmarks of the group is the presence of a conserved five-gene module that includes the four proteins involved in assembly of virions, the major (CP) and minor (CPm) coat proteins, p61, and p64, a homolog of the HSP70 chaperon. In addition, infected phloem-associated cells have clusters of vesicles considered specific to the cytopathology of closteroviruses. Although the evolution of the three genera of the family *Closteroviridae* is unknown, its is interesting to note that dRNAs of CTV analogous to each of the two RNA segments of the crinivirus genome were found in infected plants raising the possibility that criniviruses arose from a closterovirus ancestor.

Geographic Distribution

Citrus is a common fruit crop in areas with sufficient rainfall or irrigation from the equator to about 41° of latitude north and south. CTV is now endemic in most of the citrus-growing areas, with only a few places in the Mediterranean basin and Western USA still remaining free of CTV infections. The spread during the last decade of the brown citrus aphid (*Toxoptera citricida*) to Florida and its recent spread to parts of Portugal and Spain are now threatening most of the remaining CTV-free areas of North America and in the Mediterranean basin. One important aspect of CTV's geographic distribution is that some areas that have endemic isolates of CTV still do not have the most damaging stem-pitting isolates. With the spread of the vector comes the threat of extremely severe CTV isolates which so far have not spread to North America and Mediterranean countries, where only the milder CTV isolates were established in the past.

Host Range and Cytopathology

CTV infects all species, cultivars, and hybrids of *Citrus* sp., some citrus relatives such as *Aeglopsis chevalieri*, *Afraegle paniculata*, *Fortunella* sp., *Pamburus missionis,* and some intergeneric hybrids. Species of *Passiflora* are the only nonrutaceous hosts, infected both naturally and experimentally. The CTV decline strains are associated with the death of the phloem near the bud union, resulting in a girdling effect that may cause the overgrowth of the scion at the bud union, loss of feeder roots, and thus drought sensitivity, stunting, yellowing of leaves, reduced fruit size, poor growth, dieback, wilting, and death. However, other virulent and damaging CTV strains cause stem-pitting (SP), which results in deep pits in the wood under depressed areas of bark and are often associated with severe stunting and considerably reduced fruit production. The seedling-yellow reaction (SY) which includes severe stunting and yellowing on seedlings of sour orange, lemon, and grapefruit is primarily a disease of experimentally inoculated plants but might also be encountered in the field in top-grafted plants.

CTV infection is closely restricted to the phloem tissues which often show strongly stained cells, termed as chromatic. Electron microscopy of infected cells shows that they are mostly filled with fibrous inclusions, consisting of aggregates of virus particles and of membranous vesicles differing in tonicity and containing a fine network of fibrils.

The CTV Virions

The CTV virions are long flexuous particles, 2000 nm long and 10–12 nm in width. The virions have a helical symmetry with a pitch of 3–4 nm, about 8–9 capsids per helix turn, and a central hole of 3–4 nm. Unlike the virions of other elongated plant viruses that possess cylindrical nucleocapsids made of a single coat protein (CP), the CTV virions consist of bipolar helices with a long body and a short tail. Immunoelectron microscopy showed antibodies to CPm attached to only one end of the virions, with the major part (>97%) of the virion encapsidated by CP. Interestingly, the 'tail' corresponds to 5′ end region of the viral genome and the particle tails of other closteroviruses have been associated with small amounts of p61 and p65.

The CTV Genome

Figure 1 shows a schematic presentation of the 19.3 kbp RNA of CTV. Generally, the CTV genome is divided almost equally into two parts, the 5′ part consisting of ORF1a and -1b harboring the viral replication machinery and the 3′ half harboring ten ORFs encoding a range of structural proteins and other gene products involved in virion assembly and host and vector interactions. CTV replicons containing only ORF1a and -1b plus the 5′ and 3′ nontranslated ends (**Figure 1**) fulfill all the requirements for efficient replication in protoplasts.

Interestingly, while the sequences of the 3′ half of all CTV isolates that have been sequenced are 97% and 89% identical when comparing the 3′ nontranslated regions (NTRs) and the rest of the 3′ halves, respectively, the 5′ half sequences often differ considerably. For instance, the isolates T36 and VT show only 60% and 60–70% identities for their 5′ NTR and the remaining 5′ halves, respectively. The considerable deviation of strain T36 from that of the VT group suggests that T36 might have resulted from a recent recombination event involving the 3′ part of a VT-like isolate and the 5′ half derived from a different closterovirus. The common finding of numerous recombination events both within and between CTV isolates and multiple dRNAs supports such a possibility.

The Nontranslated Regions

The remarkable feature of CTV isolates are the close identities (97%) of their 3′ NTR primary sequences and the considerable divergence of their 5′ NTR sequences. Computer-assisted calculations, however, suggest that not only the 3′ NTRs of different isolates fold into similar predicted structures, but surprisingly the dissimilar sequences of the 5′ NTRs also are predicted to fold into similar secondary structures. The 3′ replication signal of several CTV isolates was mapped to 230 nt within the NTR and predicted to fold into a secondary structure composed of ten stem-and-loop (SL) structures. Three of these SL regions and a terminal 3′ triplet, CCA, were essential for replication. Replacement of T36 3′ NTR with 3′ NTRs from other strains allowed replication, albeit with slightly less efficiency, confirming the significance of the primary sequence of this part. The plus-strand sequence of the 5′ NTRs from different strains are predicted to form similar secondary structures consisting of two stem loops (SL1 and SL2) separated by a short spacer region, that were essential for replication. These structures were shown to be *cis*-acting elements involved in both replication and initiation of assembly by CPm.

Genome Organization and Functions

In infected cells, the 12 ORFs of CTV (**Figure 1**) are expressed through a variety of mechanisms, including proteolytic processing of the polyprotein, translational frameshifting, and production of ten 3′-coterminal subgenomic RNAs. The first two mechanisms are used to express proteins encoded by the 5′ half of the genome while the third mechanism is used to express ORFs 2–11. The ORF1a encodes a 349 kDa polyprotein containing

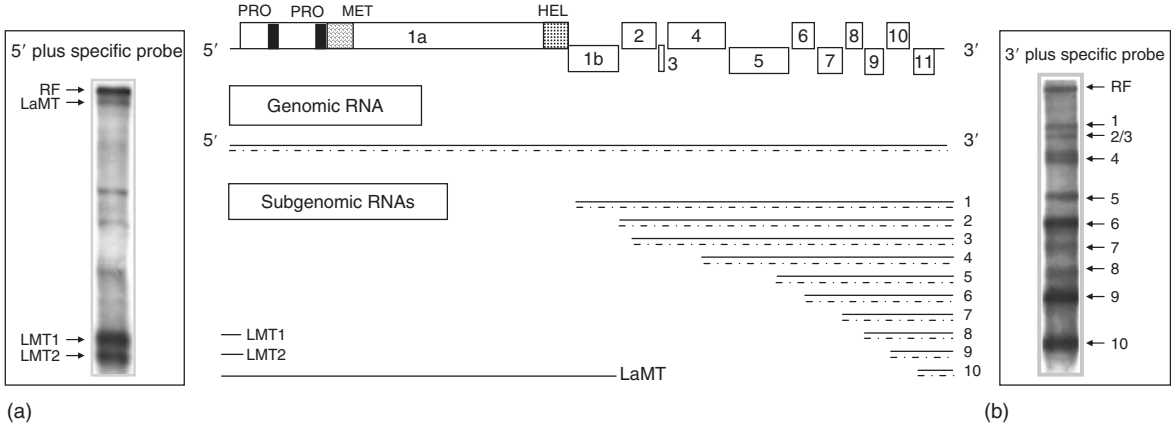

Figure 1 A schematic presentation of the citrus tristeza virus (CTV) genomic (g) and subgenomic (sg) RNAs. The putative domains of papain-like proteases (PRO), methyltransferase (MT), helicase (HEL), and the various open reading frames (ORFs) with their respective numbers are indicated. Lines shown on the left and right side below the genomic map indicate 5′ large molecular single stranded (ss) subgenomic (sg) RNA (LaMT) and two low molecular weight ssRNAs (LMT1 and LMT2) and a nested set of 3′ co-terminal sgRNAs, respectively. Inset (a), shows Northern blot hybridization of dsRNA-enriched extracts from a citrus plant infected with the VT strain of CTV using riboprobes specific to the 5′ end of the viral RNA. Note the presence of the large replicative form (RF) molecules (upper band), LaMT, and two abundant LMT molecules. Inset (b), Hybridization of dsRNA with the 3′ probe. Note the hybridization bands of the different 3′ sgRNAs indicated by arrows.

two papain-like protease domains plus methyltransferase-like and helicase-like domains. Translation of the polyprotein could also continue through the polymerase-like domain (ORF1b) by a +1 frameshift. These proteins along with the signals at the 5′ and 3′ ends of the genome are the minimal requirements for replication of the RNA. The function of p33 (ORF2) is unknown, but is required for infection of a subset of the viral host range. The next five gene products from the 3′ genes include the unique signature block characteristic of closteroviruses, which consist of the small, 6 kDa hydrophobic protein (ORF3), 65 kDa cellular heat-shock protein homolog (HSP70h, ORF4), 61 kDa protein (ORF5), and the tandem pair of p27 (CPm, ORF6) followed by p25 (CP, ORF7). The four latter proteins are required for efficient virion assembly. The small hydrophobic p6 is a single-span transmembrane protein not required for virus replication or assembly but for systemic invasion of host plants. CP is also a suppressor of RNA silencing. The function of p18 (ORF8) and p13 (ORF9) is unknown. Protein p20 (ORF10) accumulates in amorphous inclusion bodies of CTV-infected cells and has been shown to be a suppressor of RNA silencing. p23 (ORF11) has no homolog in other closteroviruses but is a multifunctional protein that (1) binds cooperatively both single-stranded and dsRNA molecules in a non-sequence-specific manner; (2) contains a zinc-finger domain that regulates the synthesis of the plus- and minus-strand molecules and controls the accumulation of plus-strand RNA during replication; (3) is an inducer of CTV-like symptoms in transgenic *C. aurantifolia* plants; (4) is a potent suppressor of intracellular RNA silencing in *Nicotiana tabacum* and *N. benthamiana*; and (5) controls the level of genomic and subgenomic negative-stranded RNAs.

The CTV Subgenomic (sg) RNAs

The replication of CTV involves the production of a large number of less than full-length RNAs. These include ten 3′ coterminal sg mRNAs, and ten negative-stranded sgRNAs corresponding to the ten 3′ sg mRNAs, plus ten 5′-coterminal sgRNAs that apparently are produced by termination just 5′ of each of the ten ORFs (**Figure 1**). The amounts of different sg mRNAs vary with the highest levels for sg mRNAs p23 and p20, located at the distal 3′ end. Infected cells also contain abundant amounts of two other small 5′ coterminal positive-stranded sgRNAs of ~600 and 800 nt designated as low molecular weight tristeza (LMT).

Defective RNAs

Most CTV contain dRNAs, which consist of the two genomic termini, with extensive internal deletions. CTV dRNAs accumulate abundantly even when their genomes contain less than 10% of the viral genome (**Figure 2**).

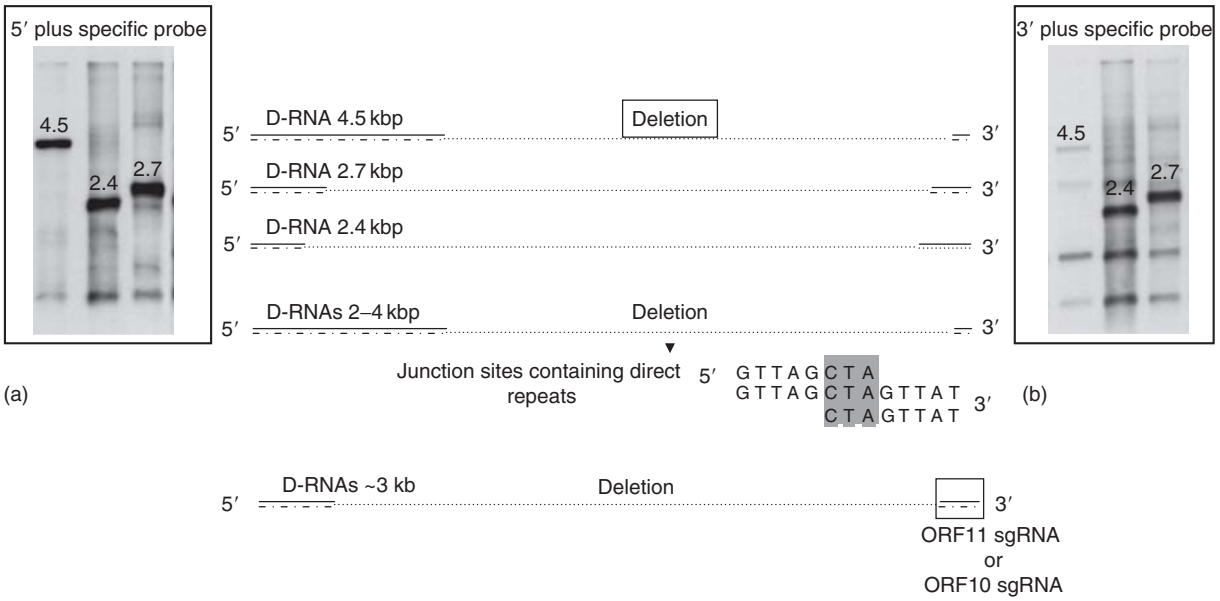

Figure 2 A diagram of class I CTV defective (d) RNAs (=D-RNA) with three different sizes and class II CTV-dRNAs that show 3′ moieties of the size and structure of the full-length sgRNA of ORF11. Insets (a) and (b) show Northern hybridization of class I dsRNAs from three different CTV-VT subisolates, hybridized with riboprobes specific to the 5′ and 3′ ends, respectively, of the genomic RNA of CTV. Note the intense bands resulting from the hybridization of the two probes with the abundantly present dRNAs. Lower part is a diagrammatic presentation of direct repeats at the junction sites of some class I dRNAs. The bottom part shows a schematic presentation of a class II dRNA, with a 3′ terminus corresponding to the ORF11 sgRNA of CTV-VT.

For convenience, the dRNAs were divided into six groups, class I molecules contained different sizes of 5′ and 3′ sequences. Some dRNAs of this class contained direct repeats of 4–5 nt flanking or near their junction sites, supporting the possibility that they were generated through a replicase-driven template-switching mechanism. Class II molecules showed 3′ moieties of the size and structure of the full-length sgRNA of ORF11 (**Figure 2**, lower part). An extra C at the junction sites of several dRNAs of this class corresponded for the extra G reported for 3′ of minus strands from sgRNAs and RF molecules. Class III molecules are large (*c.* 12 kbp) encapsidated dRNAs which are infectious when used to inoculate *N. benthamiana* protoplasts. Class IV consists of dRNAs that retained all or most of the ten 3′ ORFs, analogous to crinivirus RNA 2. Class V includes double recombinants with identical 5′ regions of 948 nt followed with an internal ORF2 sequence and 3′ parts of different sizes, and class VI molecules are closely similar to class I with variable regions from the 5′ and 3′ with junction sites comprised of non-CTV inserts of 14–17 nt.

The biological roles of CTV dRNAs remain obscure as no specific associations have been established for any of the dRNA. Examination of the dRNAs from Alemow plants infected with SY and non-SY inducing isolates revealed mostly a major single dRNA of 4.5 or 5.1 kbp in non-SY plants and two different dRNAs of 2.4 or 2.7 kbp in SY plants. These results suggested the possibility that large dRNAs might play a role in suppression of SY symptoms.

Transmission

Although the virus is phloem limited, mechanical inoculation can be done experimentally at relatively low efficiency by slashing the trunks of small citrus trees with blades containing sap extracts. In commercial groves, the virus is spread naturally by aphid vectors and by vegetative propagation in infected budwood. Long-distance spread of the virus, particularly from country to country, had been through the long-distance transfer of plant propagation material.

Several aphid species including *Aphis gossypii*, *A. spiraecola*, *A. craccivora*, and *T. citricida* transmit CTV semipersistently. The rate of transmissibility varies considerably between different virus isolates and different aphid species. The brown citrus aphid (*T. citricida*) is the most efficient vector, followed by *A. gossypii.* Despite the less efficient transmission by *A. gossypii* and the absence of brown citrus aphid in the Mediterranean region and California, mild strains are spread in these areas. Recently, the brown citrus aphid invaded Central America and Florida, and was also reported to be in the island of Madeira and Portugal.

CTV Control Measures

Strategies to control CTV have varied at different locations and periods and included (1) quarantine and budwood certification programs to prevent the introduction of CTV; (2) costly and ambitious eradication programs to contain situations of virus spread; (3) the use of CTV-tolerant rootstocks and mild (or protective) strain cross-protection, often also named preimmunization; (4) breeding for resistance; and (5) attempts to obtain resistance by genetic engineering. Mild-strain cross-protection has been widely applied for millions of citrus trees in Australia, Brazil, and South Africa to protect against stem pitting of sweet orange and grapefruit trees. However, mild-strain cross-protection has not provided field protection against CTV isolates causing quick decline of trees on the sensitive sour orange rootstock.

Useful resistance to CTV has been found in a citrus relative, *Poncirus trifoliate.* This resistance has been mapped and shown to be controlled primarily by a single dominant gene, *Ctv.* Although the region containing this gene has been identified and sequenced, a specific gene has not been identified by transformation into susceptible citrus with the resistance phenotype.

CTV Diagnosis

The outcome of CTV infections varies considerably depending on the virulence of the prevailing virus isolates and the sensitivity of infected citrus varieties and root stock combinations. Hence, the need of effective means of CTV diagnosis are of utmost importance. Biological indexing of the disease by grafting sensitive citrus indicators has been the definitive assay, although it is costly and time consuming. It has largely been replaced with more rapid immunoassays. ELISA has been widely practiced for almost 30 years for a variety of CTV sanitation programs. Development of recombinant antigens considerably advanced diagnostic possibilities and production of monoclonal antibodies has allowed for more precise differentiation of isolates. PCR and combinations of immunocapture PCR allow more sensitive CTV diagnosis. However, despite the progress in development of better diagnostic tools, none is effective for predicting the biological properties of new CTV isolates.

Economic Costs of CTV

Control strategies varied at different geographic regions and periods, depending on the extent to which CTV was spreading within the newly infested areas, the sensitivity of the specific local varieties, and the economical availability

of alternative crops to replace diseased groves. Most citrus-growing countries that managed to remain free of CTV did so by enforcing sanitation practices to prevent virus spread. These included certification schemes aimed to ensure that citrus nurseries propagate and distribute to growers only CTV-free planting material. Other areas had far more costly and ambitious programs of eradication. These efforts were mostly only temporarily successful, mainly because of lack of long-term grower and governmental commitment to such costly operation. In areas where CTV was endemic, alternative strategies to enable continued commercial citrus production in the presence of CTV were developed. Indeed, long before the viral nature of the tristeza disease was realized, Japanese citrus growers were grafting CTV-tolerant Satsuma mandarins on the cold-tolerant and CTV-resistant trifoliate orange *(P. trifoliate)* rootstocks, thus enabling them to produce quality fruits despite endemic CTV infections. Similarly, the change of rootstocks from the 'quick declining' sour orange rootstocks to rough lemon rootstocks, and to a less extent to mandarin rootstocks, allowed the South African growers to produce good crops of oranges despite the presence of the most efficient aphid vector and infections with severe CTV strains. Similarly, half a century later the Brazilian citrus industry that was completely decimated during 1940s, when all trees were grafted on sour orange rootstocks was saved by adopting CTV-tolerant rootstocks and mild-strain cross-protection.

Historically, the costs of CTV epidemics were estimated to be of the order of tens and even hundreds of millions of dollars. These estimates, however, varied depending on actual market value of the lost production capacity, alternative uses of the land, and the time needed for the CTV-tolerant replants to enter production. There were also indirect costs resulting in poorer performance and/or sensitivity of some CTV-tolerant rootstocks used to replace the widely adapted sour orange rootstocks to other citrus diseases such as citrus blight and citrus sudden death.

Attempts to Apply Transgenic Resistance to CTV

Conventional breeding for CTV resistance is a long, difficult, and inconvenient process mainly because most citrus varieties are hybrids of unknown parentage. Hence, the considerable interest in applying pathogen-derived resistance (PDR) to render both citrus rootstocks and varieties tolerant to stem-pitting isolates and decline causing CTV isolates. Yet, literally hundreds of independent transformations with a range of different types of configuration of CTV sequences have resulted in failure to obtain durable protection against CTV. These failures are especially frustrating since the control of severe stem- pitting isolates is needed in several major citrus production areas. The lack of RNA silencing against CTV in citrus might be due to more effective suppression by the combination of the three suppressors of this virus.

Glossary

CPE Viruses can have a cytopathic effect on infected cells, that is, they either kill cells or change their properties.

DI Defective interfering particles lack part(s) of their genome and they depend on complete helper virus for replication; they interfere with the replication of the helper virus by competing for essential enzymes.

ELISA Enzyme-linked immunosorbent assays are widely used for virological and serological diagnosis. Samples can be processed automatically and results are read using optical methods.
IFT Immunofluorescense tests utilize specific antibodies conjugated with fluorescent dye. Viral antigens can be visualized after binding of conjugated antibodies.
MLV Modified live vaccines consist of attenuated viruses that have lost their pathogenic properties and cause an infection without significant clinical signs in the vaccine.
PLA Enzymes like peroxidase can be conjugated to virus-specific antibodies. Binding of these antibodies to viral antigens located in infected cells can be visualized by adding substrate to the antigen–antibody–enzyme complex.
qPCR Real-time PCR allows monitoring of the polymerase chain reaction in real time on a computer screen. In contrast to gel-based PCR systems qPCR yields semi-quantitative results.
VNT Virus neutralization tests are tissue-culture-based assays for the detection and quantification of virus neutralizing antibodies. Of all antibody detection tests they are generally considered the 'gold standard'.

Introduction

Classical swine fever (CSF), formerly known as hog cholera, is a highly contagious viral disease of swine with high morbidity and mortality especially in young animals. Due to its economic impact it is notifiable to the Office International des Epizooties (OIE (World Organisation for Animal Health)). First outbreaks of the disease were observed in 1833 in Ohio, USA. The aetiological agent was long assumed to be a bacterium (hog cholera bacillus), until de Schweinitz and Dorset demonstrated in 1903 that the agent was filterable. CSF has been eradicated in Australia, Canada, the US, and almost all member states of the European Union (EU). Vaccination is banned in these countries. However, outbreaks of CSF still occur intermittently in several European countries in either wild boar or domestic pigs. The latter can cause large economic losses. During the last 16 years in the EU, close to 20 million pigs were euthanized and destroyed because of control measures imposed to combat CSF epizootics, causing total costs of about 5 billion euros. In many countries worldwide, CSF is still a major problem. In 2004, a total of 38 member states of the OIE reported CSF outbreaks.

Virus Properties

Genome Organization and Protein Expression

CSF virus (CSFV) is an enveloped virus with a diameter of *c.* 40–60 nm. The single-stranded RNA genome has a size of 12.3 kb. It has positive polarity with one open reading frame (ORF) flanked by two nontranslated regions (NTRs). The 5′ NTR functions as an internal ribosomal entry site (IRES) for cap-independent translation initiation of the large ORF that codes for a polyprotein of about 3900 amino acids. The polyprotein is co- and post-translationally processed by viral and cellular proteases. From 11 viral proteins, four constitute the structure of the particle, namely three envelope glycoproteins (E^{rns}, E1, and E2) and one core (C) protein. The remaining seven non-structural proteins are N^{pro}, p7, NS2-3, NS4A, NS4B, NS5A, and NS5B. The main target for neutralizing antibodies is the viral envelope glycoprotein E2. To a lesser extent, the host's immune system produces neutralizing antibodies to E^{rns}. This viral envelope glycoprotein occurs as a disulfide-bonded homodimer in the virus particle, and is also secreted by CSFV-infected cells. E^{rns} was shown to be a potent ribonuclease specific for uridine. N^{pro} has an autoproteolytic activity that achieves cleavage from the downstream nucleocapsid protein C. *In vitro*, it had been shown that N^{pro} interferes with the induction of interferon α/β, and *in vivo* CSFV with a deletion in the N^{pro} gene was able to infect pigs but had lost its pathogenicity.

Replication

CSFV replicates in cell lines from different species, for example, pigs, cattle, sheep, and rabbit. For most purposes, the viruses are cultivated in porcine cells. Virus replication is restricted to the cytoplasm of the cell and normally does not result in a cytopathic effect (CPE). The first progeny virus is released from the cells at 5–6 h post infection. Virion assembly occurs on membranes of the endoplasmic reticulum, and full virions appear within cisternae. They are released via exocytosis or cell lysis.

Cytopathic isolates of CSFV occur only sporadically, and most of them are defective interfering (DI) particles. Their genomes have large internal deletions, consisting mainly of the genomic regions coding for the structural proteins. The DI particles are strictly dependent on a complementing helper virus for replication.

Taxonomy and Classification

CSFV belongs together with viruses in the species *Bovine viral diarrhea virus 1* (BVDV-1), BVDV-2, and viruses in the species *Border disease virus* (BDV) to the genus *Pestivirus*, in the family *Flaviviridae*. Classification of CSFV

strains and isolates is currently performed by genetic typing. For this purpose, three regions of the CSFV genome are used, mainly 190 nt of the E2 envelope glycoprotein gene, but also 150 nt of the 5′ NTR, and 409 nt of the NS5B polymerase gene. The phylogenetic tree shows that the CSFV isolates can be divided into three groups with three or four subgroups: 1.1, 1.2, 1.3; 2.1, 2.2, 2.3; 3.1, 3.2, 3.3, 3.4. CSFV groups and subgroups show distinct geographical distribution patterns, which is important for epidemiologists. Whereas isolates belonging to group 3 seem to occur solely in Asia, all CSF virus isolates of the last 15 years isolated in the EU belonged to one of the subgroups within group 2 (2.1, 2.2, or 2.3) and were clearly distinct from historic CSFV of group 1, that are still being used as CSFV laboratory reference viruses. In contrast, current representatives of group 1 viruses continue to cause outbreaks in South America and Central America, and in the Caribbean. Interestingly, CSFVs of all groups have been found in various locations in Asia (**Figure 1**).

Antigenic Relationships and Variability

All pestiviruses were originally classified according to their host origin and the disease they cause. Later, it was found that they are not restricted to their original hosts and that they are serologically related, for example, BVDV and BDV have the capacity to naturally infect many other ruminant species and pigs. The same applies for CSFV, although its extended host range has only been determined experimentally and does not seem to reflect natural conditions. Detailed studies on the antigenic relationship between CSFV and ruminant pestiviruses have been performed using monoclonal antibodies and neutralization studies.

In recent years, progress in molecular biology has allowed a more precise assessment of their relationship. Several genomic regions have been used to study genetic diversity, for example, the 5′ NTR and genes coding for proteins (N^{pro}, C, and E2). Phylogenetic analysis confirmed the classification of the genus *Pestivirus*, comprising CSFV, BVDV-1, BVDV-2, and BDV, and has

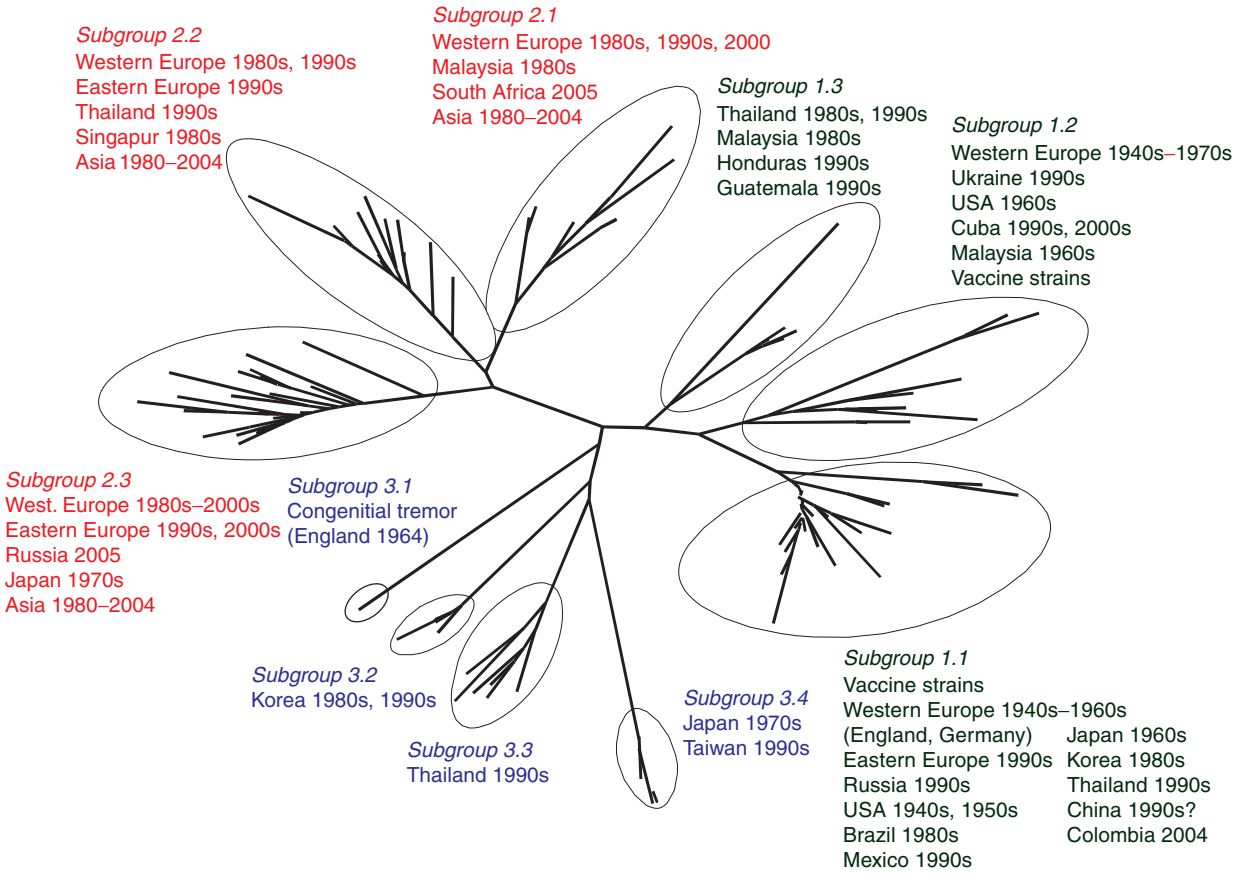

Figure 1 Diversity and geographical distribution of CSF virus isolates. The unrooted neighbor-joining phylogenetic tree was calculated using 190 nt of E2 sequences from 108 CSF viruses. The nomenclature of virus subgroups is as suggested by Paton DJ *et al.* Adapted from Paton DJ, McGoldrick A, Greiser-Wilke I, *et al.* (2000) Genetic typing of classical swine fever virus. *Veterinary Microbiology* 73: 137–157.

revealed at least one additional species, a pestivirus isolated from giraffe.

There is as yet little knowledge concerning the evolution of CSFV, although some analyses have been performed, albeit using short regions of the genome only. These results are difficult to interpret as, in contrast to other RNA viruses, CSFV has little tendency to accumulate mutations. Extensive genomic analyses of isolates obtained between February 1997 and March 1998 in the Netherlands emphasized the genetic stability of CSFV even in the highly variable antigenic region of the E2 gene during a major epidemic that lasted longer than 1 year.

Transmission and Host Range

Members of the family Suidae, in particular domestic pigs (*Sus scrofa domesticus*) and European wild boar (*Sus scrofa scrofa*), are the natural hosts of CSFV. Blood, tissues, secretions, and excretions from an infected animal contain the virus. Transmission occurs mainly by the oral–nasal route, though infection through the conjunctiva, mucous membrane, by skin abrasion, insemination, and percutaneous blood transfer (e.g., common needle, contaminated instruments) may occur. Airborne transmission is not thought to be important in the epizootiology of CSFV, but such transmission could occur between mechanically ventilated units within close proximity to each other.

Experimental transmission of CSFV to goats, sheep, cattle, peccaries (*Tayassu tajacu*), and rabbits was successful, while other vertebrates, for example, racoons, mice, and pigeons did not support the propagation of the virus. Of all species, the rabbit has been of major importance because it was, and in some countries still is, used for the attenuation of CSFV and for large-scale production of live vaccine virus.

Clinical Features

The incubation period in individual animals is 3–10 days. Since transmission from animal to animal may be slow, in large holdings symptoms of CSF may only become evident several weeks after virus introduction ('herd incubation'). The severity of clinical signs mainly depends on the age of the animal and the virulence of the virus. In older breeding pigs, the course of infection is often mild or even subclinical. The virulence of a CSFV isolate is difficult to determine on a rational basis, as the same CSFV isolate can cause different forms of disease depending on age, breed, and immune status of the host animal. Basically acute, chronic, and prenatal forms of CSF can be distinguished, and there is no classical pattern of symptoms that is invariably associated with the disease.

Acute CSF

Most piglets up to 12 weeks of age develop a severe form of acute CSF with high fatalities, whereas older breeding animals may only show mild symptoms. A constant finding in young animals is pyrexia higher than 40 °C. Initial signs are anorexia, lethargy, huddling together, conjunctivitis, respiratory symptoms, and constipation followed by diarrhea. Neurological signs are frequently seen, such as a staggering gait with weakness of hind legs, incoordination of movement, and convulsions. Hemorrhages of the skin are frequently observed on the ear, tail, abdomen, and the lower part of the limbs during the second and third week after infection until death. Virus is shed from the infected animal by all secretions and excretions. CSFV causes severe leukopenia and immunosuppression, which often leads to secondary enteric or respiratory infections. The signs of these secondary infections can mask or overlap the most typical signs of CSF and may mislead the veterinarian. With increasing age of the infected pigs (fattening and breeding animals), clinical signs are less specific and recovery is frequent. The infection is terminated by a strong, predominantly humoral immune response. First neutralizing antibodies against CSFV become detectable 2–3 weeks post infection.

Chronic CSF

The chronic form of CSF is always fatal. It develops in a low percentage of infected animals, when pigs are not able to mount an effective immune response to overcome the virus. Initial signs are similar to those characteristic for the acute infection. Later, predominantly nonspecific signs are observed, for example, intermittent fever, chronic enteritis, and wasting. Animals usually survive for 2–4 months before they die. Until death, CSFV is constantly shed from the onset of clinical signs. Antibodies may be temporarily detected in serum samples, as the immune system begins to produce antibodies, although they are not able to eliminate the virus. Consequently, the antibodies are complexed by circulating virus and cease to be detectable. Since clinical signs of chronic CSF are rather nonspecific, a broad range of other diseases must be considered for differential diagnosis.

Prenatal and Late Onset CSF

Although the course of infection in sows is often subclinical, CSFVs, as do other pestiviruses, cross the placenta of pregnant animals, thereby infecting fetuses during all stages of pregnancy. The outcome of transplacental infection depends primarily on the time of gestation and on viral virulence. Abortions and stillbirths, mummification, and malformations are observed after infection during early pregnancy. In breeding herds, this leads to a reduction

in the fertility index of the affected pig herd. Infection of sows from about 50 to 70 days of pregnancy may lead to the birth of persistently viremic piglets, which may be clinically normal at birth and survive for several months. After birth, they usually show poor growth ('runt'), wasting, or occasionally congenital tremor. This course of infection is referred to as 'late onset CSF' and the outcome is fatal. During their lifetime, these animals constantly shed large amounts of virus and are dangerous virus reservoirs, spreading and maintaining the infection within the pig population. This feature of CSFV infection is comparable to cattle or sheep persistently infected with BVDV and BDV, respectively.

Pathology and Histopathology

After infection, the tonsils are the location of primary virus replication. Thereafter, the agent progresses to neighboring lymphoreticular tissues. Through lymph channels the virus reaches regional lymph nodes, from where it spreads to the blood vascular system. Massive secondary virus replication takes place in spleen, bone marrow, and visceral lymph nodes. Major targets for the virus are cells of the immune system. In the peripheral blood, main target cells for the virus appear to be monocytes. In later stages of the disease, infected lymphocytes as well as granulocytes are found. Early events that are not completely understood play a significant role in the pathogenesis and manifestation of CSF. As early as 24 h post infection with virulent virus, that is, when animals are still asymptomatic and 2–4 days before virus can be detected in the peripheral blood, a progressive lymphopenia is observed resulting in severe immunosuppression. The reason for the massive cell death is not clear; however, a direct interaction with the virus can be ruled out. Viral E^{rns} has been shown to induce apoptosis in lymphocytes of different species. Since this protein is secreted in large quantities from infected cells, it is conceivable that it causes massive destruction of lymphocyte populations. An additional or an alternative mechanism of cell death, respectively, might be triggered by cytokines that are activated shortly after infection, for example, tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β) and IL-1α, as well as IL-6.

A severe thrombocytopenia develops once infected animals develop fever and virus is detectable in peripheral blood. Currently, there are two explanations for thrombocyte depletion: (1) abnormal peripheral consumption of thrombocytes may be responsible for thrombocytopenia; and (2) progressive degeneration of megakaryocytes, which is observed to begin at day 1 p.i., can result in cell death and shortage of thrombocyte production. It is not clear whether direct or indirect effects are responsible for the latter phenomenon. In analogy to the clinical picture, the severity of pathological lesions depends on time of infection, age of the animal, and virulence of the strain.

In acute cases, pathological changes visible on postmortem examination are observed most often in lymph nodes, spleen, and kidneys. Kidney parenchyma may display a yellowish brown colour. Infarctions of the spleen are considered pathognomonic; however, they are rarely observed. Lymph nodes are swollen, edematous, and hemorrhagic. Hemorrhages of the kidney may vary in size from petechial to ecchymotic. Petechiae can also be observed in the mucous membranes of other organs, for example, urinary bladder, larynx, epiglottis, and heart, and may be widespread over the serosae of the abdomen and chest. Inflammation in the respiratory, gastrointestinal, and urinary tract often are sequelae of secondary infections. Severe pneumonia sometimes is complicated by interstitial edema. Tonsils may display necrotic foci caused by micro infarcts followed by secondary infection. A nonpurulent encephalitis is often present.

In chronically infected animals, pathological changes are less pronounced, especially an absence of hemorrhages on organs and serosae. Instead, thymus atrophy, lymphocyte depletion in peripheral lymphatic organs, and hyperplasia of the renal cortex are often observed. In animals displaying chronic diarrhea, necrotic and ulcerative lesions on the ileum, the ileocaecal valve, and the rectum are found. 'Button' ulcers in the large intestine are pathognomonic, though rare. In cases of congenital infection, a proportion of piglets may show incomplete development of the cerebellum or other developmental abnormalities, such as atrophy of the thymus.

Epizootiology

Primary outbreaks in CSF-free regions usually occur as a consequence of the feeding of swill containing infected pork. Although this practice is officially banned in almost all CSF-free and many other countries, it is still the major risk factor for the importation of the infection into CSF-free populations of domestic pigs or wild boar. The most common route for the spread of the infection among pigs is virus excretion by infected pigs via saliva, feces and urine, and oronasal virus uptake by uninfected animals. Further sources of infection are natural breeding and artificial insemination, since the virus is also excreted in sperm. Trade of live pigs, including at auction sales, has been shown to be the most frequent cause of virus spread from herd to herd. Other farming activities, for example, livestock shows, visits by feed dealers, and rendering trucks are also high-risk factors. Infected pregnant sows ('carrier sows') may give birth to persistently infected piglets that play an important role in the spread of the infection. CSF in small holdings, commonly called 'backyard holdings', is particularly difficult to control. Swill

feeding, lack of animal registration and movement control, poor hygiene and lack of education of pig owners, as well as lack of awareness of private and government veterinarians facilitate the further spread and persistence of the infection in backyard pig populations.

CSF outbreaks in wild boar or feral pigs can be caused by contaminated garbage or 'spillover' from CSFV-infected domestic pigs. The outcome of these outbreaks mainly depends on the size and density of the wild boar populations affected. Outbreaks in small populations that live within natural confines, such as valleys, tend to be self-limiting. In contrast, infections leading to outbreaks in large areas and dense populations often become endemic. Most of the older animals survive the infection and become immune. Piglets become susceptible with waning maternal immunity and then can serve as reservoirs for the perpetuation of the infection. Most fatalities are registered in the young age class. CSFV in wild boar or feral pigs is a threat to any local domestic pig holding and strict measures have to be taken to avoid the spread to domestic pigs.

Diagnosis

The majority of outbreaks of CSF are diagnosed tentatively on clinical grounds, especially in the severe acute form of disease. However, a number of diseases must be considered for differential diagnosis: acute African swine fever leads to a very similar clinical and pathological picture. Erysipelas, porcine reproductive and respiratory syndrome, cumarin poisoning, purpura hemorragica, postweaning multisystemic wasting syndrome, porcine dermatitis and nephropathy syndrome, *Salmonella* or *Pasteurella* infections, or any enteric or respiratory syndrome with fever not responding to antibiotic treatment may display features resembling CSF. Infections of pigs with related ruminant pestiviruses occasionally cause similar symptoms and cross-reactions in diagnostic laboratory tests. In conditions of reduced fertility, CSF, next to parvovirus infections, porcine reproductive and respiratory syndrome, leptospirosis, and Aujeszky's disease (pseudorabies), should be considered in the differential diagnosis. In any case, suspected CSF outbreaks need to be verified using laboratory diagnostic methods. Techniques for the detection of CSFV and virus-specific antibodies are well established and they are described in detail in the Manual of Standards of the OIE as well as in the Diagnostic Manual attached to Decision 2002/106/EC.

Virus Isolation in Cell Culture

Virus isolation using susceptible porcine cell cultures is still considered the standard method for the direct diagnosis of CSFV infection. Suitable samples are whole blood, buffy coat, plasma, serum or clarified organ suspensions from tonsils, spleen, kidney, or gut lymph nodes. Since CSFV does not cause a CPE, the infection must be visualized by fixing and staining the cells. Antigen can then be detected either by direct or indirect immunofluorescence tests (IFTs), or by immunoperoxidase assays (PLAs), using conjugated virus-specific polyclonal or monoclonal antibodies. Virus isolation is time consuming, but the virus isolates can be stored and used for further analyses, for example, genotyping, and it allows the establishment of strain collections.

Direct Antigen Detection

Antigen detection may be carried out on fixed cryosections of organs, using IFT or PLA with polyclonal or monoclonal antibodies. The tests yield results quickly and they are often used for a first laboratory investigation in a suspected case. However, due to limited sensitivity, a CSF suspicion cannot be ruled out in case of a negative result. The correct interpretation of results requires well-trained and experienced personnel.

Commercially available antigen capture enzyme-linked immunosorbent assays (ELISAs) are used for analyzing blood, buffy coat, organ suspension, plasma, or serum samples. Although the method yields quick results (4 h), its usefulness is limited due to its low sensitivity. It is only suitable for herd diagnosis and not for individual animals. In the near future, the ELISA will most probably be replaced by polymerase chain reaction after reverse transcription of the genome (reverse transcription-polymerase chain reaction, RT-PCR) using pools of samples.

Detection of Viral Nucleic Acid by PCR

RT-PCR is becoming an increasingly important tool for the diagnosis of CSFV. Evaluation of RT-PCR can be performed either by agarose gel electrophoresis, or by real-time techniques (RT-qPCR). As laboratory equipment is becoming reliable and also more affordable, coupling of liquid handling robotics for nucleic acid isolation and RT-qPCR is becoming practicable. Another advantage of both the standard gel-based RT-PCR and the RT-qPCR is that, due to their high sensitivities, pooled samples can be tested. In particular, the use of RT-qPCR allows rapid and reliable testing of herds at the perimeter of an outbreak in order to avoid preemptive slaughter. Despite the advantages that RT-PCR methodology may have over conventional diagnostic tests, it is extremely vulnerable to false negative or false positive results. False negative results can arise when the nucleic acid is degraded, or when the reaction mixture contains inhibitors. Due to its high sensitivity, false positive results may arise from contaminations, either from sample to sample or from other sources. This implies that before diagnostic laboratories can replace any test, their

RT-PCR protocols have to be validated, and regular participation in proficiency testing must prove that performance of the methods used is accurate. In addition, specification concerning sensitivity of the detection must be defined. This is important when samples are pooled. In summary, analytical performance must be equal to or better than that of the standard method, that is, isolation of CSFV in permissive cells.

Antibody Detection

CSFV-specific antibodies in pig populations are sensitive indicators for the presence of the infection. Hence, serological tests are valuable tools for diagnosis and surveillance. CSFV infection mainly induces antibodies against viral proteins E2, E^{rns}, and NS3. Detectable levels of antibodies appear 2–3 weeks post infection and persist lifelong in recovered animals. The virus neutralization test (VNT) is the most sensitive and versatile assay. It is very useful for quantifying neutralizing antibodies as well as for discriminating between infections with CSFV or ruminant pestiviruses. This often becomes necessary since, irrespective of its clinical status, a pig herd or single animal seropositive for CSFV is considered as CSFV infected, unless an involvement of CSFV is ruled out. In contrast, in the case of BDV or BVDV infections in pigs, no disease control measures are taken. The choice of test viruses should take into account the local epidemiological situation. While the above-mentioned differentiation is often possible, the VNT is not able to discriminate between antibody titers due to CSFV field infection and antibody titers resulting from immunization with modified live CSFV vaccines. As it relies on cell culture technology, the test is labor intensive and time consuming, and it is not suitable for mass screening of samples. Therefore, it is mainly used for cases where an accurate quantitative and discriminatory assessment of antibody levels is required.

For routine serological investigation, ELISAs are suitable. These tests are either designed as blocking or as indirect ELISAs. They are widely used for screening of antibodies during and after outbreaks, for monitoring of CSFV infections in wild boar, and to test coverage of immunization of wild boars after vaccination. In general, ELISAs are less sensitive than VNTs. However, although ELISAs have some limitations considering specificity and/or sensitivity, they yield results quickly and they are well suited for mass screening of animals, and on a herd basis they are suitable to detect field virus infections.

Immune Response

Live CSFV infection induces a B-cell as well as a T-cell response, while inoculation of inactivated virus elicits only a B-cell response. The cellular immune response has not been thoroughly investigated. Antibodies are produced against viral proteins NS3, E2, and E^{rns}. Antibodies against E2 and to a lesser extent E^{rns} are protective. Neutralizing antibodies against CSFV are regarded as the most important specific defence against infection and disease. This is in accord with the immune responses to other pestivirus infections. There is some antigenic variation among CSFV isolates, but not to the extent observed with ruminant pestiviruses. Therefore, convalescent animals have a stable and long-lasting, if not lifelong, immunity against all variants of CSFV.

Vaccination

First attempts to vaccinate against swine fever date back to the beginning of the last century, when pigs were infected with live virus and simultaneously treated with serum from immune pigs. This high-risk practice was replaced in the 1940s by the use of inactivated and modified live vaccines (MLVs).While the inactivated vaccines proved rather inefficient, MLV turned out to be highly efficacious and safe in pigs of any age, for example, the GPE^{-} and the lapinized Chinese strain (C-strain) of CSFV. The latter is probably the most popular MLV against CSF. When properly used, MLVs are powerful tools for prophylactic protection of domestic pigs against CSF. In countries still struggling with endemic CSF, vaccines are being used in order to limit economical damage. The systematic use of these vaccines often was and is the first step in the eradication of CSF. In countries that have eradicated the infection, prophylactic vaccination is usually banned, mainly because animals vaccinated with conventional MLV (e.g., the C-strain) cannot be distinguished serologically from animals that have recovered from field infection and thus the CSF-free status of the country would not be regained. However, in emergency situations, vaccination may be used, followed by international trade restrictions for vaccinated animals and their products for at least 6 months. For EU member states, provisions have been made in directive 2001/89/EC for limited vaccination of domestic pigs in cases of severe outbreak emergencies.

In order to overcome the severe restrictions after vaccination, novel marker vaccines have been developed. They are based on the concept that the pattern of antibodies against CSFV from a vaccinated animal can be distinguished from that of an animal which has recovered from a field virus infection. The recently developed E2 subunit CSFV marker vaccines induce neutralizing antibodies against the E2 glycoprotein only. Consequently, CSFV antibodies which are not directed against the E2 glycoprotein are indicative of an infection with wild-type CSFV. With the availability of E2 glycoprotein-based subunit marker vaccines against CSFV, two discriminatory

ELISAs were developed as companion tests that detect antibodies directed against the E^{rns} glycoprotein. Positive results are indicative of the exposure to wild-type CSFV. The development of subunit marker vaccines was a major step forward. Compared to MLV, a few shortcomings have to be taken into account when using subunit marker vaccines. In comparison with conventional MLV, full immunity after subunit vaccination is slow (*c.* 21 days). Sometimes, a booster vaccination is needed, and it does not induce sterile immunity, for example, transplacental transmission of CSFV cannot be completely prevented. However, it was shown that the E2 subunit vaccine was able to stop virus spread among pigs that were vaccinated 10 days earlier. The discriminatory tests are suitable for herd diagnosis but they must not be used to assess the serological status of individual animals. Most likely the limitations of the first generation of marker vaccines may be overcome by a second generation of live marker vaccines. Candidates are being developed. Viral vectors carrying the E2 gene of CSFV or chimeras using the genomes of the CSFV C-strain and BVDV are promising candidates.

Prevention and Control

There is no specific treatment for CSF. In countries where CSF occurs endemically, infected animals are killed and destroyed and vaccination is used to prevent further spread of the virus. Countries free of CSF usually implement measures to avoid outbreaks of the disease. The most effective sanction to prevent introduction of CSFV into a free pig population is the ban of swill feeding and the control of trade. Attempts must be made to prevent the illegal importation of meat and meat products. Professional farms must comply with standard biosecurity rules. In order to eradicate the disease, a system for the registration and identification of all holdings and pigs should be in place. This greatly facilitates the traceability of animal movements. In case CSFV has been introduced, eradication programs are based principally on the destruction of infected and serologically positive animals. In order to avoid trade restrictions, vaccination is usually prohibited. Despite continued efforts to control CSF, outbreaks have occurred intermittently in several European countries. In areas with high pig densities very high numbers of pigs had to be culled in order to stop virus spread, and in these cases direct and indirect economical damage was very high. For example, in the course of the 1997 CSF epidemic in the Netherlands, approximately 12 million pigs had to be destroyed and total economic losses amounted to more than 2 billion euro. In severe outbreak situations, an emergency vaccination option is available. Thus far, emergency vaccination has never been used in Western Europe.

Epidemics of CSF in wild boar populations may be long-lasting and difficult to control. Oral vaccination campaigns using MLV sometimes accompanied by specific hunting measures have been shown to be suitable tools to shorten the duration of these epidemics.

Perspectives

The fascinating pathogenesis of CSFV displays similarities with other hemorrhagic diseases. Further elucidation of determinants of viral virulence and virus interaction with the host animal will contribute to the understanding of hemorrhagic diseases.

Control and eradication of CSFV will remain a challenge for many years to come. In CSF-free countries with a highly developed pig industry and densely populated livestock areas, the control of CSF outbreaks will change from the presently practiced excessive culling of pigs to a more sophisticated disease control strategy using sensitive and specific diagnostic tools (e.g., RT-PCR), for the tracing of virus at the perimeters of outbreaks, combined with emergency marker vaccination, preferably with a live marker vaccine, which is yet to be developed.

In countries where CSF is endemic and where a sizable proportion of pigs are held in backyards, extensive vaccination with MLV, in combination with movement controls and epidemiological surveillance, might help to control this pestilence. Of prime importance is thorough education in order to increase knowledge and awareness of all parties involved.

Lagomorph Gnawing herbivorous mammals including rabbits and hares.
Myocarditis Inflammation of the heart muscle.
Nosological From nosology, which is a branch of medical science which deals with disease classification.
Nymph Immature insect or tick.
Orchitis Inflammation of the testicles.
Pericarditis Inflammation of pericardium.
Sarcolemma Thin transparent homogenous sheath enclosing a striated muscle fiber.
***Trans*-ovarial** From parental ticks to progeny ticks through the eggs.
***Trans*-stadial** In-between developmental stage forms of the ticks.

Introduction

The family *Reoviridae* includes 12 recognized and 3 proposed genera. The genera *Coltivirus*, *Seadornavirus,* and *Orbivirus* are those which include causative agents of animal arboviral diseases (including human diseases). In 1991, the International Committee on Taxonomy of Viruses (ICTV) officially created the genus *Coltivirus* (sigla from *Colorado tick fever virus*) for the classification of 12-segmented dsRNA animal viruses. Until recently, this genus contained both tick-borne and mosquito-borne viruses. The tick-borne viruses included two species which are *Colorado tick fever virus* (CTFV) and *Eyach virus* (EYAV). The former species encompasses three serotypes that are the Florio isolate (CTFV-Fl, isolated from humans and ticks), California hare coltivirus (CTFV-Ca, isolated from a hare in northern California), and Salmon River virus (isolated from humans in Idaho). Many mosquito-borne viruses were also considered as tentative species including *Banna virus* (BAV, isolated from humans) and several isolates from mosquitoes. In the Seventh Report of the ICTV, the genus *Coltivirus* was subdivided into coltivirus group A which contained the various strains of CTFV and EYAV (tick-borne isolates), and coltivirus group B which contained the Southeast Asian mosquito-borne isolates. The tick-borne and mosquito-borne viruses of this group have many distinctive features and sequence data led to a re-evaluation of their taxonomic status. In the Eighth Report of the ICTV (2005), the genus *Coltivirus* encompasses only the tick-borne viruses, while the mosquito-borne viruses were assigned to a new genus designated *Seadornavirus*.

Coltiviruses have been implicated in a variety of pathological manifestations including flu-like illness, neurological disorders, and some severe complications as further described in the text below.

Historical Overview of Coltiviruses

Coltiviruses have been isolated from rodents, humans, and various ticks in the family *Ixodidae*. Colorado tick fever virus is endemic in the northwestern part of the American continent. CTFV is responsible for Colorado tick fever (CTF), a human disease that was initially confused with a mild form of Rocky Mountain spotted fever (RMSF), caused by a *Rickettsia* species. The description of fever forms with CTF manifestations was made as early as 1850 and clinical studies of these fevers were initiated in 1880s. In 1930, CTF was recognized as a distinct nosological entity. The causative agent was isolated from human serum in 1944 by Florio using inoculation in adult hamsters, and the disease was reproduced in human volunteers by inoculation with serum from infected patients or

egg-adapted CTFV. Between 1946 and 1950, the virus was adapted to mice, and suckling mice became the routine isolation system for CTFV. This considerably progressed the elucidation of the clinical features, epidemiology, and ecology of CTF. Up to 200 cases of CTF have been reported annually in Colorado State in the USA alone, in the past 10 years. Three isolates of Eyach virus were obtained from ticks in Europe. In 1976, isolate EYAV-Gr was obtained from *Ixodes ricinus* in Eyach village near Stugart, Germany. In 1981, two isolates of the virus designated EYAV-Fr577 and EYAV-Fr578 were obtained from *Ixodes ricinus* and *Ixodes ventalloi* in Mayenne, France. The antigenic relationship of EYAV to CTFV was established by a complement fixation assay.

The recent analysis of the complete genome sequences of both CTFV and EYAV has shown that these two viruses are closely related and confirmed the antigenic observations. The relatedness of EYAV to a well-known human pathogen and the identification of anti-EYAV antibodies in patients' sera indirectly have incriminated EYAV in human neurological diseases. Salmon River virus was isolated from a patient with a moderately severe CTF-like illness in Idaho.

Distribution and Epidemiology

CTF is considered as the one of the most important arboviral diseases of humans in the USA. CTF occurs in mountain forest habitats at an altitude of 1200–3000 m in the Rocky Mountain region of the USA and in Canada (**Figure 1**). The virus distribution closely matches that of its vector, *Dermacentor andersoni*. This region covers British Columbia, Alberta, and Saskatchewan in Canada, and Washington, Montana, Oregon, Idaho, Wyoming, Nevada, Utah, and Colorado in the USA. However, CTFV was also isolated from the dog tick *Dermacentor variabilis* in Long Island, New York, in the late 1940s. California hare coltivirus (CTFV-Ca), identified previously as strain S6-14-03, was isolated from the blood of the white hare *Lepus californicus* in California (outside the range of *Dermacentor andersoni*). Antibodies have been found in hares in Ontario but without any virus isolation or occurrence of human cases. CTFV infection has been contracted from infected ticks between March and September. Interestingly, the presence of antibodies reacting with CTFV antigen have also been detected in sera of humans in South Korea.

Between 1980 and 1988, over 1400 cases were reported in the USA, mainly in Colorado State. The disease is underreported since it has always been confused with other infections. More than 70% of CTF cases occur in adults and a few fatal cases have been reported, mainly in children.

The EYAV isolates EYAV-Gr, EYAV-Fr577, and EYAV-Fr578 were obtained from ticks in Europe. EYAV-Fr577 and EYAV-Fr578 were isolated in France from two ticks, *Ixodes ventalloi* and *Ixodes ricinus,* respectively, feeding on a rabbit (**Figure 1**). However, attempts to isolate these viruses from the rabbit failed. Serological surveys conducted in France identified antibodies to EYAV in rodents. It was found that 0.92% of the tested European rabbit (*Oryctolagus cunniculus*) population in Camargue and Vaucluse had antibodies to EYAV. Similar to CTFV whose principal hosts are rodents, European rabbits could represent the major reservoir for the EYAV. Other studies detected the presence of anti-EYAV antibodies in wild mice in the Sarre region and

Figure 1 The known world distribution of coltiviruses (shaded areas): CTFV, CTFV-Ca, and Salmon River virus in North America and EYAV in Europe (France, Germany, Czech Republic and Slovakia). The geographical localization of the various coltiviruses is within the same range of latitude. The question mark indicates South Korea where antibodies to CTFV have been detected but the virus has not been formally identified by isolation.

in deer, mountain goats, and sheep in the Pyrénées and southern Alps regions of France. Serological surveys in higher mammals, including ovines, deer, and caprines, in the southern half of France, identified anti-EYAV antibodies in 1.35% of tested animals. Following the original isolation of EYAV in France, the serum from a French farmer (0.2% of the tested population) was found to be positive. The presence of the virus is also suspected in Eastern Europe as anti-EYAV antibodies have been identified in patients with neurological disorders. However, the natural cycle of the virus is still unclear and it is not known whether it circulates continuously in Europe. In 2003, the virus was re-isolated from ticks in Baden Wuerttemberg, Germany.

Vectors, Host Range, and Transmission

The vectors of coltiviruses are ticks. Colorado tick fever virus is transmitted by the adult wood tick *Dermacentor andersoni,* but other ticks such as *Dermacentor occidentals, Dermacentor albopictus, Dermacentor parumapertus, Haemaphysalis leporispalustris, Otobius lagophilus, Ixodes sculptus,* and *Ixodes spinipalpis* have been found to transmit the virus. Eyach virus was isolated from the ticks *Ixodes ricinus* and *Ixodes ventalloi. Dermacentor* ticks are three-host ticks, requiring different hosts at the larval, nymph, and adult stages. Ticks become infected with CTFV on ingestion of a blood meal from an infected vertebrate host. Infected nymphs and adults transmit the virus to the host via saliva during feeding.

CTFV is transmitted *trans*-stadially but there is no evidence for *trans*-ovarial transmission. However, it is noteworthy that in other tick-borne viruses in the family *Reoviridae*, such as the orbivirus St. Croix River virus, there is strong suspicion that *trans*-ovarial transmission occurs. CTFV-infected larvae and nymphs can hibernate and both adult and nymphal ticks become persistently infected, providing an overwintering mechanism for the virus. A threshold of 10^2 pfu/ml of blood is required for a tick to become infected. Some rodent species become viremic (as high as $10^{6.5}$ pfu/ml) and this could last more than 5 months, which may also facilitate overwintering and virus persistence in the field. The prevalence of viremic rodents in an endemic area ranges from 3.5% to 25%, producing a tick infection frequency ranging from 10% to 25%. Humans represent accidental hosts and usually become infected with CTFV when bitten by the adult wood tick *Dermacentor andersoni* but most probably do not represent a source of reinfection for other ticks. CTFV has a wide host range including ground squirrels, chipmunks, wild mice, wood rats, wild rabbits and hares, porcupines, marmots, deer, elk, sheep, and coyotes.

Transmission from person to person has been recorded as a result of blood transfusion. In the USA, the virus figures on the list of agents to be screened before bone marrow transplantation. The prolonged viremia observed in humans and rodents is due to the intra-erythrocytic location of virions, protecting them from immune clearance. The maintenance cycle of EYAV in the nature is not known, though the European rabbit *Oryctolagus cunniculus* is suspected to be the primary host.

Virion Properties, Genome and Replication

Coltivirus particles have a total diameter of approximately 80 nm and a core that is about 50 nm in diameter. Electron microscopic studies, have revealed particles with a relatively smooth surface capsomeric structure and icosahedral symmetry (**Figure 2**). The majority of the

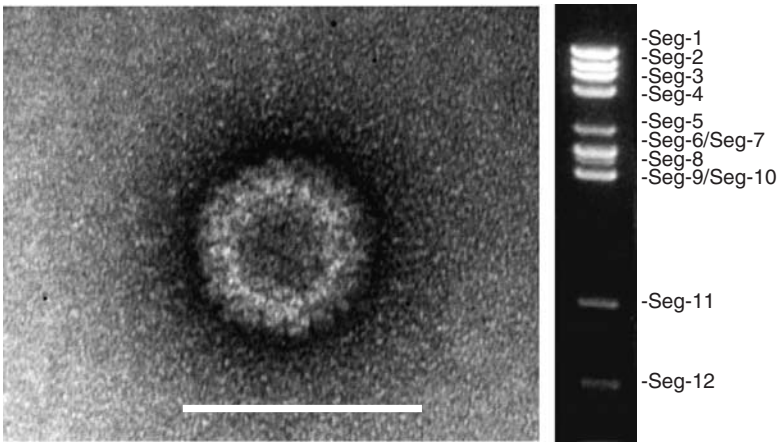

Figure 2 Electron microscopy and the genome of CTFV. (a) Negative contrast electron micrograph of the CTFV Florio strain. The bar represents 100 nm. (b) The agarose gel (1.2%) electopherotype of CTFV genome.

viral particles are non-enveloped, but a few acquire an envelope structure during passage through the endoplasmic reticulum. The buoyant density of CTFV in CsCl is 1.36–1.38 g cm^{-3}. The virus is stable between pH 7.0 and 8.0 and there is total loss of infectivity at pH 3.0. CTFV can be stored at 4 °C for 2–3 months in presence of 50% fetal calf serum in 0.2 M Tris– HC1 pH 7.8, or for years at –80 °C. Upon heating to 55 °C, CTFV rapidly loses infectivity. The virus is stable when treated with nonionic detergents (such as Tween 20) or with organic solvents such as Freon 113 or its ozone-friendly substitute Vertrel XF, but viral infectivity is abolished by treatment with sodium deoxycholate or sodium dodecyl sulfate.

The genome of coltivirus consists of 12 dsRNA segments that are named Seg-1 to Seg-12 in order of reducing molecular weight as observed by agarose and polyacrylamide gel electrophoresis. The genome comprises approximately 29 000 bp and the segment length ranges between 4350 bp and 675 bp. The genomic RNA of CTFV migrates as ten distinct bands during 1% agarose gel electrophoresis (AGE). Two of these bands contain co-migrating segments (**Figure 2**). The genome of the North American California hare coltivirus (CTFV-Ca) has shown a similar electropherotype by AGE. The dsRNA genome of EYAV has not been analyzed by AGE, since this virus is not cultivable. Sequence analysis has shown that the G+C content for coltiviruses ranges between 48% and 51%.

CTFV produces cytophatic effect (CPE) and plaque formation in many mammalian cells including KB (human carcinoma cells), BGM (monkey kidney cells), Vero (monkey kidney cells), BHK-21 (hamster kidney cells), and L-929 (mouse fibroblast). The virus has been found to replicate in a *Dermacentor variabilis* cell line with yields of $10^{6.5}$ pfu ml^{-1}. In cells infected by CTFV, granular matrices, which contain virus-like particles, are produced in the cytoplasm. These structures appear similar to viral inclusion bodies (VIBs) produced during orbivirus infections. In addition, bundles of filaments (tubules) characterized by cross-striations, and kinky threads, are found in the cytoplasm and, in some cases, in the nucleus of infected cells. These may also be comparable to the 'tubules' found in orbivirus infected cells. There is no evidence for virus release prior to cell death and disruption, after which more than 90% of virus particles remain cell-associated. Immunofluorescence has shown that viral proteins accumulate in the cytoplasm and can be detected from 12 h post infection.

The full-length genome sequence of Colorado tick fever virus has been characterized and found to be 29 210 nt long; that of Eyach virus was found to be 29 210 nt in length. In comparison to viruses classified in to other genera of the *Reoviridae,* the EYAV genome is the longest of all members sequenced (genomes range between 18 500 and 28 500 bp). All 12 segments of CTFV and EYAV have conserved sequences which are located at the termini. The conserved motifs 5′-$^{G}/_{C}$ACAUUUG-3′ and 5′-UGCAGU$^{G}/_{C}$-3′ have been found in the 5′ NCR and the 3′ NCR of CTFV, respectively, while in EYAV, these motifs are 5′-GACA$^{A}/_{U}$UU-3′ and 5′-UG$^{C}/_{U}$AGUC-3′. For both viruses, the 5′ and 3′ terminal tri-nucleotides of all segments are inverted complements.

The organization of the genome is well documented. Each genome segment contains a single ORF spanning almost the whole length of the segment (**Figure 3**), except genome segment 9 which has been found to contain a stop codon at position 1054 that is in-frame to a terminal stop codon at position 1846. The in-frame stop codon has been shown to belong to the category of so-called 'leaky stop codons' which allow a partial readthrough, generating two proteins. The first is the short form of the protein designated VP9 (ORF 41–1054) which is structural, and the second, which is the readthrough product designated VP9′ (ORF 41–1846), is nonstructural. The readthrough phenomenon (reading through a stop codon) is well characterized in some plant viruses, retroviruses, and aplhaviruses. None of the members of family *Reoviridae* had been known to use this translational regulatory feature until the identification of readthrough in genome segment 9 of coltiviruses (both CTFV and EYAV). VP9 is supposed to interfere with the action of eukaryotic peptide chain release factors (ERF1 and ERF3), thus facilitating readthrough of the stop codon and synthesis of VP9′.

Segment 6 of CTFV (encoding VP6) is homologous to segment 7 of EYAV (encoding VP7). The amino acid sequence (residues 370–490) of EYAV VP7 shows 50% similarity to the sarcolemmal-associated protein of the European rabbit *Oryctolagus cunniculus*, which is suspected to be its primary host. By comparison, the cognate protein VP6 of CTFV showed no match with this rabbit protein. This is probably due to the insertion of a sequence encoding a lagomorph protein into segment 7 of EYAV.

Antigenic and Genetic Relationship among Coltiviruses

Antigenic variation between CTFV strains has been investigated using immune sera, and antigenic heterogeneity has been observed, especially between strains recovered from humans. However, the variation is not enormous and durable immunity to reinfection appears to be the rule. CTFV from North America and EYAV from Europe show little cross-reaction in neutralization assays. CTFV-Ca cross-reacts with CTFV-Fl but not with EYAV and is considered to be a serotype of CTFV-Fl. Three antigenic variants of EYAV are recognized: EYAV-Gr, EYAV-Fr577, and EYAV-Fr578. RNA cross-hybridization analysis

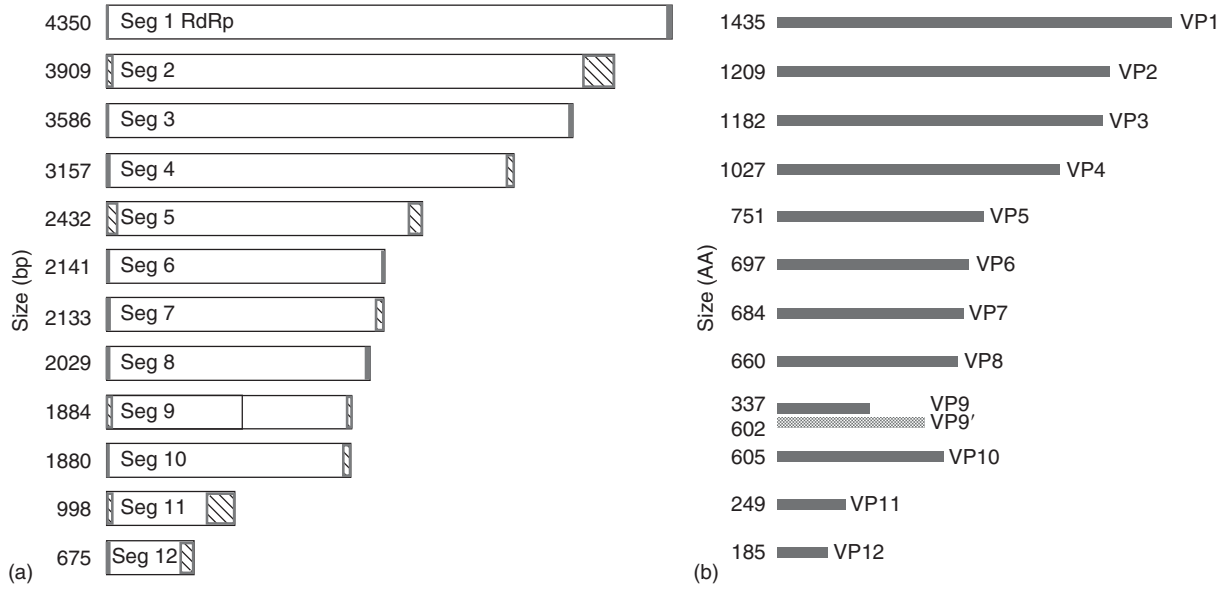

Figure 3 (a) Organization of the genome segments of CTFV and (b) their putative encoded proteins. Shaded areas in A: 5′ and 3′ NCRs. Segment 9 is interrupted by an in-frame stop codon (position 1054) which has been shown to be leaky allowing readthrough, and therefore generating two proteins: a truncated short form designated VP9 (a structural component) and a long readthrough form designated VP9′ (a nonstructural component).

shows that CTFV isolates have remained relatively homogenous (some variation has been reported based on cross-hybridization in genome segments 4 and 6, compared to the prototype strain CTFV-F1). This level of genetic divergence in CTFV is low compared to that found, for example, within the various species in the genus *Orbivirus*, suggesting that the CTFV is sheltered from immunological pressures causing genetic drift. The overall identities between nucleotide sequences of segments 9, 10, 11, and 12 of CTFV strains range between 90% and 100% : 97–100% (segment 9), 96–99% (segment 10), 90–94% (segment 11), and 94–96% (segment 12). The degree of identity between nucleotide sequences of segment 1–12 of CTFV and EYAV isolates ranges from 55% to 88%.

Within family *Reoviridae*, the most conserved gene between the various genera is that encoding the RNA-dependent RNA polymerase. Values lower than 30% amino acid sequence identity distinguish members of distinct genera. A tree constructed from an alignment of polymerase sequences from the various representative members of the *Reoviridae* (**Table 1**) is shown in **Figure 4**. Calculations of the amino acid sequence identity based on this alignment indicate that coltiviruses show only 15% identity with seadornaviruses, confirming the status of coltiviruses and seadornaviruses as members of distinct genera. Amino acid identities as high as 28% occur between coltiviruses and mycoreoviruses (reoviruses of fungi containing 11 or 12 genome segments).

Genome characterization has helped to shed more light on the origin of EYAV. Analysis of the most variable genes (segments 6, 7, and 12) indicates as high as 45% amino acid sequence divergence (37% nucleic acid divergence) as shown in **Figure 5**. Trees displayed in **Figure 5** show that it is possible to distinguish coltivirus species by sequence analysis of their variable genes (segment 6, 7, or 12). It has been proposed that EYAV was derived from CTFV following the introduction into Europe, in 1953 and 1972, of the North American cottontail rabbit *Sylvilagus floridanus* (following the myxoma disease that ravaged the European rabbit *Oryctolagus cuniculus*). EYAV may have then evolved from CTFV under the selective pressure of adaptation to the European rabbit, *Oryctolagus cuniculus,* and European ticks. It follows that the observed genetic divergence of 37% (in segments 6, 7, and 12) occurred over a very short period of time (less than 50 years). This implies a molecular evolutionary rate in the order of 0.5×10^{-2} mutations/nt/year.

Alternatively, it has been also proposed that EYAV might have been derived from an ancestral virus introduced into Europe with the migration of ancestral lagomorphs (hares, rabbits) from North America through Asia. Lagomorph ancestors first appeared during the Eocene epoch (57.8–36.6 MYA) in what was then North America. They are thought to have first migrated into Asia during the Oligocene epoch (34–23 MYA) and by the high Miocene epoch (23–5 MYA) they were common in Europe. This hypothesis implies a molecular evolutionary rate in the order of 10^{-8} to 10^{-9} mutations/nt/year, a rate similar to that of dsDNA genomes. Genetic findings support the second hypothesis.

Table 1 Sequences of RdRp used in phylogenetic analysis of various members of family *Reoviridae*

Species	*Isolate*	*Abbreviation*	*Accession number*
Genus *Seadornavirus* (12 segments)			
Banna virus	Ch	BAV-Ch	AF168005

Micromonas pusilla reovirus	MPRV	MPRV	DQ126102

The antigenic and genetic relation between CTFV and EYAV is further corroborated by morphological characteristics. Electron microscopic analysis has shown that EYAV and CTFV are morphologically identical.

Clinical Features and Diagnostic Assays

CTF is characterized in humans by the abrupt onset of fever, chills, headache, retro-orbital pains, photophobia, myalgia, and generalized malaise. Abdominal pain occurs in about 20% of patients. Rashes appear in less than 10% of patients. A diphasic, or even triphasic, febrile pattern has been observed, usually lasting for 5–10 days. Severe forms of the disease, involving infection of the central nervous system, or hemorrhagic fever, pericarditis and orchitis have been infrequently observed (mainly in children under 12 years of age). A small number of such cases are fatal. Severity is sufficient to result in hospitalization in about 20% of patients. Congenital infection with CTFV may occur, although the risk of abortion and congenital defects remains uncertain. It has been shown that there is

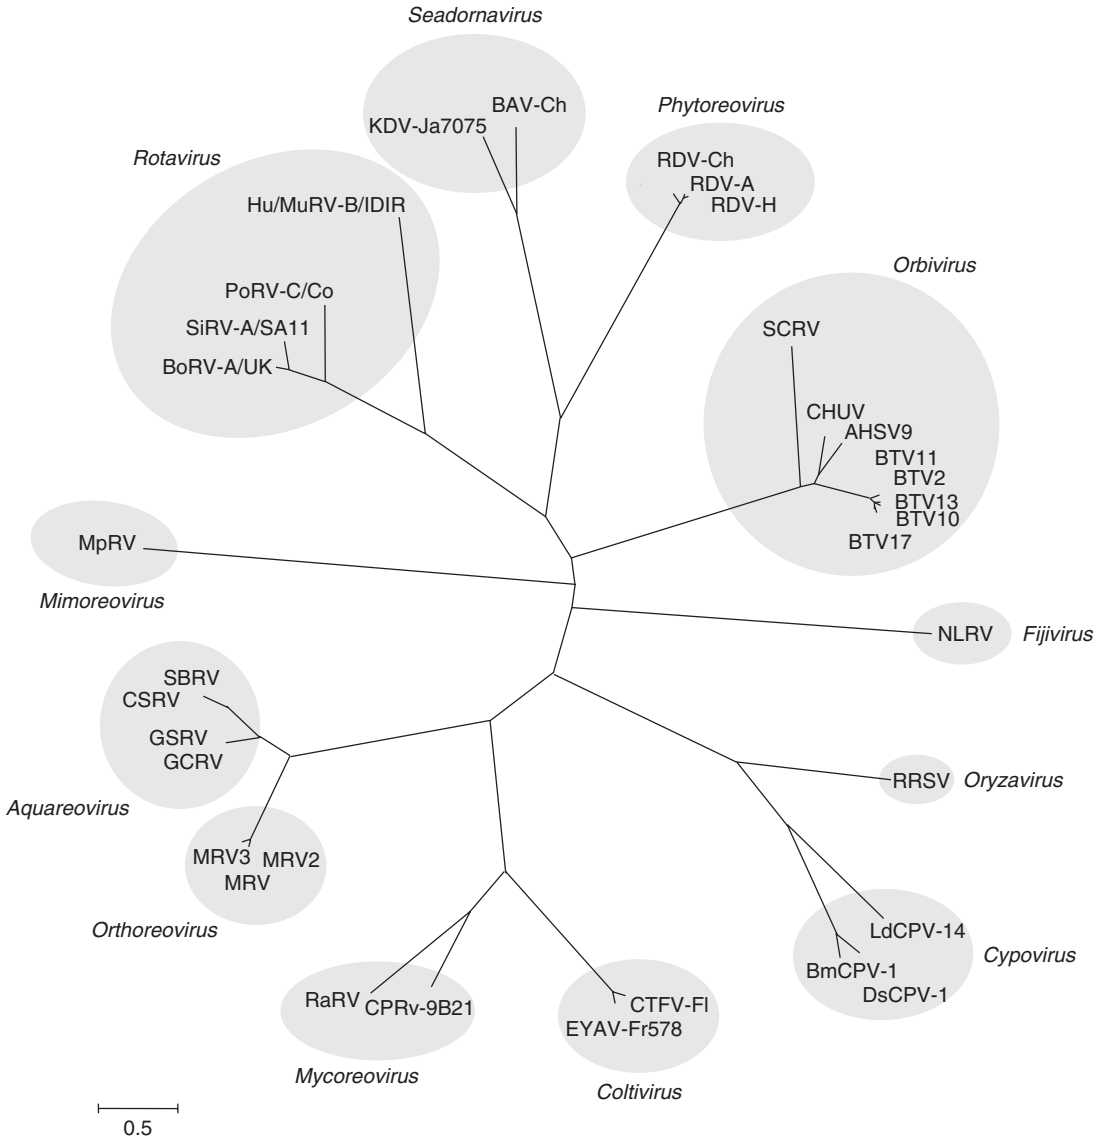

Figure 4 Phylogenetic relations among members of the *Reoviridae* based on the sequences of their putative RdRps. Neighbor-joining phylogenetic tree built with available polymerase sequences (using the Poisson correction or gamma distribution algorithms) for representative members of 12 genera of family *Reoviridae*. The abbreviations and accession numbers are those provided in **Table 1**.

an incidence of teratogenic effects in the offspring of mice experimentally infected with CTFV. Congenital mother to infant transmission has been reported in pregnant women. According to different reports, the incidence of complications has reached up to 7%. CTFV causes leucopoenia (65% of infected humans) with the mean leukocyte count reaching 900 to 3900 mm^{-3} and thrombocytopenia with platelet counts between 20 000 and 95 000. Patients with neurological disorders (meningitis, meningo-encephalitis, and encephalitis) have lymphocyte infiltration of cerebrospinal fluid (CSF) from which the virus has been isolated. Other complications such as pericarditis, myocarditis, and orchitis have been reported. The presence of CNS signs can confuse CTF with other causes of viral meningitis and encephalitis, including enteroviral infections, St. Louis encephalitis and Western equine encephalitis. CTFV infections have also been confused with other tick-borne infections such as Rocky Mountain spotted fever (RMSF: a rickettsial disease), tularemia, relapsing fever, and Lyme disease. Nevertheless, the character of the rash and the presence of leukocytosis distinguish RMSF from CTF.

The virus can be isolated from blood, since it is present in circulating erythrocytes for as long as 4 months after onset. This is because the virus infects hematopoetic progenitor cells and remains sheltered in erythrocytes after maturation. The presence of virus within erythrocytes can be demonstrated by immunofluorescence. Intracerebral

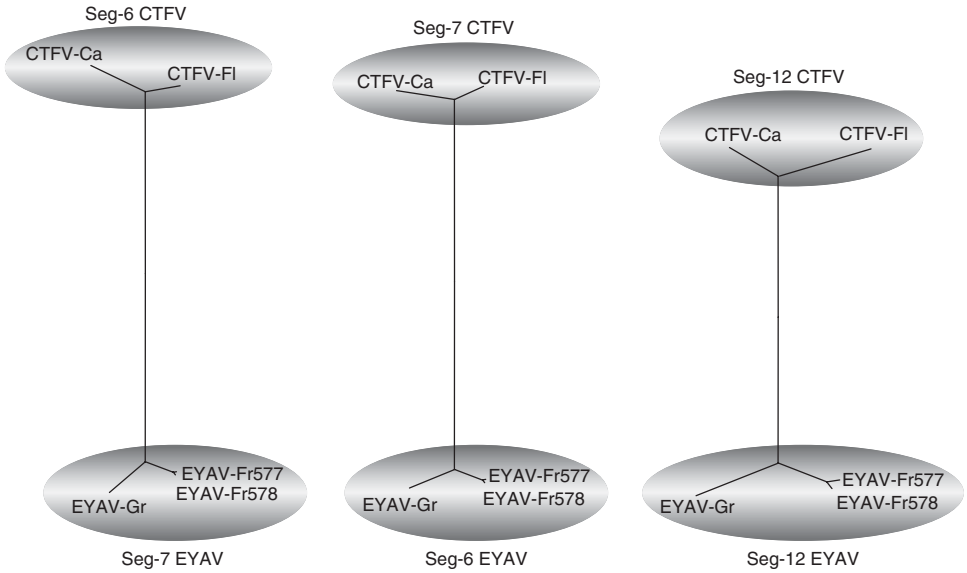

Figure 5 Phylogenetic trees for the most variable genome segments (segments 6, 7, and 12) of different coltiviruses. Unrooted neighbor-joining tree created using MEGA program from Clustal W alignments. The groupings for the deduced amino acid sequence of homologous genes of different coltiviruses. The two species CTFV and EYAV that are currently recognized are labeled. The tree branching is almost identical using the three segments 6, 7, and 12. The genetic distance between species is expressed in percent. These have been calculated for the amino acid sequence of segment 12 and are between species CTFV/EYAV (40%) among isolates of EYAV (<8%); among isolates of CTFV (< 8%).

inoculation of blood in suckling mice has been considered for years to be the most sensitive isolation system. Reverse transcriptase polymerase chain reaction (RT-PCR) has now been developed for the diagnosis of CTFV infection, which permits the detection of human and tick virus isolates as early as 3 days post infection in experimentally infected mice. As little as one genome copy can be detected using the PCR assay.

Serological methods, which utilize infected cell cultures as antigens, have also been developed. These include a complement fixation test, which is relatively insensitive since 25% of patients do not develop CF antibodies, and in 75% of patients CF antibodies appear late. Another test is the virus neutralization test. Neutralizing antibodies appear 14–21 days after onset. An immunofluorescence assay using CTFV-infected BHK-21 or Vero cells offers an easy and rapid means to detect anti-CTFV antibodies. IgM and IgG antibodies can also be detected by enzyme-linked immunosorbent assay (ELISA) and appear concurrently or a few days after neutralizing antibodies (peak at 30–40 days). IgM antibodies decline sharply after day 45. A Western blot assay, which detects antibodies in the acute phase of infection, has also been developed. An ELISA based on the recombinant VP7 of CTFV has been developed and proved efficient and sensitive in detecting various antibodies to CTFV.

A complement fixation assay has been developed for EYAV. In the former Czechoslovakia, a population of 158 patients suffering from encephalitis diagnosed as tick-borne encephalitis (TBE) was tested for TBEV (genus *Flavivirus*), Kemerovo, Lipovnik, or Tribec viruses (all three are tick borne orbiviruses) and EYAV antibodies. Seventeen sera (11%) were found to contain solely anti-EYAV antibodies. Forty-seven patients with polyradiculoneuritis and meningopolyneuritis were tested for the same viruses and eight (17%) were found to have solely anti-EYAV antibodies. Recently, an ELISA based on the recombinant VP6 of EYAV was developed for serological diagnosis of the infection. Antibodies from mice immunized with EYAV and CTFV were used as controls for the assay of the specificity and sensitivity. This test selectively identifies anti-EYAV antibodies. An RT-PCR assay has also been developed for the specific detection of EYAV genome, based on the sequence of genome segment 12.

Treatment, Immunity, and Prevention

There is no specific treatment for CTFV infection. Symptomatic treatment includes relief of fever and pain with paracetamol. Salicylates should be avoided because of thrombocytopenia and occurrence of bleeding disorders. An experimental vaccine (formalin-inactivated, purified CTFV) developed in the 1960s (stopped in l970s) has been used for people at high risk of exposure to infection, and produced long-lasting immunity. After three doses, neutralizing antibodies persist for 5 years. Acaricides or repellents such as permethrin, DEET (*N,N*-diethyl-meta-toluamide), and picaridin may be used to control ticks in rodent niches and as repelling agents to ticks.

Glossary

ASM Acid sphingomyelinase (EC 3.1.4.12), enzyme cleaving sphingomyelin to ceramide and phosphatidylcholine under low pH conditions.
ICAM-1 Intercellular adhesion molecule-1, belongs to the immunoglobulin superfamily.
IRES Internal ribosomal entry site; the sequence enables ribosomes to start translation within a mRNA.
ITAM Immunoreceptor-tyrosine based activation motif; enables proteins to bind to non-receptor tyrosine kinases.
NPDA Niemann–Pick disease type A; patients lack a functional ASM gene and suffer from a malfunctioning lipid storage due to the accumulation of sphingomyelin.
MBCD Methyl-β-cyclodextrin; drug depleting cholesterol out of membranes.

Introduction

Everyone knows the first signs of a common cold. Symptoms usually begin 2–3 days after infection and often include obstruction of nasal breathing, swelling of the sinus membranes, sneezing, cough, and headache. Although the symptoms are usually mild, this (probably the most common illness known to man) exhibits an enormous economic impact due to required medical attention or restriction of activity. According to estimations of the National Center for Health Statistics (NCHS), the common cold caused 157 million days of restricted activity and 15 million days lost from work in 1992. The progress of molecular biology in the twentieth century allowed the isolation and *in vitro* culture of rhinoviruses as well as their ultrastructural and molecular analysis. From the beginning of recorded history to our time people have been interested in how the common cold is spread. Famous ancient investigators, among them Hippocrates and Benjamin Franklin to name two, were the first to suggest inhalation of contaminated air as the origin of infection. This observation still holds its validity, but touching infectious respiratory secretions on skin and on environmental surfaces (desktops, doorknob, etc.) and subsequently touching the eyes or nose is now believed the most common mode of transmission. This article aims to summarize the knowledge about rhinoviral infections and discusses mechanisms of internalization, activation of host-cell receptor molecules, and details of possible therapeutic strategies.

Taxonomic Identification, Genome Organization, and Replication Cycle of Rhinoviruses

The establishment of cell and tissue culture techniques as well as nucleotide sequencing methods allowed for taxonomic classification of rhinoviruses. An overall RNA sequence compilation revealed a close genetic similarity to polio- and coxsackiviruses; hence, rhinoviruses were identified as members of the family *Picornaviridae*.

Genome Organization

The genomic organization is similar in all genera of *Picornaviridae* (**Figure 1**). The 5′ end of the RNA is joined to a small viral protein called VPg, which is a prerequisite for the synthesis of the negative RNA strand as a template for replication. The genomes of *aphtho-*, *erbo-*, *kobu-*, *tescho-*, *cardioviruses* (e.g., the foot and mouth disease virus) contain an additional gene (leader) at the 5′ end of the RNA. The 5′ end also contains the internal ribosomal entry site (IRES) sequence and allows binding to the ribosomal subunits of the host translational machinery. Following the IRES sequence is a single long open reading frame (ORF) encoding the structural (or capsid forming) proteins designated as the P1 precursor and nonstructural proteins (proteases and RNA-dependent RNA polymerase) designated as the P2/P3 precursors(s) (see **Figure 1**). The RNA genome is completed by the 3′ nontranslated region and a poly-A tail.

Translation of the Polyprotein, Processing, and Capsid Maturation

The protease $2A^{pro}$ coded by the P2 precursor was found to have multiple functions. It is required for the inital proteolytic separation of the P1 and P2/P3 precursors in the nascent rhinoviral polyprotein, but also inactivates the cellular *eLF-4F* complex, thereby inhibiting the translation of the cellular mRNA and initiating the virus host shutoff (VHS – the translational machinery of the host cell is producing viral proteins only). Further steps of the post-translational maturation are catalyzed by the protease $3C^{pro}/3CD^{pro}$ (see below). Products of the latter proteolytic activity are the VPg protein and the RNA polymerase. The capsid is composed of four proteins (viral proteins, VP1–VP4, see **Figure 1**), which arise from a single polyprotein generated from the viral RNA genome functioning as an mRNA. The very first cleavage occurs while translation is still in process. This first proteolytic maturation *in cis* is carried out by the protease $2A^{pro}$, which separates structural proteins from those necessary for the replication (designated as P1 and P2/P3, see **Figure 1**). A series of further cleavages form VP1, VP3, and VP0; the latter is finally processed to result in VP2 and VP4. Many picornaviruses undergo VP0 cleavage during virion maturation. Apparently, intact VP0 is necessary for correct assembly of the protomers, whereas processing of VP0 is necessary for the final maturation of the virion. Both viral proteases are targets for an inhibitor screen (see below).

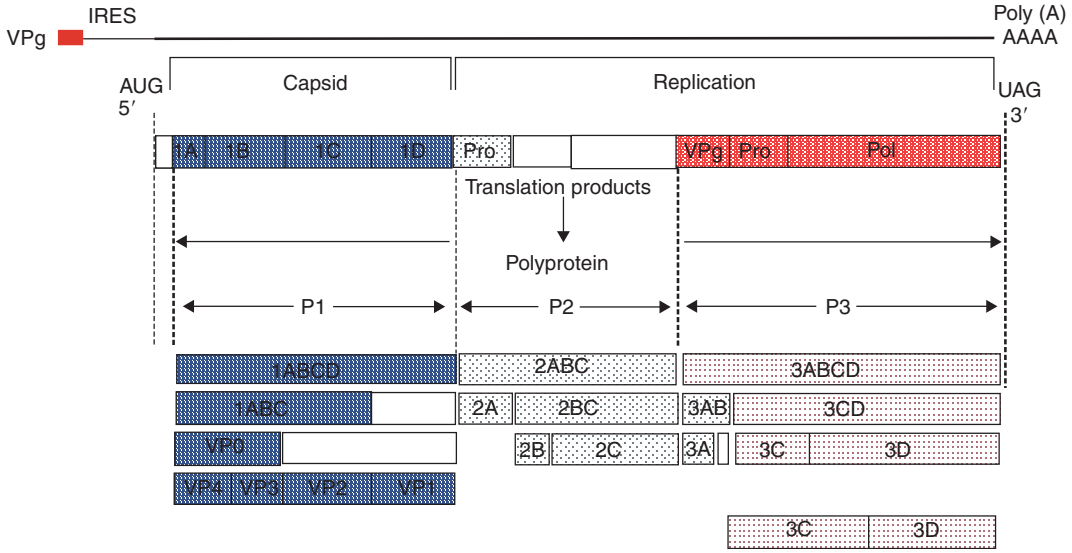

Figure 1 Schematic map of the rhinoviral genome and the encoded proteins. The rhinoviral genome consists of the 5′ IRES sequence (thin black line), followed by one open reading frame (bold black line) and the polyadenylation site. At the 5′ end the VPg protein is linked covalently to the RNA. Below, the regions representing the rhinoviral polyprotein are given. Compounds forming the capsid (structural proteins P1, blue boxes) and nonstructural proteins (P2–P3) such as proteases and the polymerase (light-blue dotted boxes and red dotted boxes, respectively) are translated into one polyprotein. The polyprotein becomes (auto-) proteolytically cleaved until the mature proteins are ready to form new viral particles.

Genome Replication

The following steps of rhinoviral reproduction probably do not differ from other members of the *Picornaviridae*. The RNA genome can be instantly translated; however, for replication of the genome a complementary (–) strand must be synthesized first. Essential for this step is a priming reaction, which is started by the VPg precursor 3AB. The hydrophobic portion of this protein is anchored in endomembranes and is linked to a poly-U tail. After formation of an RNA:RNA duplex at the 3′ end of the (+) strand, the polymerase synthesizes new (–) RNA strands. Only 5–10% of all rhinoviral RNAs are (–) strands. The synthesis of a complete genome takes 45 s to a minute, underlining that the reproduction cyle of picornaviruses in general and of rhinoviruses in particular is a fast process.

Synthesis of rhinoviral RNA in nasal washings could be detected 12 h post infection by quantitative reverse transcription-polymerase chain reaction (RT-PCR). The production of viral RNA and viral particles peaks within 48–72 h and declines thereafter.

Attachment and Entry

Studying any viral reproduction prompts the question of how viruses attach and invade cells. Therefore, the identification of cellular receptors binding to rhinoviruses was a landmark in examining how the infection cycle works. Intercellular adhesion molecule-1 (ICAM-1; CD54) was first detected as the receptor for major group rhinoviruses and later very low density lipoprotein (V)LDL as the receptor for minor group rhinoviruses (**Figure 2**). The receptors were isolated by using monoclonal antibodies directed against cellular surface proteins (see below). The receptors for the minor and major group rhinoviruses are structurally nonrelated, and the molecular reason why rhinoviruses as well as other members of the *Picornaviridae* (e.g., coxsackieviruses) use different receptors is not well understood. One strain (CAV-A21) of the rhinovirus-related family of coxsackieviruses needs to engage both ICAM-1 and decay-accelerating factor (DAF; CD55), whereas other coxsackieviruses require DAF or integrins for binding. HRV binding to ICAM-1 allows a conformational change of the rhinoviral capsid and is a prerequisite for the uncoating of viral RNA. Although binding to (V)LDL receptors is also important for the internalization, the acidification of the endosome seems to be indispensable for proper entry, in particular for minor group rhinoviruses. (V)LDL receptors are well-described molecules, and the uptake of their natural ligands via clathrin-coated vesicles suggested that minor group rhinoviruses enter the host cell via the same pathway. Microscopical studies have detailed the uptake of the minor group rhinovirus HRV2. This viral serotype was shown

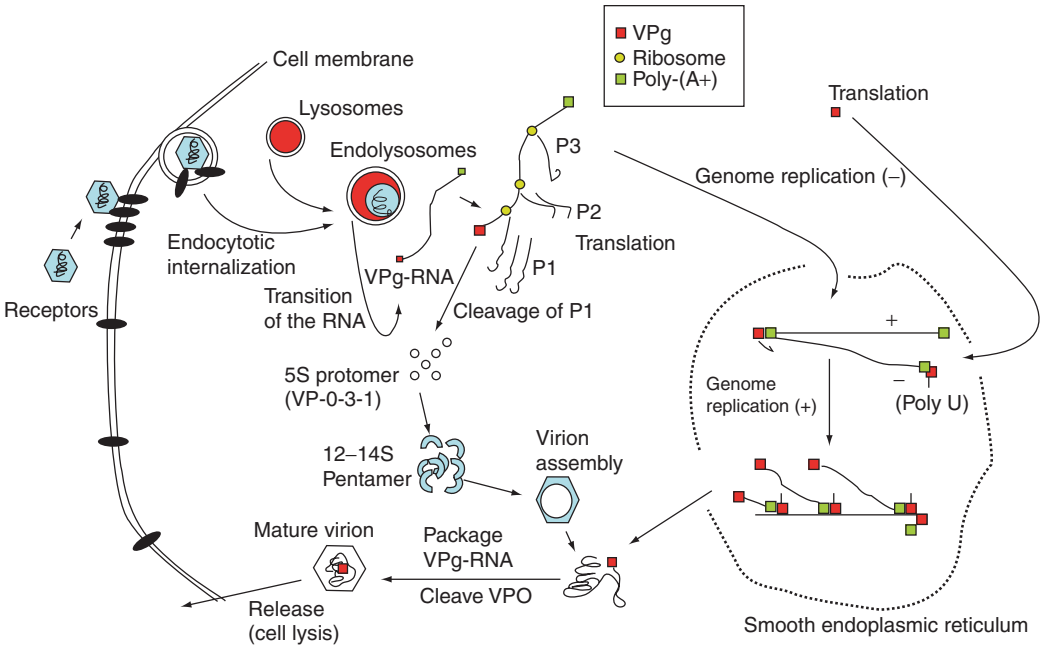

Figure 2 Infection cycle of rhinoviruses. The scheme summarizes the rhinoviral infection cycle from the attachment of the capsid to the release of newly synthesized capsids. Shown are the internalization of the capsids via endocytosis, the transport to the endolysosmal compartment, transition of the RNA to the cytoplasm, synthesis of viral RNA within the smooth endoplasmic reticulum, maturation of the capsid proteins, and self-assembly.

to cluster to membrane domains positive for clathrin, supporting the notion of an uptake mechanism depending on clathrin-coated vesicles. In line with this finding is the blockade of HRV2 uptake by overexpression of dynamin-K44, a transdominant negative isoform of dynamin, which is required for pinching off clathrin-coated vesicles from the plasma membrane. Uptake of rhinoviruses via clathrin-coated vesicles is very fast and does not take longer than 30 min. Moreover, preincubation with methyl-β-cyclodextrin (MBCD) interrupts the uptake of HRV2 at an early stage. Rhinoviral capsids pile up close to the plasma membrane and are not transported to the endolysosomal compartment in cells treated with MBCD. MBCD depletes cholesterol from cellular membranes and leads to destabilization of membrane domains which are thought to play a central role in signal transduction and endocytosis. Recent work indicates that another subgroup of membrane domains termed ceramide-enriched membrane platforms plays a crucial role in the infection cycle of rhinoviruses. These studies demonstrate that pharmacological or genetic inhibition of ceramide-enriched platforms reduces rhinoviral titers in epithelial cells. Membrane domains may not only be involved in the first steps of internalization, but also play a role in transport of vesicles and fusion of transport vesicles, endosomes, and endolysosomal vesicles, finally triggering acidification of the vesicle which is required for uncoating of rhinoviruses and transition of the RNA to the cytoplasm (see below).

Virion/Particle Structure and Phylogenetic Considerations

Human rhinoviruses (HRVs) represent the serologically most diverse group of picornaviruses (over 100 serotypes have already been identified). The reason for this diversity is not known.

The Canyon Hypothesis

Ultrastructural analysis of rhinoviruses by X-ray crystallography resulted in a structural model of rhinoviruses (**Figure 3**). Along the fivefold icosahedral axis of the virion a 2.5 nm depression, the so-called 'canyon', was detected. The genomic region encoding the peptide residues that form this structure is more conserved than regions encoding any other structure on the virion surface. Studies using mutated viral strains showed that point mutations in the genomic region covering the capsid protein VP1 changed the affinity of radiolabeled mutant viruses to purified host cell membranes (**Figure 4** and **Table 1**). Alterations of amino acids at position 103 (Lys),

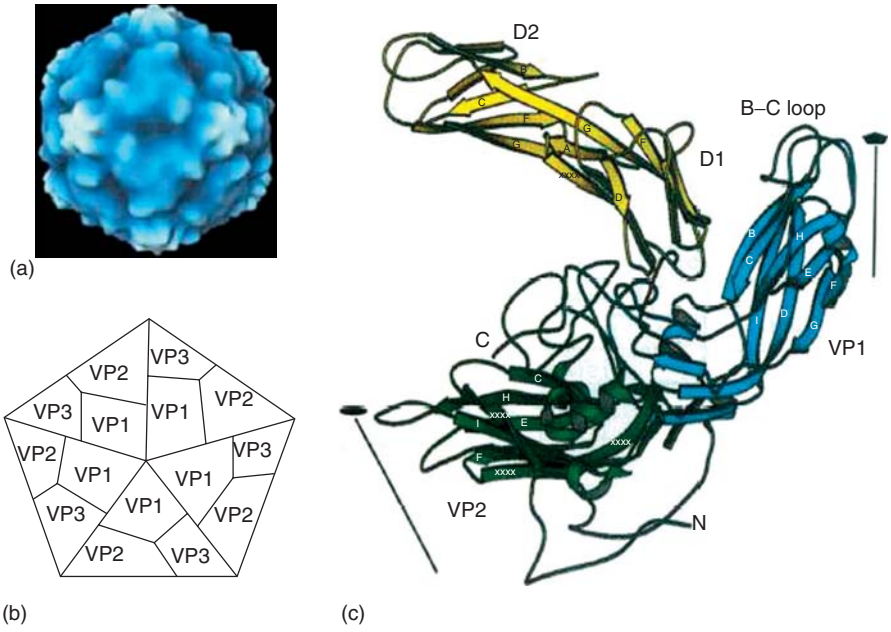

Figure 3 Structural model of rhinoviruses and receptor interaction. (a) The structural model of rhinoviruses was evaluated from cryo-electron microscopic data, the schematic drawing (b) represents the position of the capsid proteins VP1–VP3 in the rhinoviral capsid. (c) Schematic drawing of the viral canyon structure (represented by the capsid compounds VP1 and VP2 given in blue and green, respectively) and the D1 and D2 domains of the receptor ICAM-1. The antiparallel β-strand structures of VP1, VP2, and ICAM-1 are listed in alphabetical order.

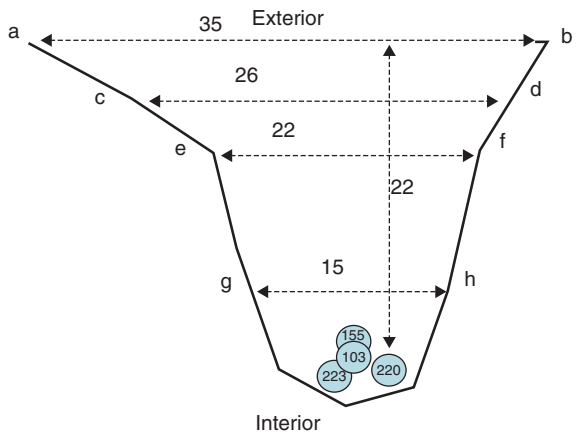

Figure 4 Mutations in the rhinoviral protein VP1 interfere with attachment and growth. The figure displays a scheme of the HRV-14 canyon. Distances are shown in angstrom and circled numbers represent the four amino acids targeted in the studies. Coordinate points used in determining distances are as follows: a, O^{81} of Asp-91; b, O^{e2} of Glu-210; c, O^{81} Asn–92; d, O Glu–210; e, O^{e2} Glu-95; f, N^{e2} Gln–212; g, O^{11} Asp–101; h, C^{81} Ile–215. Modified from Colonno RJ, Condra JH, Mizutani S, Callahan PL, Davies ME, and Murcko MA (1988) Evidence for the direct involvement of the rhinovirus canyon in receptor binding. *Proceedings of the National Academy of Sciences, USA* 85(15): 5449–5453.

Table 1 Mutations in the rhinoviral protein VP1 interfere with attachment and growth

Position of wt amino acids	*Substitutions*	*Virus yield (pfu/cell)*
103 Lys	—	160
	Ile	84
	Arg	54
	Asn	140
155 Pro	—	160
	Gly	1
220 His	—	160
	Ile	10
	Trp	14
223 Ser	—	160
	Ala	8
	Thr	70
	Asn	88

155 (Pro), 220 (His), or 223 (Ser), had the strongest effect regarding the binding affinity of rhinoviral capsids. The structural analysis revealed a juxtaposition of these amino acids at the 'bottom of the canyon'. It is noteworthy that most of the substitutions reduced the binding of capsids to host cell membranes; however, the biochemical property of one amino acid (Pro 155) is of special importance because a change to glycine led to a higher binding affinity and an enhanced yield of mutated virus. Most publications concerning rhinoviral structure described members of the major group rhinoviruses, while only few publications dealt with the structure of minor group rhinoviruses. It was possible to define structural differences between HRV2 (representing minor group rhinoviruses) and HRV14 (representing major group viruses) by analyzing a special subportion of the 'canyon', the 'pocket' region within the VP1 protein. This region binds in particular to hydrophobic compounds – for example, fatty acids supplemented by membranes of the host cell. The interaction of the virus with the fatty acid seems to stabilize the virus during its spread from cell to cell, but it must be removed prior to the uncoating process. For major group viruses the fatty acid is displaced by ICAM-1. The minor group viruses exhibit a higher affinity for the fatty acids and binding of LDL-R is insufficient to expel the fatty acid in the 'pocket' of VP1. The conformational change of the viral capsid is obligatory for the transition of the viral RNA into the cytoplasm. Acidification of the endolysosomal compartment transfers the native virus to a so-called C-antigenic subviral particle in which VP1 forms a channel with a diameter around 10 A – large enough for the RNA to escape. Concomitantly, the N-terminus of VP1 and the entire VP4 are extruded and interact with the endolysosomal membrane. Studies with rhinovirus-related poliovirus identified a 3 kDa peptide from the N-terminus of VP1 capable of integrating into artificial liposomes.

Rhinoviral Antigenicity

Antibodies that neutralize rhinoviruses *in vitro* and *in vivo* permitted the identification of the epitopes in the viral capsid critically important for binding to the receptors and/or release of the RNA into the cytoplasm. Antigenicity in HRVs has been extensively studied in serotypes HRV2 and HRV14. In HRV14 four antigenic sites were identified, designated NIm-IA, NIm-IB, NIm-II, and NIm-III. The sites could be accurately located at the external surface of the virus. In HRV2 three antigenic sites, called A, B, and C could also be mapped. Antigenic site A is located within the B–C loop of VP1 that flanks the rim of the canyon structure, thus, corresponding to the NIm-IA, NIm-IB site of HRV14. Site B encompasses residues from VP1, VP2, and VP3. VP2 residues of site B comprise a continuous epitope that is equivalent to the NIm-II site of HRV14 and mainly defined by the VP2 loop between the β-barrel strands E and F. Antigenic site C includes two amino acids of VP2 which do not correspond to any of the immunogenic sites of major group rhinoviruses.

Phylogenetic Considerations

In addition to the classification based on serotyping, rhinoviruses can be grouped in different ways, on the basis of shared structural and biological properties (e.g., receptor

specificity), sensitivity to antiviral agents or at least genetic similarity. The phylogenetic analysis of the genomic VP4/VP2 interval of 97 different rhinoviral serotypes resulted in two phylogenetic clades, A and B. Surprisingly, some of the 76 serotypes of class A were identified as minor group rhinoviruses such as HRV 1A, 2, etc., whereas class B consists of 25 serotypes, among them major group HRV 14. According to the phylogenetic analysis, two rhinoviral serotypes (HRV 23 and HRV25) which bind to ICAM-1 (major group) constitute an 'intermediate' class between A and B, respectively. Further studies showed that soluble ICAM-1 could not compete with viral binding to cellular ICAM-1. Furthermore, the phylogenetic analysis identified one serotype, namely HRV 87, as closely related to another *Picornaviridae* genus the enteroviruses, namely enterovirus 70. HRV87 does not bind to either ICAM-1 or (V)LDL receptors, but to sialoproteins, which also bind enterovirus 70. Although HRV 87 is acid-labile like all other rhinovirus serotypes, it appears to belong to the enterovirus species D. In general, the analysis shows a greater phylogenetic heterogeneity for minor group rhinoviruses than for major group rhinoviruses, which may indicate that minor group serotypes evolved more recently.

Rhinovirus Infection Models

Rhinoviruses show an almost strict specificity for human cells. Most studies, therefore, have to be carried out in human volunteers or, alternatively, in primates, which necessitates special requirements regarding biosafety of the rhinoviral stock preparations, and raises ethical questions. Some publications reported that host restriction could be overcome by using a method to select rhinovirus strains which are able to infect murine cells. Another possible technique to overcome the host range problem is by expression of human/murine chimeric rhinoviral receptors. Engineered ICAM-1 molecules, stably expressed in murine cell lines, bind rhinoviruses and permit the uptake in murine respiratory cells and L-cells. The latter study underlined that mutations in noncapsid proteins (genomic region P2) are necessary to adapt viral proteins to the new host cell and finally allow an appropriate replication in murine cells. Other researchers developed human ICAM-1 transgenic mice that were recently used in infection studies with coxsackiviruses, and might also be utilized to study rhinoviral infections. Interestingly, a common finding of the field is noteworthy: receptors such as ICAM-1, VCAM-1, and also the (V) LDL play a predominant role in rhinovirus binding, uptake, and associated signal transduction processes. However, these data were determined from infection experiments employing poorly differentiated epithelial cells in culture. In contrast, these molecules are only infrequently expressed *in vivo* on the apical surface, leading to the question of how viruses access these receptors *in vivo*. In addition, the issue whether epithelial cell layers are the primary targets of rhinoviruses remains to be determined, since infections do not result in cytopathic effects in the ciliated epithelial cells as shown for many other respiratory viruses. Many studies focused primarily on the detection of rhinovirus RNA in rhinopharyngeal tissues by means of RT-PCR or *in situ* hybridization showed that cells and tissues (e.g., the germinal layer in the adenoid tissue below the epithelial layer) are positive for rhinoviral RNA. Rhinoviruses can be cultured in WI-38 fibroblasts suggesting that fibroblasts in the rhinopharyngeal tissue can be targets for rhinoviral infection. It is also possible that rhinoviruses attach to and invade the epithelial layer by a mechanism different from that observed in cultured epithelial cells, that is, binding to ICAM-1 and (V)LDL receptors. Further studies are required to address these questions.

Host Cell Reactions upon Rhinoviral Infections – The Molecular Origin of Symptoms

Infection of the upper respiratory tract by HRV16 has been demonstrated to occur at localized portions of the epithelia and does not cause widespread lysis of the infected epithelia. This observation has suggested that the pathology induced by rhinovirus may be due in part to cytokine dysregulation rather than extensive epithelial necrosis observed in other viral infections.

HRV, as well as other respiratory pathogens, have been shown to induce production of many cytokines and chemokines, among them IL-4, IL-6, IL-8, and granulocyte macrophage colony stimulating factor (GMCSF), to name the most frequently published. The induction of chemokines triggers the inflammatory response, which is considered to enhance exacerbations like asthma and chronic obstructive pulmonary disease (COPD). A common feature of asthma and COPD exacerbations is a high level of IL-8 and an increased number of neutrophils in the sputum and nasal secretions of patients suffering an HRV infection.

Little is known, however, about the primary signaling pathways initiated by the rhinoviral infection cycle. Because signal transduction pathways of the LDL receptor family are difficult to understand, the experimental design concentrated on ICAM-1, the receptor for major group rhinoviruses. ICAM-1-inhibiting antibodies abrogated IL-8 production, but infection with UV-inactivated rhinovirus failed to do so, indicating that binding and entry events induced the chemokine response rather than causing effects resulting from viral replication.

HRV ligation to ICAM-1 provokes recruitment of the tyrosine kinase syk to membrane domains in human airway epithelial cells. The tyrosine kinase syk belongs to the family of src receptor tyrosine kinases. The immunoreceptor tyrosine-based activation motif (ITAM) of syk recruits another protein, ezrin, and the syk–ezrin complex finally binds to ICAM-1. Autophosphorylation of syk activates the MAP-kinase p38-K in a biphasic manner, that is, after 1 h and 8–12 h after infection with major group rhinovirus HRV14. This finding is especially interesting because the induction of chemokines is temporally correlating with the second p38-K activation peak. The PI-3 kinase is related to the family of MAP kinases. Again, subsequent studies concentrated on very early phases (5–60 min post infection) of rhinoviral infection. Active PI-3 kinase could be precipitated from lysates of infected cells and isolated plasma membranes showed the presence of metabolic products (i.e., PI (3,4,5)P_3) of the PI-3 kinase. The same studies identified Akt and nuclear factor kappa B (NF-κB) as downstream targets of PI-3 kinase and thus completing this signal transduction pathway showed the binding of NF-κB to the IL-8 promoters.

Interestingly, the activation of PI-3 kinase is functionally connected to the HRV entry. Inhibition of PI-3 kinase by application of the drug Wortmannin reduced the uptake of radiolabeled HRV, due to the retention of HRV2 in endosomal compartments, which results in a reduced transition of the RNA and, therefore, a reduced viral titer.

Inflammatory reactions require effector cells such as macrophages and monocytes. A recent publication addressed the question if the production of chemokines is restricted to the nasal epithelial tissues or if chemokines are synthesized and secreted by lymphocytes. Therefore, alveolar macrophages and monocytes were infected with rhinovirus. After infection with HRV16 the production of the macrophage attractive protein-1 (MCP-1) was shown to be increased in monocytes and macrophages. Surprisingly, HRV16 induces the same signal transduction pathways in lymphocytes as in epithelial cells. Again, the p38-K is activated and engages the nuclear factor ATF-2 involving NF-κB. The signal transduction could be attenuated by preincubation of the lymphocytes with ICAM-1, suggesting that HRV can bind to and enter lymphocytes. However, propagation of rhinoviruses in lymphocytes was not an aim of this study. Finally, these results present the novel idea that cell types other than epithelial cells contribute to viral exacerbations of asthma as well as causing the symptoms of the common cold.

Antirhinoviral Strategies

Although the common cold is usually mild, with symptoms lasting a week or less, it is a leading cause of physician visits and of school/job absence in addition to several more severe exacerbations like asthma (see above). Initial studies that employed monoclonal antibodies to define candidates of viral receptors demonstrated a surprising 'immunological resistance' of rhinoviruses. On the one hand this is due to the fact that over 100 different rhinoviral serotypes have been isolated and antibodies raised against one serotype after immunization are not necessarily protective against a different serotype. However, the identification of the so-called 'canyon' allowed an additional explanation: if this 'canyon' represents the predominant site of receptor interactions, it is difficult to block with antibodies since the canyon is too narrow to enable interactions with the antigen. Both findings seem to rule out vaccination as a standard antirhinoviral treatment. Hence, the canyon structure dominated the development of therapeutic strategies (**Table 2**). Researchers were able to

Table 2 Substances interfering with the rhinoviral propagation

Tested compound	*Functions in or interferes with*
WIN factors	Interaction with the canyon structure, viral adhesion is suppressed
AG 7088	Blocks protease 3 C irreversibly and stops capsid maturation
Soluble ICAM-1	Competition with ICAM-1
Cytochalasin B	Interference with microfilaments and inhibition of vesicle maturation
Bafilomycin	Blocking endosomal acidification
Erythromycin	Reduction of ICAM-1 receptor, blocking endosomal acidification
Impramine	Blocking ASM and inhibiting ceramide-enriched platforms
Desipramine	Blocking ASM and inhibiting ceramide-enriched platforms
Nocodazole	Interference with macrofilaments and inhibiting vesicle maturation
zVAD	Antiapoptotic agent blocking caspases and release of new viruses
Wortmannin	PI-3-kinase inhibitor, blocks vesicle maturation
MBCD	Depletes cholesterol, destroys functional membrane domains, transport of virus is blocked

design chemical structures designated as 'pocket factors', interacting with amino acid residues in the canyon. Because of their chemical similarity to the primarily described drug WIN51711, an isoxazole derivative, such chemicals are generally termed WIN compounds. WIN compounds seem to function both as competitors for binding to the receptor and in a steric blockage interfering with the conformational change of the capsid necessary for the release of the genomic RNA. While WIN compounds have a significant effect in reducing the viral titer *in vitro*, the *in vivo* application was difficult. Structurally related substances like flavinoids, for example 4–6 Dichlorflavane, exhibited a better feasibility regarding application, but caused only little reduction of rhinovirus titers. The chemokines interferon-α/β are produced after viral infection. Host cells detect the presence of double-stranded RNA via activation of the toll-like receptor 3 (TLR-3), and the main function of interferons is to induce IFN-stimulated genes, which attenuate viral replication. Some groups tested the application of interferons and interferon-inducers, respectively, and their interference with rhinoviral replication and production. Although high doses of interferons applied intranasally exhibited a prophylactic effect, these high doses of interferons required for the protective effect caused local erosions and nasal stuffiness.

Therefore, the interest shifted to alternative methods to attenuate or even to block rhinoviral infections and their symptoms. Even though vaccination seemed to be impossible (as pointed out before), some studies dealt with the question of how the human immune system responds to a rhinoviral infection. Rhinovirus inoculation induced both IgG and IgA presence in the serum and the airway, respectively, which neutralized the identical serotype upon reinfection. In studies using several different rhinovirus serotypes the generation of cross-reacting antibodies could be observed. Individuals with preexisting cross-reacting antibodies or cross-reacting antibodies derived from rabbits exhibited a partial immunity when challenged with any new rhinovirus serotype. However, a complete immunity is barely to be expected, because many studies showed that antirhinovirus-protecting IgA titers decreased already 2 months after infection. Nevertheless, a vaccination could attenuate the exacerbations of the infection, that is, reduce asthma and COPD.

Recent work indicates that lipid domains in the plasma membrane of infected cells are functional in signal transduction events caused by rhinoviral infections. Moreover, the lipid composition could influence the interaction of viral proteins with vesicular membranes during the transition of the RNA and replication. For example, rhinovirus uptake is sensitive to treatment with MBCD and blocks p38-K signaling, thus interrupting the release of chemokines and attenuate symptoms. The acid sphingomyelinase (ASM), which was shown to be crucial for generation of ceramide-enriched platforms, a subentity of lipid domains, might be an additional target to prevent HRV infections. Fibroblasts isolated from NPDA patients (Niemann-Pick disease type 1) lacking functional ASM were shown to be resistant to HRV infections. The ASM can be inactivated pharmaceutically by tricyclic antidepressants such as amitryptiline and imipramine. Studies in which the ASM was inhibited by these substances showed a dramatic decrease of viral reproduction, suggesting that the ASM is critically involved in the propagation of rhinoviruses in human cells. Drugs derived from the structure of tricyclic antidepressants might therefore be effective against rhinovirus infections.

Aside from antiviral drugs targeting the attachment and entry processes, antirhinovirus therapy could benefit from the identification of chemicals inhibiting viral maturation. As pointed out earlier, activation of protease 3C is a crucial step in the assembly of the capsid. Tripeptidyl alpha-ketoamides were identified as human rhinovirus protease 3C inhibitors. The protease 3C-inhibiting drug AG7088 (*ruprintivir*) showed a 100-fold reduction of rhinoviral titers and abrogated inflammatory responses as well. Clinical trials indicated that AG7088 could be administered to volunteers without adverse reactions. Subsequent studies are in progress, aiming at another rhinoviral protease (i.e., 2A) as a target for antirhinoviral therapy.

Glossary

Infectious clone A full-length DNA copy of an RNA virus genome from which full-length viral RNA can be generated, leading to production of infectious virus.
Nidovirales (nidoviruses) An order comprising positive-sense RNA coronaviruses, toroviruses, arteriviruses, and roniviruses that have a common genome organization and expression, similar replication/transcription strategies, and form a nested set of 3′ co-terminal subgenomic mRNAs (*nidus*, Latin for nest).
Ribosomal frameshifting Movement (shift) backward by one nucleotide of a ribosome that is on an RNA, caused by particular RNA structures and sequences. Subsequent continuation of the progress of the ribosome is in a different open reading frame.

Introduction

Coronaviruses are known to cause disease in humans, other mammals, and birds. They cause major economic loss, sometimes associated with high mortality, in neonates of some domestic species (e.g., chickens, pigs). In humans, they are responsible for respiratory and enteric diseases. Coronaviruses do not necessarily observe species barriers, as illustrated most graphically by the spread of severe acute respiratory syndrome (SARS) coronavirus among wild animals and to man, with lethal consequences. As a group, coronaviruses are not limited to particular organs; target tissues include the nervous system, immune system, kidney, and reproductive tract in addition to many parts of the respiratory and enteric systems. A great advance in recent years has been the development of systems ('infectious clones') for modifying the genomes of coronaviruses to study all aspects of coronavirus replication, and for the development of new vaccines.

Taxonomy and Classification

The genus *Coronavirus* together with the genus *Torovirus* form the family *Coronaviridae*; members of these two genera are similar morphologically. The *Coronaviridae*, *Arteriviridae*, and *Roniviridae* are within the order *Nidovirales*. Members of this order have a similar genome organization and produce a nested set of subgenomic mRNAs (*nidus*, Latin for nest). To date, coronaviruses have been placed into one of three groups (**Table 1**). Initially, this was on the basis of serological relationships which subsequently have been supported by gene sequencing.

Virion Properties

Virions have a buoyant density of approximately 1.18 g ml^{-1} in sucrose. Being enveloped viruses (**Figure 1**(**a**)), they are destroyed by organic solvents such as ether and chloroform.

Virion Structure and Composition

All coronaviruses have four structural proteins in common (**Figure 1**(**b**)): a large surface glycoprotein (S; *c.* 1150–1450 amino acids); a small envelope protein (E; *c.* 100 amino acids, present in very small amounts in virions); integral membrane glycoprotein (M; *c.* 250 amino acids); and a phosphorylated nucleocapsid protein (N; *c.* 500 amino acids). Group 2a viruses have an additional structural glycoprotein, the hemagglutinin-esterase protein (HE; *c.* 425 amino acids). This is not essential for replication *in vitro* and may affect tropism *in vivo*.

Virions are *c.* 120 nm in diameter, although they can be up to twice that size, and the ring of S protein spikes is approximately 20 nm deep. When present, the HE protein forms a layer 5–10 nm deep. In some species, the S protein is cleaved into two subunits, the N-terminal S1 fragment being slightly smaller than the C-terminal S2 sequence. The S protein is anchored in the envelope by a transmembrane region near the C-terminus of S2. The functional S protein is highly glycosylated and exists as a trimer. The bulbous outer part of the mature S protein is formed largely by S1 while the stalk is formed largely by S2, having a coiled-coil structure. S1 is the most variable part of the S protein; some serotypes of IBV differ from one another by 40% of S1 amino acids. S1 is the major inducer of protective immune responses. Variation in the S1 protein enables one strain of virus to avoid immunity induced by another strain of the same species.

The M glycoprotein is the most abundant protein in virions. In most cases, only a small part (~20 amino acids) at the N-terminus protrudes at the surface of the virus. There are three membrane-spanning segments and the C-terminal half of the M protein is within the lumen of

Table 1 Species of coronavirus[a]

Group 1	*Group 2*	*Group 3*

[a]Recognized virus species.
[b]The viruses duck coronavirus, goose coronavirus, and pigeon coronavirus have been recommended by the Coronavirus Study Group for recognition as species by the ICTV.
Official virus species names are in italics. Coronaviruses that have not yet been recognized as distinct species have names that are not italicized. Rabbit coronavirus is considered as a tentative member of the genus. A coronavirus has been isolated from a parrot. On the basis of very limited sequence data, it is not clear in which, if any, of the three groups that this virus would be placed.

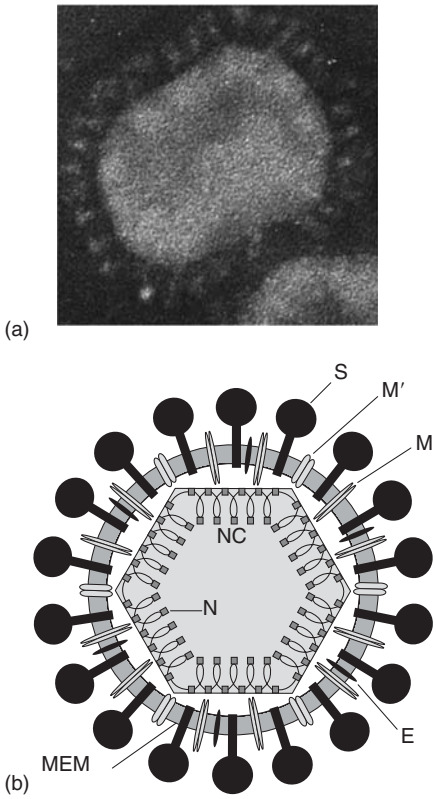

Figure 1 (a) Electron micrograph of an IBV virion, showing the bulbous S protein. (b) Diagrammatic representation of the composition and structure of a coronavirus virion: S, spike glycoprotein; M, M′, integral membrane glycoprotein; E, small envelope protein; N, nucleocapsid protein; NC, nucleocapsid (nucleoprotein) comprising the RNA genome and N protein. Cryoelectron microscopy of TGEV has indicated a core structure comprising the NC and the M protein. Two forms of M protein (M, M′) have been observed for TGEV (see main text). The coronavirus membrane proteins, S, E, M, and M′, are inserted into a lipid bilayer (MEM) derived from internal cell membranes. (b) Reproduced from González JM, Gomez-Puertas P, Cavanagh D, Gorbalenya AE, and Enjuanes L (2003) A comparative sequence analysis to revise the current taxonomy of the family *Coronaviridae*. *Archives of Virology* 148: 2207–2235, with permission from Springer-Verlag.

the virus. In transmissible gastroenteritis virus (TGEV), a proportion of M molecules have four membrane-spanning segments, resulting in the C-terminus also being exposed on the outer surface of the virus (M′ in **Figure 1**(**b**)). The E protein is anchored in the membrane by a sequence near its N-terminus.

Genome Organization and Expression

Coronaviruses have the largest known RNA genomes, which comprise 28–32 kb of positive sense, single-stranded RNA. The overall genome organization is being 5′ UTR–polymerase gene–structural protein genes–3′ UTR, where the UTRs are untranslated regions (**Figure 2**). The first 60–90 nucleotides at the 5′ end form a leader sequence. The structural protein genes are in the same order in all coronaviruses: (HE)–S–E–M–N. Interspersed among these genes are one or more gene (depending on the species; SARS-CoV has four) that encode small proteins of unknown function. Some of these genes encode two or three proteins. In some cases (e.g., gene 3 of IBV and gene

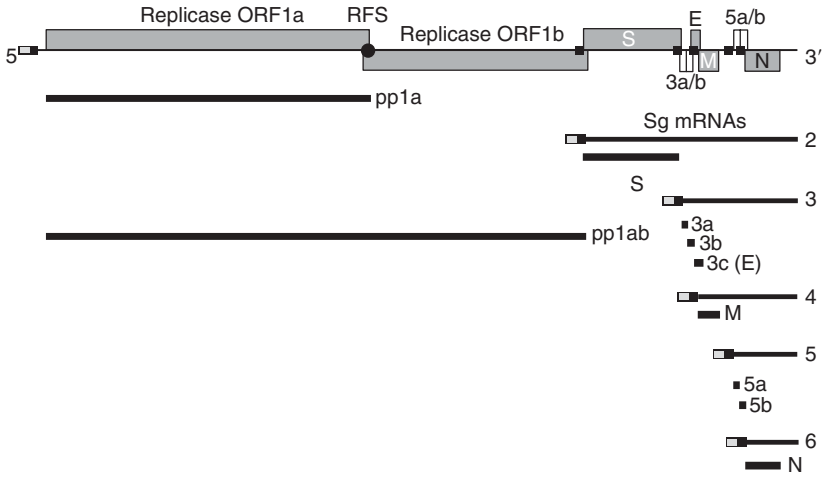

Figure 2 Schematic diagram representing the genomic expression of the avian coronavirus IBV. The upper part of the diagram shows the IBV genomic RNA, with the various genes highlighted as boxed regions. The black boxes represent the transcription regulatory sequences (TRSs) found upstream of each gene and direct the synthesis, via negative-sense counterparts, of the sg mRNAs (2–6 for IBV). The leader sequence, represented by a gray box, is at the 5′ end of the genomic RNA and at the 5′ ends of the sg mRNAs. The genomic RNA is translated to produce two polyproteins, pp1a and pp1ab, that are cleaved by virus-encoded proteases to produce the replicase proteins. The structural proteins, S, E, M, and E, and the accessory proteins, 3a, 3b, 5a, and 5b, produced from IBV genes 3 and 5, respectively, are translated from the sg mRNAs. The proteins produced by the sg mRNAs are represented by lines below the corresponding sg mRNA. All of the sg mRNAs, except the smallest species, are polycistronic but only produce a protein from the 5′-most gene. The ribosome frameshift (RFS) region, denoted as a black circle on the genomic RNA, directs the –1 frameshift event for the synthesis of pp1ab. Translation of the genomic RNA results in the production of pp1a. However, the translating ribosomes undergo the –1 frameshift about 30% of the time resulting in pp1ab. The 5′ and 3′ UTR sequences are represented as single lines downstream of the leader and N gene sequences, respectively.

5 of murine hepatitis virus (MHV)), translation of the third and second open reading frame (ORF), respectively, is effected by the preceding ORFs acting as internal ribosome entry sites. The proteins encoded by these small ORFs are mostly not required for replication *in vitro*; some of them might function as antagonists of innate immune responses, though this has not yet been demonstrated.

Following entry into a cell and the release of the virus ribonucleoprotein (genome surrounded by the N protein) into the cytoplasm, ribosomes translate gene 1, which is approximately 20 kb, into two polyproteins (pp1a and pp1ab). These are cleaved by gene 1-encoded proteases, to generate 15 or 16 proteins (**Figure 3**). Translation of ORF 1b involves ribosomal frameshifting, which has two elements, a slippery site followed by an RNA pseudoknot. At the slippery site (UUUAAAC in IBV), the ribosome slips one nucleotide backward and then moves forward, this time in a –1 frame compared with translation ORF 1a, resulting in the synthesis polyprotein 1ab.

Proteins, including the RNA-dependent RNA polymerase, from gene 1 associate to form the replicase complex, which is membrane associated. Coronavirus subgenomic mRNAs are generated by a discontinuous process. At the beginning of each gene is a common sequence (CUUAACAA in the case of IBV) called a transcription regulatory sequence (TRS). It is believed that when the polymerase producing the nascent negative sense RNA, reaches a TRS, RNA synthesis is attenuated, followed by continuation at the 5′ end of genomic RNA. This results in the addition of a negative copy of the leader sequence to the negative-sense RNA, resulting in a negative-sense copy of an sg mRNA. Of course, progress of the polymerase is not always halted at a TRS. Rather, it sometimes continues, producing a nested set of negative-sense sg mRNAs. These are the templates for the generation of the positive-sense sg mRNAs (**Figure 2**). The amount of each sg mRNA does not necessarily decrease in a linear fashion; the efficiency of termination by a TRS is dependent on adjacent sequences, which are different for each gene. The leader sequence is found at the very 5′ end of the genomic RNA and at the 5′ ends of each sg mRNA.

Replication Cycle

The N-terminal (S1) part of the S protein mediates that mediates attachment to cells. It is a determinant of host species specificity and, in some cases, pathogenicity, by determining susceptible cell range (tissue tropism) within a host. The C-terminal S2 part triggers fusion of the virus envelope with cell membranes (plasma membrane or endosomal membranes), which can occur at neutral or slightly acidic pH, depending on species or even strain. The virus glycoproteins (S, M, and HE, when present) are synthesized at the endoplasmic reticulum. Both subunits

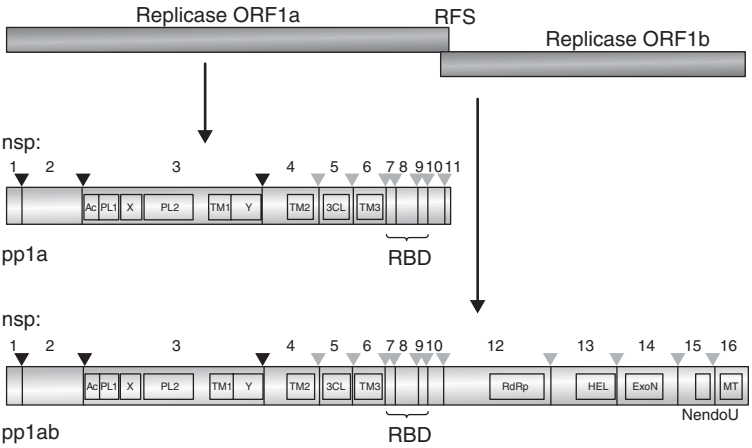

Figure 3 Organization of the coronavirus replicase gene products. Translation of the coronavirus replicase ORF 1a and ORF 1b sequences results in pp1a and pp1ab; the latter is a C-terminal extension of pp1a, following a programmed –1 frameshift event (see legend to **Figure 2**). The two polyproteins are proteolytically cleaved into 10 (pp1a; nsp1–11) and 16 (pp1ab; nsp1–16) products by the papain-like proteinases (PL1^{pro} and PL2^{pro}) and the 3C-like (3CL^{pro}) proteinase. The PL^{pro} proteinases cleave at the sites indicated with a black triangle and the 3CL^{pro} proteinase cleaves at the sites indicated with a gray triangle. The nsp11 product of pp1a is produced as a result of the ribosomes terminating at the ORF 1a translational termination codon, a –1 frameshift results in the generation of nsp12, part of the pp1ab replicase gene product. Various domains have been identified within some of the replicase products: Ac is a conserved acidic domain; X = ADP-ribose 1′-phosphatase (ADRP) domain; PL1 and PL2 the two papain-like proteinases; Y is a conserved domain; TM1, TM2, and TM3 are conserved putative transmembrane domains; 3CL = 3CL^{pro} domain; RdRp, RNA-dependent RNA polymerase domain; HEL, helicase domain; ExoN, exonuclease domain; NendoU, uridylate-specific endoribonuclease domain; MT, 2′-*O*-ribose methyltransferase domain. nsp's 7–9 contain RNA-binding domains (RBDs).

of the S protein are multiply glycosylated, while the M protein has one or two glycans close to its N-terminus. Interestingly, glycosylation of the M protein can be either N- or O-linked, depending on the type of coronavirus, although experiments using reverse genetics showed that conversion of an O-linked glycosylated M protein to an N-linked version had no effect on virus growth.

Early and late in infection, formation of virus particles can occur in the endoplasmic reticulum–Golgi intermediate compartment (ERGIC) and endoplasmic reticulum, but most assembly occurs in the Golgi membranes. The M protein is not transported to the plasma membrane; its location at internal membranes determines the sites of virus particle formation. It interacts with the N protein (as part of the RNP) and C-terminal part of the S protein, retaining some, though not all, of the S protein at internal membranes. The E protein is essential for virus particle formation, though it is not known how it functions. It has a sequence that determines its accumulation at internal membranes, and its interaction with the M protein. The latter interacts with the C-terminus of the S protein, retaining some of it at internal membranes, and with the N protein (itself part of the ribonucleoprotein structure), enabling the formation of virus particles with spikes.

Genome Replication and Recombination

Following infection of a susceptible cell, the coronavirus genomic RNA is released from the virion into the cytoplasm and immediately recognized as an mRNA for the translation of the replicase pp1a and pp1ab proteins. These proteins are cleaved by ORF1a-encoded proteases, after which they become part of replicase complexes for the synthesis of either complete negative-sense copies of the genomic RNA or negative-sense copies of the sg mRNAs. The negative-sense RNAs are used as templates for the synthesis of genomic RNA and sg mRNAs (**Figure 2**). Following synthesis of the sg mRNAs, the structural proteins are produced for the assembly and encapsidation of the *de novo*-synthesized genomic RNA, resulting in the release of new infectious coronavirus virions. The release of new virions starts 3–4 h after the initial infection. As indicated above, the synthesis of the sg mRNAs is the result of a discontinuous process in which the synthesis of a negative-sense copy of an sg mRNA is completed by the addition of the negative-sense leader sequence by a recombination mechanism. If a cell is infected with two related coronaviruses, the polymerase may swap between two RNA templates, in a similar way to addition of the leader sequence. This 'copy-choice' mechanism of genetic recombination results in a chimeric RNA. Such RNAs may give rise to new viruses with modified genomes with a capacity to infect a different cell and, in some cases, new host species.

Evolutionary Relationships among Coronaviruses

Phylogenetic analyses of the structural proteins have resulted in the grouping of coronavirus species in accordance with earlier antigenic groups (**Table 1** and **Figure 4**).

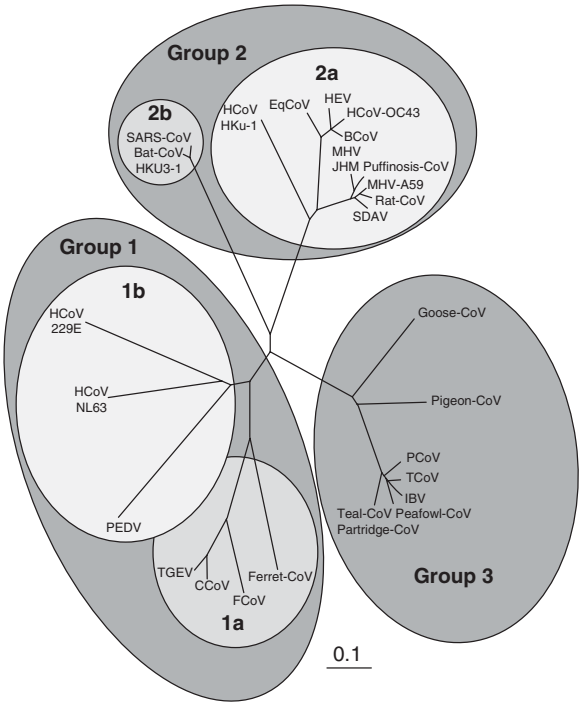

Figure 4 Phylogenetic relationship of aligned coronavirus-derived nucleoprotein amino acid sequences. The complete N protein sequences represent coronaviruses from each of the three groups (**Table 1**). The tree is unrooted and the three main coronavirus groups, 1–3, are highlighted as dark gray ellipsoids. Groups 1 and 2 are divided into two subgroups, a and b, representing some divergence of the sequences within their corresponding groups. Similar relationships are observed when comparing other structural proteins and replicase-derived proteins.

Members of subgroups have higher amino acid sequence identities to each other ($\geq$60%) than to members of another group in the same group (with which they share $\leq$40% identity). Comparing one group with another, protein sequence identities are generally in the range 25–35%. Unlike other members of group 2, SARS-CoV does not have an HE glycoprotein. Phylogenetic analysis using all the encoded proteins indicates that recombination has been a feature of coronavirus evolution. For example, some group 1a viruses are clearly recombinants between a feline and canine group 1 coronavirus.

Diseases and Host Range

Probably all coronaviruses replicate in epithelial cells of the respiratory and/or enteric tracts, though not necessarily producing clinical damage at those sites. Avian IBV not only causes respiratory disease but can also damage gonads in both females and males, and causes serious kidney disease (dependent on the strain of virus, and to some extent on the breed of chicken). IBV is able to replicate at virtually every epithelial surface in the host. Some coronaviruses have their most profound effect in the alimentary tract (e.g., porcine TGEV causes $\geq$90% mortality in neonatal pigs). Human coronaviruses are known to be associated with enteric and respiratory diseases (e.g., diarrhea), in addition to respiratory disease. SARS-CoV was also associated with diarrhea in humans, in addition to serious lung disease. Other coronaviruses, for example, MHV and porcine HEV, spread to cells of the central nervous system, producing disease, for example, acute or chronic demyelination in the case of MHV.

Coronavirus replication and disease are not necessarily restricted to a single host species. Canine enteric CoV and feline CoV can replicate and cause disease in pigs; these two viruses have proteins with very high amino acid identity to those of porcine TGEV. Canine respiratory CoV has proteins, including the S protein (which is the attachment protein and a determinant of host range), with very high amino acid identity ($\geq$95%) to other group 2 viruses Hu CoV-OC43 and BCoV. This raises the possibility of co-infection in these hosts. Bovine CoV causes enteritis in turkeys following experimental oral infection. There is evidence that pheasant CoV can infect chickens, and IBV infect teal (a duck), though without causing disease. The most dramatic demonstration that coronaviruses can have a wide host range was provided by SARS-CoV. This may have had its origin in bats, was transferred to various other species (e.g., civet cat) that were captured for trade, and then caused lethal disease in humans.

Persistent infections *in vivo* are well known for MHV, and less well known for other coronaviruses (e.g., IBV). Following infection of very young chickens, IBV is re-excreted when hens start to lay eggs. The trigger for release is probably the stress of coming into lay.

The S protein is a determinant of both tissue tropism within a host and host range. This has been elegantly demonstrated by genetic manipulation of the genome of MHV, which is unable to attach to feline cells. Replacement of the MHV S protein gene with that of CoV from feline coronavirus resulted in a recombinant virus that was able to attach, and subsequently replicate in, feline cells. However, other proteins can also affect pathogenicity. Research with genetically modified coronaviruses, using targeted recombination or 'infectious clones', has shown that modifications to proteins encoded in ORF1 and the small genes interspersed among the structural protein genes, result in attenuation of pathogenicity. Although the roles of these 'accessory proteins' are not known, this may offer a route to the development of a new generation of live vaccines. Currently, the most widely used prophylactics for control of IBV in chickens include killed vaccines and live vaccines attenuated by passage in embryonated eggs. However, disease control is complicated by extensive variation in the S1 protein which is the inducer of protective immunity.

Glossary

Cell tropism Process that determines which cells can be infected by a virus. Factors such as receptor express can influence the cell type that can be infected.

Discontinuous transcription Process by which the coronavirus leader sequence and body sequence are joined to generate subgenomic RNAs.

Double membrane vesicles (DMVs) Vesicles that are generated during coronavirus replication when viral replicase proteins sequester host cell membranes. These vesicles are the site of coronavirus RNA synthesis.

Transcriptional regulatory sequences (TRSs) Sequences that are recognized by the coronavirus transcription complex to generate leader-containing subgenomic RNAs.

Introduction

Coronaviruses (CoVs) were first identified during the 1960s by using electron microscopy to visualize the distinctive spike glycoprotein projections on the surface of enveloped virus particles. It was quickly recognized that CoV infections are quite common, and that they are responsible for seasonal or local epidemics of respiratory and gastrointestinal disease in a variety of animals. CoVs have been named according to the species from which they were isolated and the disease associated with the viral infection. Avian infectious bronchitis virus (IBV) infects chickens, causing respiratory infection, decreased egg production, and mortality in young birds. Bovine coronavirus (BCoV) causes respiratory and gastrointestinal disease in cattle. Porcine transmissible gastroenteritis virus (TGEV) and porcine epidemic diarrhea virus (PEDV) cause gastroenteritis in pigs. These CoV infections can be fatal in young animals. Feline infectious peritonitis virus (FIPV) and canine coronavirus (CCoV) can cause severe disease in cats and dogs. Depending on the strain of the virus and the site of infection, the murine CoV mouse hepatitis virus (MHV) can cause hepatitis or a demyelinating disease similar to multiple sclerosis. CoVs also infect humans. Human coronaviruses (HCoVs) 229e and OC43 are detected worldwide and are estimated to be responsible for 5–30% of common colds and mild gastroenteritis. Interestingly, HCoV-OC43 and BCoV share considerable sequence similarity, indicating a likely transmission across species (either from cows to humans or vice versa) and then adaptation of the virus to its host. In contrast to the relatively mild infections caused by HCoV-229e and HCoV-OC43, the CoV responsible for severe acute respiratory syndrome (SARS-CoV) causes atypical pneumonia with a 10% mortality rate. Two additional HCoVs, HCoV-NL63 and HCoV-HKU1, have been recently identified using molecular methods and are associated with upper and lower respiratory tract infections in children, and elderly

and immunosuppressed patients. CoVs are grouped according to sequence similarity. CoVs that infect mammals are assigned to group 1 and group 2, whereas CoVs that infect birds are in group 3.

To date, the most infamous example of zoonotic transmission of a CoV is the outbreak of SARS in 2002–03. We now know that the outbreak started with cases of atypical pneumonia in the Guangdong Province in southern China in the fall of 2002. The infection was spread to tourists visiting Hong Kong in February, 2003, resulting in the dissemination of the outbreak to Hong Kong, Vietnam, Singapore, and Toronto, Canada. After attempting to treat cases of atypical pneumonia in Vietnam and acquiring the infection himself, Dr. Carlo Urbani alerted the World Health Organization (WHO) that this disease of unknown origin may be a threat to public health. The WHO rapidly organized an international effort to identify the cause of the outbreak, and within months a novel CoV was isolated from SARS patients and identified as the causative agent. Sequence analysis revealed that the virus was related to, but distinct from, all known CoVs. This led to an intensive search for an animal reservoir for this novel CoV. Initially, the masked palm civet and raccoon dog were implicated in the chain of transmission, since a SARS-CoV-like virus could be isolated from some animals found in wild animal markets in China. However, SARS-CoV-like viruses were never detected in animals captured from the wild, indicating that the civets may have only served as an intermediate host in the chain of transmission. Further investigation revealed that the likely reservoir for SARS-CoV is the Chinese horseshoe bat (*Rhinolophus* spp.), which is endemically infected with a virus, named bat-SARS-CoV, that is closely related to SARS-CoV. The existence of an animal reservoir presents the possibility of re-emergence of this significant human pathogen. By improving our understanding of the molecular aspects of CoV replication and pathogenesis, we may facilitate development of appropriate antiviral agents and vaccines to control and prevent diseases caused by known and potentially emerging CoV infections.

Molecular Features of CoVs

CoV virions (**Figure 1**(**a**)) are composed of a large RNA genome, which combines with the viral nucleocapsid protein (N) to form a helical nucleocapsid, and a host cell-derived lipid envelope which is studded with virus-specific proteins including the membrane (M) glycoprotein, the envelope (E) protein, and the spike (S) glycoprotein. CoV particles vary somewhat in size, but average about 100 nm in diameter. The genomic RNA (gRNA) inside the virion, which ranges in size from 27 to 32 kb for different CoVs, is the largest viral RNA identified to date. CoV gRNAs have a broadly conserved structure which is illustrated by the SARS-CoV genome shown in **Figure 1**(**b**). The gRNA is

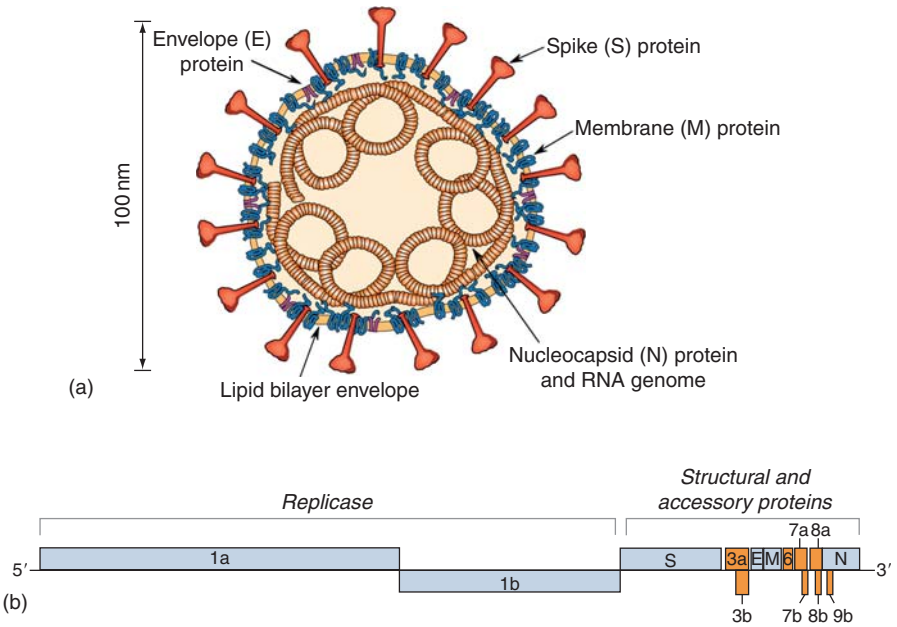

Figure 1 CoV virion and the genome of SARS-CoV. (a) Schematic diagram of a CoV virion with the minimal set of four structural proteins required for efficient assembly of the infectious virus particles: S, spike glycoprotein; M, membrane glycoprotein; E, envelope protein; and N, nucleocapsid phosphoprotein which encapsidates the positive-strand RNA genome. (b) Schematic diagram of the gRNA of SARS-CoV. Translation of the first two open reading frames (ORF1a and ORF1b) generates the replicase polyprotein. ORFs encoding viral structural and accessory (orange) ORFs are indicated at the 3′ end of the genome. (a) Reprinted from Masters PS (2006) The molecular biology of coronaviruses. *Advances in Virus Research* 66: 193–292, with permission from Elsevier.

capped at the 5′ end, with a short leader sequence followed by two long open reading frames (ORFs) encoding the replicase polyprotein. The remaining part of the genome encodes the viral structural and so-called accessory proteins. The structural protein genes are always found in the order S–E–M–N, but accessory protein genes may be interspersed at various sites between the structural genes. SARS-CoV has the most complex genome yet identified, with eight ORFs encoding accessory proteins. The expression of these ORFs is not required for viral replication, but they may play a role in the pathogenesis of SARS. In addition, the products of accessory genes may be incorporated into the virus particle, potentially altering the tropism or enhancing infectivity. For SARS-CoV, the proteins encoded in ORFs 3a, 6, 7a, and 7b have been shown to be incorporated in virus particles, but the exact role of these proteins in enhancing virulence is not yet clear.

The features of CoV structural proteins are shown in **Figure 2**. For each structural protein, a schematic diagram of the predicted structure of the protein is shown on the left and a linear display of the features is shown on the right. The CoV spike glycoprotein is essential for attachment of the virus to the host cell receptor and fusion of the virus envelope with the host cell membrane. CoV spike glycoproteins assemble as trimers with a short cytoplasmic tail and hydrophobic transmembrane domain anchoring the protein into the membrane. The spike glycoprotein is divided into the S1 and S2 regions, which are sometimes cleaved into separate proteins by cellular proteases during the maturation and assembly of virus particles. S1 contains the receptor-binding domain (RBD) and has been shown to provide the specificity of attachment for CoV particles. The cellular receptors and corresponding RBDs in S1 have been identified for several CoVs. MHV binds to murine carcinoembryonic

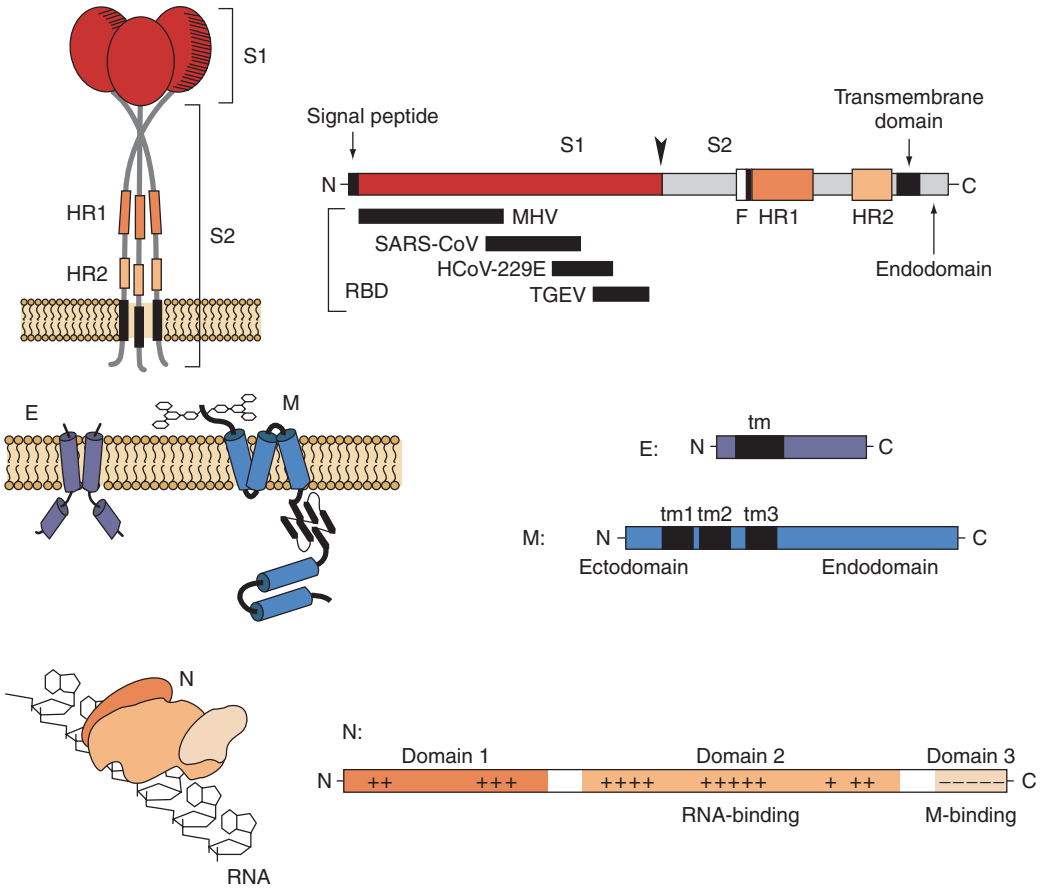

Figure 2 Diagrammatic representation of the spike trimer assembled on membranes, with the S1 receptor binding domain (RBD) and S2 fusion domain indicated. The linear map of spike indicates the location of the RBDs for three CoVs, and the relative location of the heptad repeat domains 1 and 2 (HR1 and HR2) which mediate the conformational changes required to present the fusion peptide (F) to cellular membranes. The membrane (M), envelope (E), and nucleocapsid (N) proteins represented in association with membranes or viral RNA. The linear map of each protein highlights the transmembrane domains of M and E and the RNA-binding and M protein-binding domains of N. Domains 1 and 2 of N are rich in arginine and lysine (indicated by +). antigen-related cell adhesion molecules (mCEACAM1 and MCEACAM2); TGEV, FIPV, and HCoV-229e bind to species-specific versions of aminopeptidase N. Interestingly, both HCoV-NL63 and SARS-CoV have been shown to bind to human angiotensin-converting enzyme 2 (ACE2). ACE2 is expressed in both the respiratory and gastrointestinal tracts, consistent with virus replication at both these sites.

Once the S1 portion of the spike has engaged the host cell receptor, the protein undergoes a dramatic conformational change to promote fusion with the host cell membrane. Depending on the virus strain, this can occur at the plasma membrane on the surface of the cell, or in acidified endosomes after receptor-mediated endocytosis. The critical elements in the conformational change are the heptad repeats, HR1 and HR2, and the fusion peptide, F. After engaging the receptor, there is a dissociation of S1 which likely triggers the rearrangement of S2 so that HR1 and HR2 are brought together to form an antiparallel, six-helix bundle. This new conformation brings together the viral and host cell membranes and promotes the fusion of the lipid bilayers and introduction of the nucleocapsid into the cytoplasm. During infection, the spike glycoprotein is also present on the surface of the infected cell where it may (depending on the virus strain) promote fusion with neighboring cells and syncytia formation. The spike glycoprotein is also the major antigen to which neutralizing antibodies develop. The spike protein is a target for development of therapeutics for treatment of CoV infections. Monoclonal antibodies directed against the spike neutralize the virus by blocking binding to the receptor; synthetic peptides that block HR1-HR2 bundle formation have also been shown to block CoV infection.

The membrane (M) and envelope (E) proteins are essential for the efficient assembly of CoV particles. M is a triple-membrane-spanning protein that is the most abundant viral structural protein in the CoV virion. The ectodomain of M is generally glycosylated, and is followed by three transmembrane domains and an endodomain which is important for interaction with the nucleocapsid protein and packaging of the viral genome. The E protein is present in low copy numbers in the virion, but is important for efficient assembly. In the absence of E protein, few or no infectious virus particles are produced. The exact role of the E protein in the assembly of virus particles is still unknown, but recent studies suggest that E may act as an ion channel. The nucleocapsid protein (N) is an RNA-binding protein and associates with the CoV gRNA to assemble ribonucleoprotein complexes. The N protein is phosphorylated, predominantly at serine residues, but the role of phosphorylation is currently unknown. The N protein has three conserved domains, each separated by highly variable spacer elements. Domains 1 and 2 are rich in arginine and lysine residues, which is typical of many RNA-binding proteins. Domain 3 is essential for interaction with the M protein and assembly of infectious virus particles. The N protein has been shown to be an important cofactor in CoV RNA synthesis and is proposed to act as an RNA chaperone to promote template switching, as described below.

Replication and Transcription of CoV RNA

The replication and transcription of CoV RNA takes place in the cytoplasm of infected cells (**Figure 3**). The CoV virion attaches to the host cell receptor via the spike glycoprotein and, depending on the virus strain, the spike mediates fusion directly with the plasma membrane or the virus undergoes receptor-mediated endocytosis and spike-mediated fusion with endosomal membranes to release the viral gRNA into the cytoplasm. Once the positive-strand RNA genome is released, it acts as a messenger RNA (mRNA) and the 5′ end (ORF1a and ORF1b) is translated by ribosomes to generate the viral RNA-dependent RNA polymerase polyprotein, termed the viral replicase. Translation of ORF1b is dependent on ribosomal frameshifting, which is facilitated by a slippery sequence and RNA pseudoknot structure present in all CoV gRNAs. The replicase polyprotein is processed by replicase-encoded proteases (papain-like proteases and a poliovirus 3C-like protease) to generate 16 mature replicase products. These viral replicase proteins sequester host cell membranes to generate distinctive double-membrane vesicles (DMVs) that have been shown to be the site of CoV RNA synthesis. The replicase complex on the DMVs then mediates the replication of the positive-strand RNA genome to generate full-length and subgenomic negative-strand RNAs, and the subsequent production of positive-strand gRNAs and sgmRNAs. The sgmRNAs are translated to generate viral structural and accessory proteins, and virus particles assemble with positive-strand gRNA in the endoplasmic reticulum-Golgi intermediate compartment (ERGIC) and bud into vesicles, with subsequent release from the cell. Depending on the virus strain, this replication can be robust and result in destruction of the host cell or a low-level, persistent infection that can be maintained in cultured cells or infected animals.

A hallmark of CoV transcription is the generation of a nested set of mRNAs, with each mRNA having the identical 'leader' sequence of approximately 65–90 nt at the 5′ end (**Figure 4(a)**). The leader sequence is encoded only once at the 5′ end of the gRNA. Each subgenomic mRNA (sgmRNA) has the identical leader sequence fused to the 5′ end of the body sequence. How are the leader-containing mRNAs generated during CoV transcription? Current evidence supports a model of discontinuous transcription, whereby the replicase complex switches templates during the synthesis of negative-strand RNA

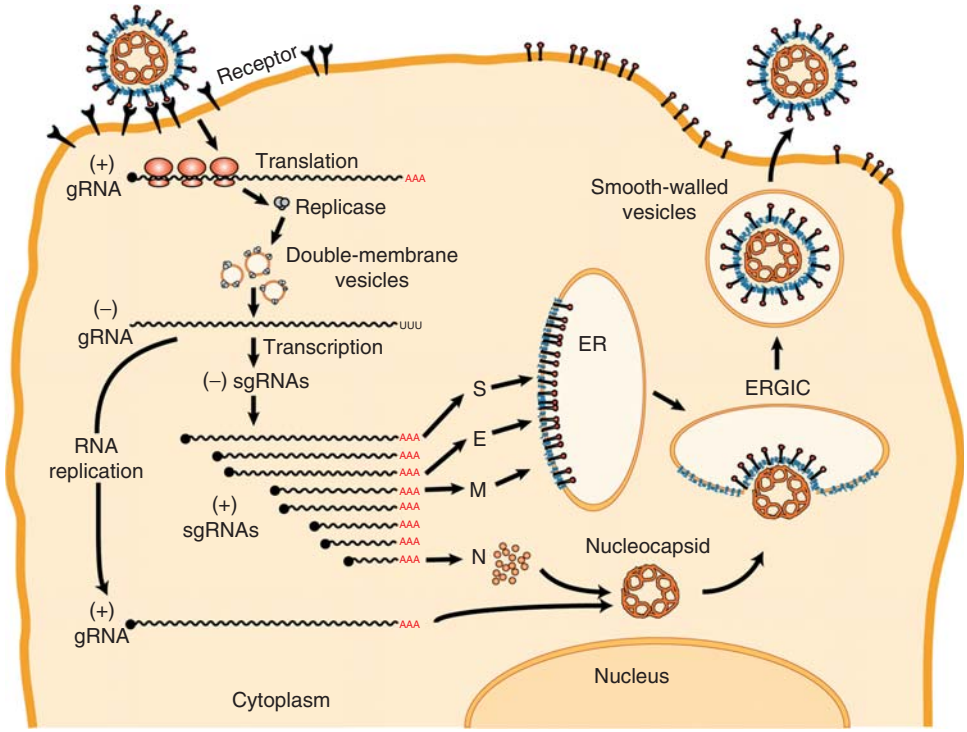

Figure 3 Replication cycle of CoVs. The spike glycoprotein on the virus particle interacts with host cell receptors to mediate fusion of the virus and host cell membranes and release of the positive-strand RNA genome into the cytoplasm. The 5′-proximal open reading frames (ORF1a and ORF1b) are translated from the gRNA to generate the replicase polyprotein. The replicase polyprotein is processed by viral proteases into 16 nonstructural proteins which assemble with membranes to generate double-membrane vesicles (DMVs) where RNA synthesis takes place. A nested set of 3′ co-terminal subgenomic (sg) RNAs is generated by a discontinuous transcription process. The sgRNAs are translated to generate the viral structural and accessory proteins. Viral gRNA is replicated and associates with nucleocapsid protein and viral structural proteins in the endoplasmic reticulum-Golgi intermediate compartment (ERGIC), where virus particles bud into vesicles before transport and release from the cell. Reprinted from Masters PS (2006) The molecular biology of coronaviruses. *Advances in Virus Research* 66: 193–292, with permission from Elsevier.

(**Figure 4(b)**). The key sequence element in this process is the transcriptional regulatory sequence (TRS). The TRS is a sequence of approximately 6–9 nt (5′-ACGAAC-3′ for SARS-CoV) which is found at the end of the leader sequence and at each intergenic region (the sites between the open reading frames encoding the viral structural and accessory proteins). Site-directed mutagenesis and deletion analysis has revealed the critical role of the TRS in mediating transcription of sgmRNAs. Deletion of any intergenic TRS results in loss of production of the corresponding sgmRNA. In addition, the CoV leader TRS and the intergenic TRS sequences must be identical for optimal production of the sgmRNAs. A three-step working model for template switching during negative-strand RNA synthesis has been proposed to describe the process for the generation of CoV leader-containing sgmRNAs (**Figure 4(b)**). In this process, the 5′ end and 3′ end of the gRNA form a complex with host cell factors and the viral replication complex. The 3′ end of the positive strand is used as the template for the initiation of transcription of negative-strand RNA. Negative-strand RNA synthesis continues up to the point of the TRS. At each TRS, the viral replicase may either read through the sequence to generate a longer template, or switch templates to copy the leader sequence. The template switch allows the generation of a leader-containing sgmRNA. In this model, alignment of the leader TRS, the newly synthesized negative-strand RNA, and the genomic TRS is critical for the template switching to occur. Disruption of the complex, or loss of base-pairing within the complex, will result in the loss of production of that sgmRNA. Further studies of the CoV replication complex may yield new insights into the role of the viral helicase and endoribonuclease in the generation of the leader-containing CoV RNAs.

Another hallmark of CoV replication is high-frequency RNA recombination. RNA recombination occurs when a partially synthesized viral RNA dissociates from one template and hybridizes to similar sequences present in a second template. Viral RNA synthesis continues and generates a progeny virus with sequences from two different parental genomes. This RNA recombination event is termed copy-choice recombination. Copy-choice RNA recombination can be demonstrated experimentally when two closely related CoV strains (such as MHV-JHM and

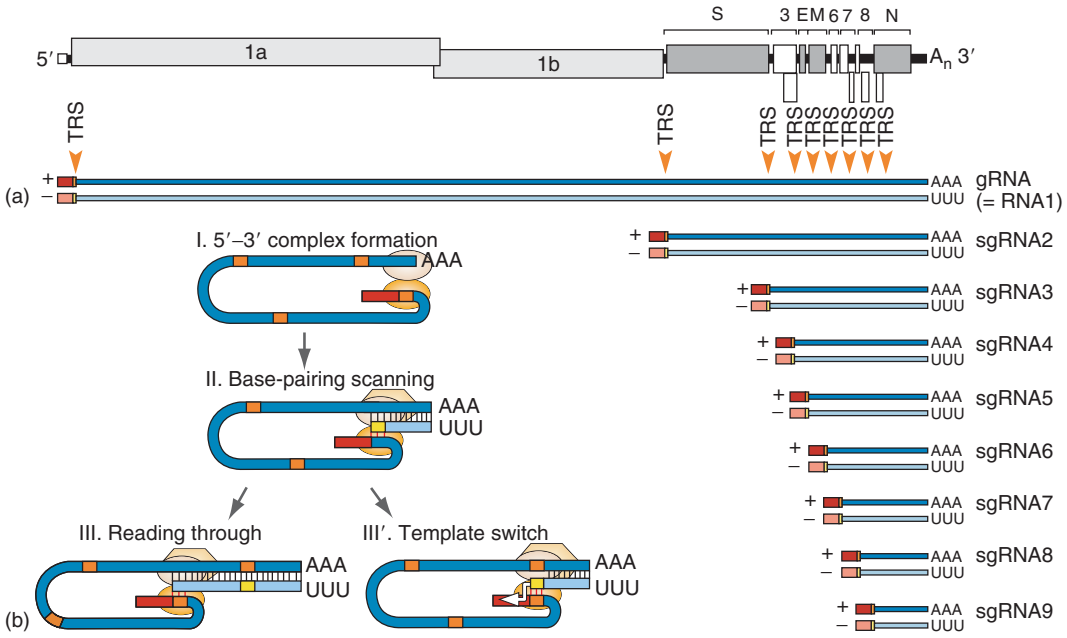

Figure 4 Model of SARS-CoV gRNA and sgRNAs, and a working model of discontinuous transcription. (a) Diagram of gRNA and the nested set of sgRNAs of SARS-CoV. The 5′ leader sequence, the transcriptional regulatory sequences (TRSs), and the positive- and negative-sense sgRNAs are indicated. (b) A working model of CoV discontinuous transcription. I. 5′–3′ complex formation. Binding of viral and cellular proteins to the 5′ and 3′ ends of the CoV gRNA is represented by ellipsoids. The leader sequence is indicated in red, the TRS sites are in orange. II. Base-pair scanning step. Minus-strand RNA (light blue) is synthesized from the positive-strand template by the viral transcription complex (hexagon). At the TRS site, base-pairing may occur between the template, the nascent negative-strand RNA, and the leader TRS sequence (dotted lines). III. The synthesis of negative-strand RNA can continue to make a longer sgRNA III, or a template switch can take place III′ to generate a leader-containing subgenomic negative-strand RNA, which could then serve as the template for leader-containing positive-strand sgRNAs. Modified from Enjuanes L, Almazán F, Sola I, and Zunia S (2006) Biochemical aspects of coronavirus replication: A virus–host interaction. *Annual Reviews in Microbiology* 60: 211–230.

MHV-A59) are used to coinfect cells. Recombinant viruses with cross-over sites throughout the genome can be isolated, although sequences within the spike glycoprotein may be a 'hot spot' for recombination due to the presence of RNA secondary structures that may promote dissociation and reassociation of RNA. It has been proposed that copy-choice recombination is also the mechanism by which many CoVs have acquired accessory genes, and it has been exploited experimentally for the deletion or insertion of specific sequences in CoV genomes to assess their role in virus replication and pathogenesis.

CoV Accessory Proteins

Sequence analysis of CoVs isolated from species ranging from birds to humans has revealed that all CoVs encode a core canonical set of genes, replicase (rep), spike (S), envelope (E), membrane (M), and nucleocapsid (N), and additional, so-called accessory genes (**Table 1**). The canonical genes are always found in the same order in the genome: rep-S-E-M-N. Reverse genetic studies (see below) have shown that this is the minimal set of genes required for efficient replication and assembly of infectious CoV particles. However, the genomes of all CoVs sequenced to date encode from one to eight additional ORFs, which code for accessory proteins. As the

name implies, these accessory proteins are not required for CoV replication in tissue culture cell lines, but they may play important roles in tropism and pathogenesis *in vivo*. How were these additional genes acquired? Current evidence indicates that these additional sequences may have been acquired by RNA recombination events between co-infecting viruses. For example, the hemagglutinin-esterase (HE) glycoprotein present in four different CoVs (MHV, BCoV, HCoV-OC43, and HCoV-HKU-1) was likely acquired by recombination of an ancestral CoV with the HE glycoprotein gene of influenza C. Interestingly, the expression of the HE gene has no effect on replication of the virus in cultured cell lines, but has been shown to enhance virulence in infected animals. Other CoV accessory genes may have been acquired through recombination with host cell mRNA or other viral mRNAs. The specific role of the accessory proteins in CoV replication and pathogenesis is under investigation. For SARS-CoV, accessory protein 6 has been implicated as an important factor in viral pathogenesis. Researchers have shown that mice infected with murine CoV expressing SARS-CoV protein 6 rapidly succumb to the infection, indicating that the protein 6 enhances virulence. In addition, recent studies suggest that SARS-CoV accessory proteins may play a role in blocking host cell innate immune responses, which may enhance viral replication and virulence. Other accessory proteins, such as SARS-CoV 3a and 7a, have been shown to be packaged into virus particles, where they may enhance infectivity or alter cell tropism. Future studies will be aimed at elucidating how CoV accessory proteins may modulate the virulence of CoV infection.

Manipulating CoV Genomes Using RNA Recombination and Reverse Genetics

Genetic manipulation of CoV sequences is challenging because of the large size (27–32 kbp) of the RNA genomes. However, two approaches have been developed to allow researchers to introduce mutations, deletions, and reporter genes into CoV genomes. These approaches are (1) targeted RNA recombination and (2) reverse genetics using infectious cDNA constructs of CoV. The first approach exploits high-frequency copy-choice recombination to introduce mutations of interest into the 3′ end of the CoV gRNA. In the first step of targeted RNA recombination, a cDNA clone encoding the region from the spike glycoprotein to the 3′ end of the RNA is generated. These sequences can be easily manipulated in the laboratory to introduce mutations or deletions, or for the insertion of reporter or accessory genes, into the plasmid DNA. Next, RNA is transcribed from the plasmid DNA and the RNA is transfected into cells coinfected with the CoV of interest. RNA recombination occurs between the replicating CoV and the transfected substrate RNA, and viruses with the 3′ end sequences derived from the transfected substrate RNA will be generated. The recombinant viruses are generated by high-frequency copy-choice recombination, but the challenge is to sort or select for the recombinant virus of interest from the background of wild-type virus. To facilitate selection of recombinant viruses, Masters and Rottier introduced the idea of host range-based selection. They devised a clever plan to use a mouse hepatitis virus (MHV) that encodes the spike glycoprotein from a feline CoV as the target for their recombination experiments. This feline-MHV, termed fMHV, will infect only feline cell lines. Substrate RNAs that encode the MHV spike and mutations of interest in the 3′ region of the genome can be transfected into feline cells infected with fMHV, and progeny virus can be collected from the supernatant and subsequently selected for the ability to infect murine cell lines. Recombinant CoVs that have incorporated the MHV spike gene sequence (and the downstream substrate RNA with mutations of interest) can be selected for growth on murine cells, thus allowing for the rapid isolation of the recombinant virus of interest. This host range-based selection step is now widely used by virologists to generate recombinant viruses with specific alterations in the 3′ end of the CoV genome.

The second approach for manipulating CoV sequences, generating infectious cDNA constructs of CoV, has been developed in several laboratories. Full-length CoV sequences have been cloned and expressed using bacterial artificial chromosomes (BACs), vaccinia virus vectors, and from an assembled set of cDNA clones representing the entire CoV genome. The generation of a full-length cDNA and subsequent generation of a full-length CoV gRNA allows for reverse genetic analysis of CoV sequences. Successful reverse genetics systems are now in place to study the replication and pathogenesis of SARS-CoV, MHV, HCoV-229e, and IBV. These reverse genetics systems have allowed researchers to introduce mutations into the replicase gene and identify sites that are critical for enzymatic activities of many replicase products such as the helicase, endoribonuclease, and the papain-like proteases. Reverse genetic approaches are also being used to investigate the role of the TRSs in controlling the synthesis of CoV mRNAs. Interestingly, the SARS-CoV genome can be 're-wired' using a novel, nonanonical TRS sequence, which must be present at both the ends of the leader sequence and at each intergenic junction. This 're-wired' SARS-CoV may be useful for generating a live-attenuated SARS-CoV vaccine. An important feature of this 're-wired' virus is that it would be nonviable if it recombined with wild-type virus, since the leader TRS and downstream TRS would no longer match in a recombinant virus. The development of reverse genetics systems for CoVs has opened

the door to investigate how replicase gene products function in the complex mechanism of CoV discontinuous transcription, and provides new opportunities to generate novel CoVs as potential live-attenuated or killed virus vaccines to reduce or prevent CoV infections in humans and animals.

Vaccines and Antiviral Drug Development

Because of the economic importance of CoV infection to livestock and domestic animals, a variety of live-attenuated and killed CoV vaccines have been tested in animals. Vaccines have been developed against IBV, TGEV, CCoV, and FIPV. However, these vaccines do not seem to provide complete protection from wild-type virus infection. In some cases, the wild-type CoV rapidly evolves to escape neutralization by vaccine-induced antibodies. In studies of vaccinated chickens, a live-attenuated IBV vaccine has been shown to undergo RNA recombination with wild-type virus to generate vaccine escape mutants. Killed virus vaccines may also be problematic for some CoV infections. Vaccination of cats with a killed FIPV vaccine has been shown to exacerbate disease when cats are challenged with wild-type virus. Therefore, extensive studies will be required to carefully evaluate candidate vaccines for SARS-CoV. A variety of approaches are currently under investigation for developing a SARS-CoV vaccine, including analysis of killed virus vaccines, live-attenuated virus vaccines, DNA immunization, and viral vector vaccines (such as modified vaccine virus Ankara, canarypox, alphavirus, and adenovirus vectors). The development of improved animal models for SARS will be essential for evaluating SARS-CoV candidate vaccines. Transgenic mice expressing human ACE-2 may be an appropriate small animal model. Initial studies suggest that Syrian hamsters and ferrets develop pneumonia and lung pathology similar to that seen in humans after infection with SARS-CoV, and therefore may be appropriate animal models for viral pathogenesis. CoV vaccine studies will benefit from an improved understanding of conserved viral epitopes that can be targeted for vaccine development.

The use of neutralizing monoclonal antibodies directed against the SARS-CoV spike glycoprotein is another approach that may provide protection from severe disease. The success in the development and use of humanized monoclonal antibodies against respiratory syncytial virus (family *Paramyxoviridae*) to protect infants from severe disease indicates that this approach is certainly worth investigating. Preliminary studies have indicated that patient convalescent serum and monoclonal antibodies directed against the SARS-CoV spike glycoprotein efficiently neutralize infectious virus. Further studies are essential to evaluate any concerns about potential antibody-mediated enhancement of disease and to determine if neutralization escape mutants arise rapidly after challenge with infectious virus. Studies evaluating monoclonal antibodies directed against a variety of structural proteins, and monoclonal antibodies directed against conserved sites in the spike glycoprotein will provide important information on the efficacy of passive immunity to protect against SARS.

Currently, there are no antiviral drugs approved for use against any human CoV infection. With the potential for the emergence or re-emergence of pathogenic CoV from animal reservoirs, there is considerable interest in identifying potential therapeutic targets and developing antiviral drugs that will block viral replication and reduce the severity of CoV infections in humans. Two promising targets for antiviral drug development are the SARS-CoV protease domains, the papain-like protease (PL^{pro}) and the 3C-like protease ($3CL^{pro}$, also termed the main protease, M^{pro}) (**Figure 5**). These two protease domains

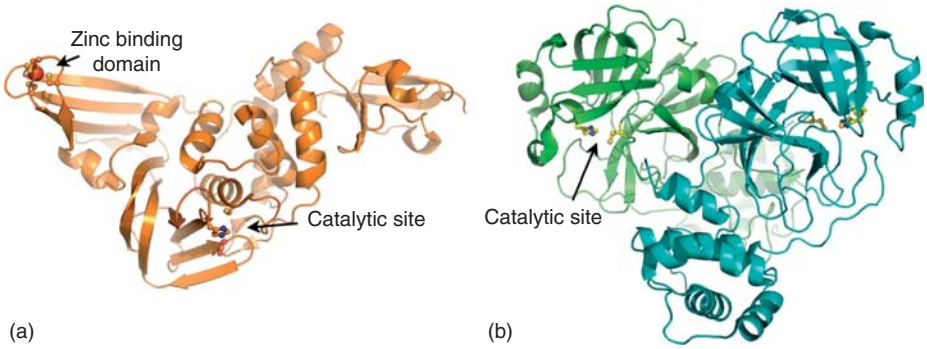

Figure 5 CoV proteases are targets for antiviral drug development; X-ray structures of the two SARS-CoV protease domains encoded in the replicase polyprotein. (a) The SARS-CoV papain-like protease (PL^{pro}) with catalytic triad cysteine, histidine, and aspartic acid residues, and zinc-binding domain indicated. (b) The 3C-like protease ($3CL^{pro}$, also termed main protease, M^{pro}) dimer with catalytic cysteine and histidine residues indicated.

are encoded within the replicase polyprotein gene and protease activity is required to generate the 16 replicase nonstructural proteins (nsp1–nsp16) that assemble to generate the viral replication complex. The crystal structure of the $3CL^{pro}$ was determined first from TGEV and then from SARS-CoV. Rational drug design, much of which was based on our knowledge of inhibitors directed against the rhinovirus 3C protease, has provided promising lead compounds for $3CL^{pro}$ antiviral drug development. Interestingly, these candidate antivirals have been shown to inhibit the replication of SARS-CoV and other group 2 CoVs such as MHV, and the less related group 1 CoV, HCoV-229e. This indicates that the active site of $3CL^{pro}$ is highly conserved among CoVs and that antiviral drugs developed against SARS-CoV $3CL^{pro}$ may also be useful for inhibiting the replication of more common human CoVs such as HCoV-229e, HCoV-OC43, HCoV-NL63, and HCoV-HKU1. Further studies are needed to determine if these inhibitors can be developed into clinically useful antiviral agents.

Analysis of SARS-CoV papain-like protease led to the surprising discovery that this protease is also a viral deubiquitinating (DUB) enzyme. The SARS-CoV PL^{pro} was shown to be required for processing the amino-terminal end of the replicase polyprotein and to recognize conserved cleavage site (-LXGG). The LXGG cleavage site is also the site recognized by cellular DUBs to remove polyubiquitin chains from proteins targeted for degradation by proteasomes. Analysis of the X-ray structure of the SARS-CoV PL^{pro} has revealed that it has structural similarity to known cellular DUBs. These studies suggest that CoV papain-like proteases have evolved to have both proteolytic processing and DUB activity. The DUB activity may be important in preventing ubiquitin-mediated degradation of viral proteins, or the DUB activity may be important in subverting host cell pathways to enhance viral replication. PL^{pro} inhibitors are now being developed using structural information and by performing high-throughput screening of small molecule libraries to identify lead compounds. Additional CoV replicase proteins, particularly the RNA-dependent RNA polymerase, helicase, and endoribonuclease, are also being targeted for antiviral drug development.

Future Perspectives

The development of targeted RNA recombination and reverse genetics systems for CoVs has provided new opportunities to address important questions concerning the mechanisms of CoV replication and virulence, and to design novel CoV vaccines. In the future, improved small animal models for testing vaccines and antivirals, and the availability of additional X-ray crystallographic structure information for rational drug design will be critical for further progress toward development of effective vaccines and antiviral drugs that can prevent or reduce diseases caused by CoVs.

Glossary

Host plant resistance Refers to the ability of a natural host species to control population of the parasite. This is the most desired way to limit damage caused by the causative agent.

Koch's postulates The criteria conceived by Robert Koch in 1890 to establish a causal relationship between a microbe and a disease. These conditions are that the pathogen must be found in all symptomatic hosts, be grown in pure culture, and should be able to cause the disease when reintroduced into a healthy host. The pathogen must then be reisolated from the experimentally infected host.

Pathogen-derived resistance An engineered type of resistance to pathogens created by expression of pathogen-derived genes, or sequences, that interfere with infection by the homologous and closely related pathogens.

Introduction

Cotton leaf curl disease (CLCuD) is a serious disorder of cotton and several other malvaceous hosts that is transmitted by the whitefly *Bemisia tabaci*. CLCuD is endemic across most of Pakistan and northwestern India. The disease has also been reported from Egypt, Sudan, Nigeria, Malawi, and South Africa. Affected plants exhibit very distinctive symptoms; they consist of vein swelling, upward or downward curling of the leaves, and the formation of enations on the main veins on the undersides of leaves. The enations frequently develop into cup-shaped, leaf-like structures (**Figure 1**). Conspicuously CLCuD-infected cotton plants are greener than noninfected plants due to the proliferation of chloroplast-containing tissues. Symptoms are highly variable between cotton varieties, and they also depend on the age of the plant at infection. Plants infected late in the season show only mild symptoms and do not suffer a significant yield reduction. Plants infected early are severely stunted, with tightly rolled leaves, and they usually yield no harvestable lint.

Cotton has been grown in tropical and subtropical regions of the world since prehistoric times and is increasingly being adapted to more temperate climates as well. The genus *Gossypium* encompasses *c.* 50 species, of which five are tetraploid and the remainder are diploid. Of these, four produce spinable fiber and are cultivated as cotton. These include two diploid species, *G. arboreum* and *G. herbaceum*, and two tetraploid species, *G. hirsutum* and *G. barbadense*. More than 90% of world cotton production is obtained from *G. hirsutum*. Diploid cotton species were grown throughout Asia and Africa before the introduction of tetraploid cotton from the New World. The diploid cotton species grown in the Old World are completely immune to CLCuD.

History of CLCuD

CLCuD in Africa

The first report of CLCuD was from Nigeria in 1912, where the disease was a sporadic but minor problem, with a second outbreak in this country occurring in 1924. In North Africa (mainly Egypt and Sudan), *G. barbadense* is the main cotton species cultivated. In these areas, CLCuD is endemic, although it is only sporadically a problem. This was not the case during the early part of the twentieth century when the disease caused major crop losses, particularly in Sudan. An epidemic in Sudan in 1927–28 stimulated interest, and it was during this time that the disease was shown to be transmitted by the whitefly, *B. tabaci*. Extensive work to understand the disease showed that it was also graft transmissible. Although the causative agent was not identified, a virus-like agent was suspected. The disease in this case was brought under control by imposing a cotton-free cultivation period and the introduction of virus-tolerant *G. barbadense* varieties. The disease continues to occur sporadically throughout the region but does not cause major losses.

CLCuD in Southern Asia

CLCuD was noted infrequently across the Indian subcontinent prior to the 1980s. In Pakistan, cotton production, the main foreign exchange earner for the country, suffered heavily from an epidemic of CLCuD which initiated in the vicinity of the city of Multan in the mid-1980s and spread to virtually all cotton-growing areas, as well as into western India. The epidemic has been attributed to the introduction of high-yielding, but also highly susceptible, cotton varieties such as S-12 and CIM70. The cotton

Figure 1 Typical symptoms of CLCuD-affected cotton (*G. hirsutum*) plants. Symptoms include upward curling of the leaves, vein swelling, vein darkening, and enations on the main veins on the undersides of leaves which frequently develop into cup-shaped, leaf-like structures (left). A severely infected plant showing a reduction in leaf size, downward leaf curling, leaf crumpling, and severe stunting (right).

species native to this region, *G. arboreum*, is immune to CLCuD, but unfortunately this does not produce the high-grade cotton lint desired by the processing industry. Nevertheless, *G. arboreum* continues to be grown on a small scale. Although CLCuD remained endemic, losses due to the disease were reduced in both India and Pakistan during the 1990s by the gradual replacement of susceptible varieties with locally developed, tolerant, and resistant cotton varieties. By the late 1990s, cotton production was again at record levels, exceeding the output achieved prior to the epidemic. Then, in 2001, there was a change in the prevalent virus population affecting cotton in Pakistan, as will be described later.

Etiology of CLCuD

The etiology of CLCuD from two regions (North Africa (Egypt and Sudan) and the Indian subcontinent) has been determined. In both regions, the disease is caused by begomovirus complexes consisting of monopartite begomoviruses (genus *Begomovirus*, family *Geminiviridae*) and a recently identified single-stranded DNA satellite termed DNA β. Invariably, begomovirus-DNA β infections of cotton are also associated with a third component, known as DNA-1. This is a satellite-like molecule that plays no essential part in the etiology of CLCuD.

Elucidation of the Etiology of CLCuD

During the early 1990s, the losses to the Pakistan and Indian cotton industries due to the newly emergent CLCuD initiated an urgent investigation into the etiology of the disease. A number of distinct begomoviruses were initially cloned and fully sequenced but infectivity of these was not shown to cotton; thus, Koch's postulates were not fulfilled. Later efforts to introduce one of these viruses, now known as cotton leaf curl Multan virus (CLCuMV), into cotton resulted in mild, atypical symptoms. This indicated that either CLCuMV was not involved in causing the disease or that some other essential component was required to do so.

The genomes of many begomoviruses consist of two components. Component DNA-A encodes all viral functions required for replication, control of gene expression, and encapsidation. The second, DNA-B, encodes two products involved in movement of the virus between and within plant cells. A small number of begomoviruses, mostly isolated from tomato, have monopartite genomes, appearing to be able to dispense with the functions encoded by DNA-B, their genomes consisting of only a homolog of the DNA-A component of bipartite viruses. For these viruses, the products of other genes are able to take over the functions of the DNA-B products in movement. One possible effect of the absence of DNA-B is that monopartite begomoviruses are limited to phloem-associated cells, whereas the majority of bipartite begomoviruses can spread to tissues outside the phloem. The monopartite begomoviruses include tomato yellow leaf curl virus, a major cause of losses to tomato crops globally.

The absence of a detectable DNA-B component associated with CLCuMV suggested that this was a monopartite virus. However, the inability to infect cotton and induce typical disease symptoms was troubling and mirrored the situation with several other begomoviruses at the time. Further analysis of plants identified an additional, novel, subviral component in CLCuD-affected plants. Similar components have been shown to be associated with a number of other monopartite begomoviruses and

this group of molecules has been named DNA-1. However, DNA-1 was found not to play a part in the etiology of CLCuD. Nevertheless, this finding caused a renewed analysis of subviral DNA molecules associated with the monopartite begomoviruses. The breakthrough finally came with the identification of a second subgenomic DNA associated with the monopartite begomovirus, ageratum yellow vein virus, and soon thereafter with CLCuMV, as well as numerous other viruses. This group of molecules has become known as DNA β. Inoculation of CLCuMV with CLCuD DNA β induced full CLCuD symptoms in cotton and established the etiology of the disease as well as fulfilled Koch's postulates.

Components of the CLCuD Complex

CLCuD-associated DNA-1 component

DNA-1 components are satellite-like molecules that are associated with most (but not all) begomovirus-DNA β complexes (**Figure 2**). Their function remains unclear, since they are not required for infectivity or symptom induction in host plants. They are small (~1380 nt), circular, single-stranded DNA molecules that contain a single gene which encodes a rolling-circle replication initiator protein (known for plant-infecting, single-stranded DNA viruses as the replication-associated protein (Rep)). These molecules are capable of autonomous replication in the cells of host plants; hence they are described as satellite-like since, by definition, satellites depend upon their helper virus for replication. However, these components require the helper begomovirus for movement in plants and for transmission between plants, presumably by *trans*-encapsidation in the helper virus' coat protein.

Surprisingly, the DNA-1 components are closely related to the Rep-encoding, satellite-like components of nanoviruses. Nanoviruses are a second family of plant-infecting, single-stranded DNA viruses which are transmitted by aphids. As well as the so-called master Rep (mRep) component, the component which encodes the Rep responsible for replicating all the *bona fide* virus components, some nanovirus infections are also associated with additional Rep-encoding components. These satellite-like molecules are distinct from the mRep in both sequence and in the organization of the genome (the positioning of the promoter being different from that of the mRep). The DNA-1 components associated with begomovirus complexes are believed to have evolved from the nanovirus satellite-like components; most probably by component exchange during co-infection.

The major difference between DNA-1 molecules and nanovirus satellite-like components is size. The components of nanoviruses are typically 1000–1100 nt in length, whereas DNA-1 components are on average 1380 nt – almost exactly half the size of the genomes of their helper begomoviruses. The majority of this size increase is due to the presence, in DNA-1, of ~200 nt region of sequence which is rich in adenine. The function of this A-rich sequence is unclear; it is not essential for the molecule, since DNA-1 components with the A-rich sequence deleted remain capable of replication and movement in plants in the presence of a begomovirus. It is likely that there is a very subtle selection mechanism for maintenance of these additional sequences, most likely for efficient encapsidation by the helper virus' coat protein.

The presence of a DNA-1 component with the CLCuD complex in North Africa has not been investigated.

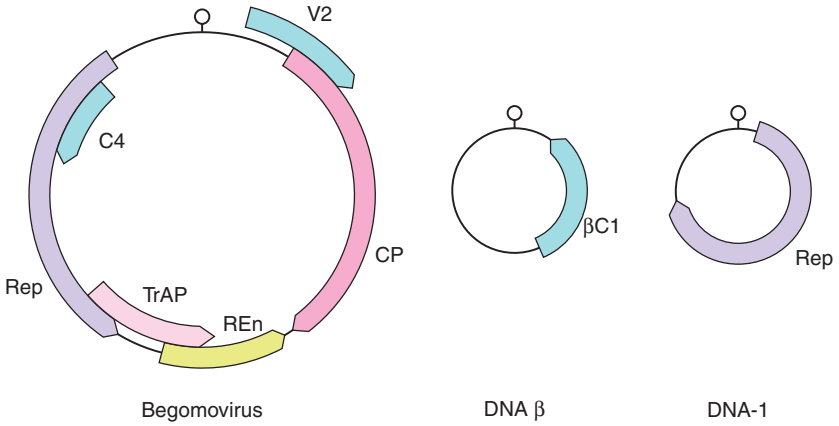

Figure 2 Components associated with CLCuD. Shown are the begomovirus genome and the associated DNA β and DNA-1 components. Only the begomovirus and DNA β component are required to cause the disease. The position and orientation of genes encoded on these are indicated as arrows and labeled as coat protein (CP), replication-associated protein (Rep), transcriptional-activator protein (TrAP), replication enhancer protein (REn), and DNA βC1 protein (βC1). The function of the begomovirus-encoded V2 and C4 genes remain unclear. The ubiquitous stem–loop structure containing the nonanucletide loop sequence TAATATTAC (which for geminiviruses is the origin of virion-strand, rolling-circle DNA replication) is indicated by the small circle for each component.

CLCuD-associated DNA β components

DNA β components are a recently identified class of single-stranded DNA satellites that are associated with monopartite begomoviruses (family *Geminiviridae*). DNA β depends on the begomovirus for its proliferation and is responsible for the accumulation of the helper virus to levels normally found in their original hosts in the field, suggesting its involvement in either replication, systemic movement, or the suppression of a host defense mechanism. They are typically half the length of their helper begomoviruses (~1350 nt) and share no sequence homology with their helper virus other than the presence of a potential stem–loop structure containing the ubiquitous nonanucleotide sequence TAATATTAC. DNA β components encode a single gene, the product of which (known as βC1) is a pathogenicity determinant (determines the symptoms of the infection), a suppressor of post-transcriptional gene silencing (overcoming host plant defenses), upregulate viral DNA levels *in planta*, and bind DNA. DNA β satellites depend upon their helper viruses for replication, movement in plants, and transmission between plants, presumably by *trans*-encapsidation in the helper virus' coat protein. DNA β components have been cloned from a diverse range of hosts and DNA sequence comparison shows them to be highly diverse. Despite their highly diverse nature, only a single type of DNA β is associated with CLCuD and is replicated by several distinct begomoviruses, both experimentally and in the field. Expression of βC1 of CLCuD in tobacco, either stably transformed or from a virus vector, induces virus-like symptoms, demonstrating that DNA β is the most important pathogenicity determinant of the disease. However, the DNA β associated with CLCuD from Sudan is distinct from the one associated with the disease on the Indian subcontinent.

Monopartite begomoviruses associated with CLCuD

On the Indian subcontinent, seven distinct begomovirus species (CLCuMV, cotton leaf curl Alabad virus (CLCuAV), cotton leaf curl Kokhran virus (CLCuKV), cotton leaf curl Rajasthan virus (CLCuRV), papaya leaf curl virus (PaLCuV), tomato leaf curl Bangalore virus (ToLCBV), and cotton leaf curl Burewala virus (CLCuBV)), either singly or as dual/multiple infections, have been shown to be involved in causing CLCuD (**Figure 3**). Some of these viruses have been shown experimentally to induce CLCuD in cotton when co-inoculated with CLCuD DNA β. Among these begomoviruses, only ToLCBV is infectious to tomato, in the absence of a DNA β, causing tomato leaf curl disease. An eighth virus, cotton leaf curl Bangalore virus (**Figure 3**), is associated with CLCuD in southern India (isolated from *G. barbadense*) and is thus unlikely to be part of the epidemic of CLCuD affecting the north of the country; its infectivity to cotton has not been shown experimentally. The viruses shown to be associated with CLCuD are not monophyletic (**Figure 3**), and thus are unlikely to have a common recent ancestor. This suggests that the viruses have been drawn into the disease by gaining an interaction with CLCuD DNA β, likely from other malvaceous hosts since a host range including cotton is a prerequisite for causing CLCuD.

The majority of begomoviruses associated with CLCuD show features both of monopartite as well as bipartite begomoviruses. These viruses replicate to high level in experimental hosts such as *Nicotiana benthamiana*, a situation that differs from bipartite begomoviruses which accumulate to only very low levels, or not at all, in the absence of DNA-β. Experimentally CLCuD DNA β can be replicated and maintained by other begomoviruses that are not found in cotton, including the bipartite begomovirus tomato leaf curl New Delhi virus (ToLCNDV; a virus that occurs widely in solanaceous crops across the Indian subcontinent). However, ToLCNDV has not been reported to infect cotton, suggesting that begomoviruses mobilized into cotton are also limited by their host range. The presence of so many viruses causing a single disease in cotton suggests that they were mobilized into this host after gaining an interaction with CLCuD DNA β, most probably following co-infection of a common host such as tomato. The presence of multiple begomoviruses may help the disease complex to adapt to other hosts or help in overcoming resistance. Nevertheless, there are other monopartite begomoviruses found on the Indian subcontinent that are not found in cotton, suggesting that some begomoviruses are better adapted to cotton. Experimentally some begomoviruses that are not found in the region (such as ageratum yellow vein virus originating from Southeast Asia and tomato leaf curl virus originating from Australia) are capable of supporting replication of CLCuD DNA β. The ability of CLCuD DNA β to interact with begomoviruses from other parts of the world indicates that CLCuD is a global threat to cotton cultivation. No study has been carried out to assess the ability of bipartite begomoviruses from the New World to support replication of CLCuD DNA β. No native monopartite begomoviruses occur in the New World, although TYLCV has recently been introduced and now affects crops in the Caribbean, southern North America, and Central America.

In North Africa, a single begomovirus, cotton leaf curl Gezira virus, has been shown to be associated with CLCuD. This virus is only distantly related to the Asian CLCuD-associated begomoviruses, being instead more closely related to other begomoviruses infecting plants of the Malvaceae originating from Africa and the Mediterranean (**Figure 3**). This is typical of the relationship of begomoviruses within an area (viruses being more related geographically than by the host from which they are

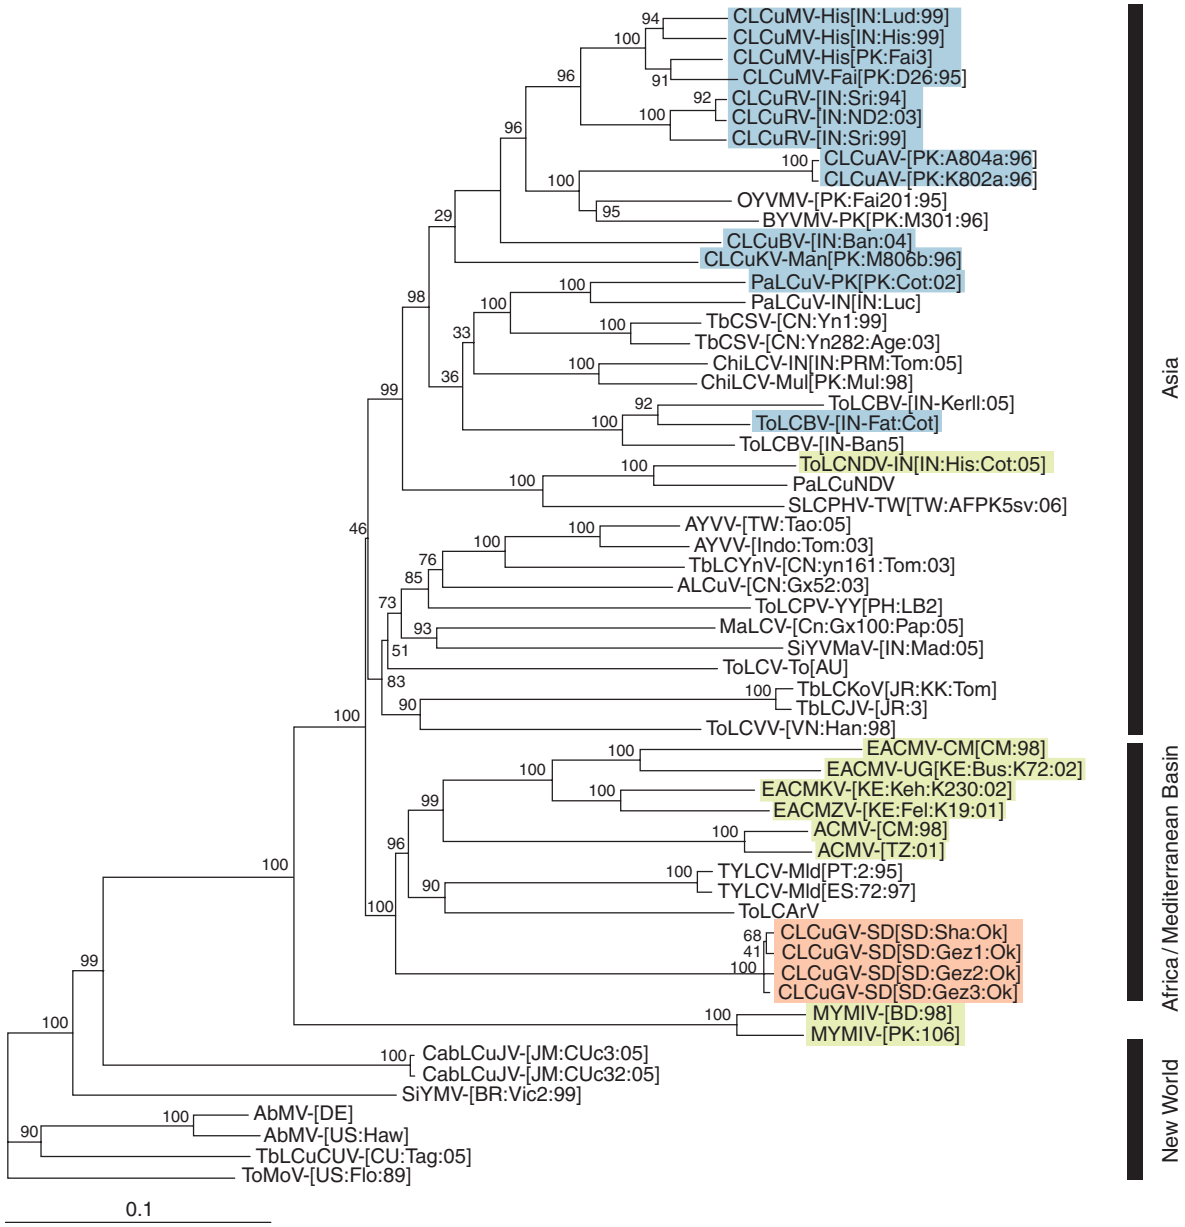

Figure 3 Phylogenetic dendrogram derived from an alignment of 58 selected full-length sequences of the genomes (or DNA A genomic components) of begomoviruses. Indicated on the right are the viruses originating from the New World, Africa/Mediterranean Basin, and Asia. Viruses associated with CLCuD on the Indian subcontinent are highlighted in blue whereas those associated with CLCuD in North Africa are highlighted in brown. Viruses known to be bipartite are highlighted in yellow. The viruses are labeled as abutilon mosaic virus (AbMV), African cassava mosaic virus (ACMV), ageratum leaf curl virus (ALCuV), ageratum yellow vein virus (AYVV), Bhendi yellow vein mosaic virus (BYVMV), cabbage leaf curl Jamaica virus (CabLCuJV), chilli leaf curl virus (ChiLCV), cotton leaf curl Bangalore virus (CLCuBV), cotton leaf curl Gezira virus (CLCuGV), cotton leaf curl Kokhran virus (CLCuKV), cotton leaf curl Multan virus (CLCuMV), cotton leaf curl Rajasthan virus (CLCuRV), cotton leaf curl Alabad virus (CLCuAV), East African cassava mosaic Kenya virus (EACMKV), East African cassava mosaic virus (EACMV), East African cassava mosaic Zanzibar virus (EACMZV), malvastrum leaf curl virus (MaLCV), okra yellow vein mosaic virus (OYVMV), mungbean yellow mosaic India virus (MYMIV), papaya leaf curl New Delhi virus (PaLCuNDV), papaya leaf curl virus (PaLCuV), sida yellow mosaic virus (SiYMV), sida yellow vein Madurai virus (SiYVMaV), squash leaf curl Philippines virus (SLCPHV), tobacco curly shoot virus (TbCSV), tobacco leaf curl Cuba virus (TbLCuCUV), tobacco leaf curl Japan virus (TbLCJV), tobacco leaf curl Kochi virus (TbLCKoV), tobacco leaf curl Yunnan virus (TbLCYnV), tomato leaf curl Bangalore virus (ToLCBV), tomato leaf curl New Delhi virus (ToLCNDV), tomato leaf curl Pune virus (ToLCPV), tomato leaf curl virus (ToLCV), tomato leaf curl Vietnam virus (ToLCVV), tomato mottle virus (ToMoV), tomato yellow leaf curl virus (TYLCV), and tomato leaf curl Arusha virus (ToLCArV). Strain and isolate designation follow established convention. Vertical lines are arbitrary; horizontal lines are proportional to calculated mutation distances. The numbers at nodes indicate percentage bootstrap values (1000 replicates). The tree was rooted on the sequence of ToMoV originating from North America.

isolated or the disease they cause) and indicates that the CLCuDs occurring in Asia and Africa likely have distinct evolutionary origins and are not, as some have claimed, the result of accidental introduction of the virus to Pakistan/India from North Africa.

Control of CLCuD

Natural Resistance to the CLCuD Complex

Resistance to the Asian CLCuD complex is available in the form of *G. arboreum*. This cotton species is immune to CLCuD (in fact, no geminiviruses are reported that infect it) and is grown commercially on a small scale. However, the cotton fiber it produces is not of a sufficient quality or quantity to make it a viable alternative to *G. hirsutum*. Introgression of resistance from *G. arboreum* into *G. hirsutum* is also technically not a simple task (*G. arboreum* being diploid whereas *G. hirsutum* is tetraploid), although some efforts in that direction are in progress.

Limited resistance/tolerance is available in *G. hirsutum* germplasm. The cultivars LRA 511 and CP15/2 were the basis of much of the conventional resistance used to control CLCuD in Pakistan/India during the late 1990s. Cultivation of these cultivars was successful in alleviating losses to CLCuD in endemic areas and during this period cotton production in Pakistan showed an upward trend. However, recently, leaf curl symptoms were noted on previously resistant cotton varieties, indicating a change in the prevalent CLCuD complex.

Breakdown of resistance to CLCuD

During 2001, in the vicinity of the town of Burewala (Punjab, Pakistan), previously resistant cotton varieties began to exhibit the symptoms typical of CLCuD infection. Since then there has been a resurgence of the disease with all previously resistant varieties and virtually all cotton-growing areas of Pakistan and neighboring India affected. Initial analysis of the resistance-breaking strain of CLCuD shows it to be a typical begomovirus-DNA β complex (although the presence of a DNA-1 component has not been confirmed). Only a single begomovirus, which has since been named cotton leaf curl Burewala virus (CLCuBV), a recombinant virus consisting of sequences derived from the previously occurring CLCuMV and CLCuKV, has been identified in all resistant varieties infected. Similarly, the DNA β associated with resistance breaking is recombinant. In this case, the molecules consist for the most part of sequences derived from the original CLCuD DNA β, but with a small fragment of the satellite conserved region (SCR), ~80 nt, derived from a DNA β first identified from tomato exhibiting tomato leaf curl disease symptoms. Although these components are infectious to experimental hosts, it has thus far not been possible to infect resistant cotton varieties with clones of CLCuBV and the recombinant DNA β; the precise molecular basis for resistance breaking thus remains unclear.

Engineered Resistance to the CLCuD Complex

With the absence of any diversity in the natural resistance to CLCuD in the *G. hirsutum* germplasm, efforts have been made to obtain genetically engineered resistance to the disease complex prevalent on the Indian subcontinent. The major challenge to obtaining transgenic CLCuD resistance is the diversity of viruses which cause the disease. It is essential to introduce a broad-spectrum resistance, which is effective against all the viruses present in the field, if the approach is to stand any chance of durability. The strategies under investigation all rely on post-transcriptional gene silencing (PTGS) or transcriptional gene silencing (TGS) – homology-dependent, RNA-mediated phenomena which stimulate the plant's own defenses to target the invading virus. Since the one 'target' present in all CLCuD-affected plants is CLCuD DNA β, initial studies attempted to induce PTGS/TGS against this molecule, with little success. More fruitful have been the studies that have targeted the Rep and AV2 genes, by antisense expression as either full-length (AV2) or truncated (Rep) coding sequences. Both these strategies are presently being assessed in cotton under field conditions. However, it remains to be seen whether the sequences being used provide a sufficiently broad-spectrum resistance to all the CLCuD-associated begomoviruses to be effective and durable under field conditions.

Introduction

Cowpea mosaic virus (CPMV) is the type member of the genus *Comovirus* which includes 13 additional members in the family *Comoviridae*. CPMV was first isolated from an infected cowpea (*Vigna unguiculata*) plant in Nigeria in 1959. Subsequently, it has been found to occur in Nigeria, Kenya, Tanzania, Japan, Surinam, and Cuba. While its natural host is cowpea, it can infect other legumes, and *Nicotiana benthamiana* has proven to be an extremely valuable experimental host. In nature, CPMV is usually transmitted by leaf-feeding beetles, especially by members of the Chrysomelidae. CPMV has also been reported to be transmitted by thrips and grasshoppers. The beetle vectors can acquire the virus by feeding for as little as one minute and can retain and transmit the virus for a period of days or weeks. The virus does not, however, multiply in the insect vector. Experimentally, CPMV is mechanically transmissible.

In Nigeria, infection of cowpeas with CPMV causes a considerable reduction in leaf area, flower production, and yield. Infected plant cells show a number of characteristic cytological changes. These include the appearance of viral particles, a proliferation of cell membranes and vesicles in the cytoplasm, and a variety of modifications to plasmodesmata.

Physical Properties of Viral Particles

Viral particles can reach a yield of up to 2 g kg^{-1} of fresh cowpea tissue and can be readily purified by polyethylene glycol precipitation and differential centrifugation. The particles are very stable with a thermal inactivation point in plant sap of 65–75 °C and a longevity in sap of 3–5 days at room temperature. Once purified, the particles can be stored for prolonged periods at 4 °C. The ease with which virus particles can be propagated, purified, and stored has undoubtedly contributed to the early popularity of CPMV as an object of study.

CPMV preparations consist of nonenveloped isometric particles, 28 nm in diameter, which can be separated on sucrose density gradients into three components, designated top (T), middle (M), and bottom (B), with sedimentation coefficients of 58S, 95S, and 115S, respectively. The three components have identical protein compositions, containing 60 copies each of a large (L) and small (S) coat protein, with sizes 42 and 24 kDa, respectively, as calculated from the nucleotide sequence. The discovery, in 1971, that CPMV particles contained equimolar amounts of two different polypeptides suggested that the capsids had an architecture more similar to the animal picornaviruses than to other plant viruses of known structure. This provided an early clue as to the common origins of plant and animal viruses.

The difference in the sedimentation behavior of the three centrifugal components of CPMV lies in their RNA contents. Top components are devoid of RNA, while middle and bottom components each contain single molecules of positive-strand RNA of 3.5 and 6.0 kbp, respectively. The two RNA molecules were originally termed middle (M) and bottom (B) component RNA after the component from which they were isolated. However, more recently they have been referred to as RNA-2 and RNA-1, respectively. The three-component nature of CPMV preparations is summarized in **Figure 1**. The determination of the component structure of the virus, and particularly the relationship between this and infectivity, was important in establishing the principle that plant viruses frequently have divided genomes, the individual components of which are separately encapsidated.

Because of their differing RNA contents, the three components of CPMV also differ in density and can hence be separated by isopycnic centrifugation on cesium chloride gradients. While T and M components give single bands of densities of 1.30 and 1.41 g ml^{-1}, respectively,

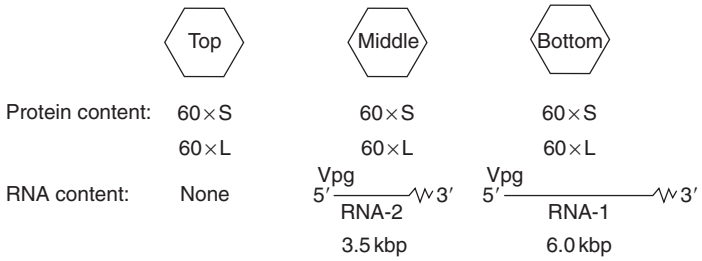

Figure 1 The three-component nature of CPMV indicating the protein and RNA content of each component.

B component gives two bands of 1.43 and 1.47 g ml^{-1}, the proportion of the denser band increasing under alkaline conditions. This increase in density results from an increase in capsid permeability, which allows the exchange of the polyamines present in B components (where they serve to neutralize the excess negative charges from RNA-1) for cesium ions.

CPMV preparations are not only centrifugally heterogeneous but can also be separated in two forms, fast and slow, electrophoretically. Both electrophoretic forms contain all three centrifugal components. The proportion of the two electrophoretic forms in a given virus preparation varies both with the time after infection at which the virus was isolated and the age of the preparation itself. Conversion of one form to the other is caused by loss of 24 amino acids from the C-terminus of the S protein.

Viral Structure

X-ray crystallographic studies on CPMV, as well as the related comoviruses bean pod mottle virus (BPMV) and red clover mottle virus (RCMV), have provided a detailed picture of the arrangement of the two viral coat proteins in the three-dimensional structure of the particle. Overall, the virions are icosahedral, with 12 axes of fivefold and 20 axes of threefold symmetry, and resemble a classic $T = 3$ particle. The two coat proteins taken together consist of three distinct β-barrel domains, two being derived from the L and one from the S protein. Thus, in common with the $T = 3$ viruses, each CPMV particle is made up of 180 β-barrel structures. The S protein, with its single domain, is found at the fivefold symmetry axes and therefore occupies a position analogous to that of the A-type subunits in $T = 3$ particles (**Figure 2**). The N- and C-termini domains of the L protein occur at the threefold axes and occupy the positions equivalent to those of the C- and B-type subunits of a $T = 3$ particle, respectively (**Figure 2**). This detailed analysis confirmed the earlier suggestion that CPMV particles are structurally homologous to those of picornaviruses, with the N- and C-terminal domains of the L protein being equivalent to viral protein VP2 and viral protein VP3, respectively, and the S protein being equivalent to viral protein VP1 (**Figure 2**). However, CPMV particles are structurally less complex than those of picornaviruses. The L and S subunits lack the extended N- and C-termini found in VP2, VP3, and VP1 of picornaviruses and there is no equivalent of VP4. Moreover, CPMV subunits lack the relatively large insertions between the strands of β-sheet, sequences that form the major antigenic determinants of picornaviruses. No RNA is visible in either the M or B components of CPMV, in contrast to the situation found with BPMV where segments of ordered RNA could be detected in middle components.

Genome Structure

Both M and B (but not T) components of a virus preparation are essential for infection of whole plants. As CPMV is a positive-strand RNA virus, a mixture of the genomic RNAs within the particles can also be used to initiate an infection. However, RNA-1 is capable of independent replication in individual plant cells but this leads to the establishment of gene silencing, rather than a productive infection, in the absence of RNA-2. Both genomic RNAs have a small basic protein (VPg) covalently linked to their 5′ termini and both are polyadenylated at their 3′ ends. The elucidation of the overall structure of the RNA segments once more underscored the similarity between CPMV and picornaviruses. However, unlike picornaviruses, the VPg is linked to the viral RNA via the β-hydroxyl group of its N-terminal serine residue rather than via a tyrosine. The VPg is not required for the viral RNAs to be infectious.

The complete nucleotide sequences of both genomic RNAs were reported in 1983, making CPMV one of the first RNA plant viruses to be completely sequenced. The length of the RNAs are 5889 and 3481 nucleotides, for RNA-1 and RNA-2, respectively, excluding the poly(A) tails and the full sequences appear in GenBank under accession numbers NC_003549 and NC_003550. The two genomic RNAs have no sequence homology apart from that at the 5′ and 3′ termini. Full-length infectious cDNA clones of both RNAs of CPMV have been

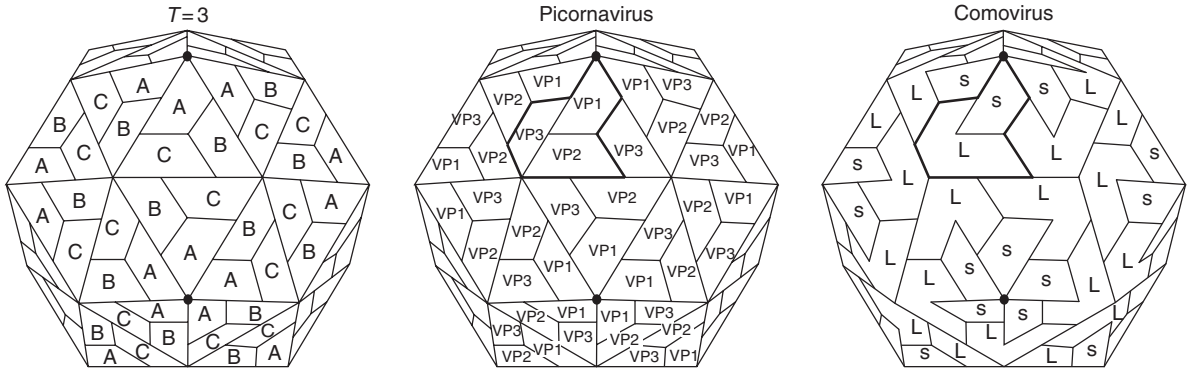

Figure 2 Arrangement of the coat protein subunits of comoviruses (including CPMV) compared with those of simple $T = 3$ viruses and picornaviruses. The asymmetric unit of $T = 3$ viruses contains three β-barrels contributed by three coat protein subunits with identical amino acid sequences (labeled A, B, and C). The asymmetric unit of a picornavirus also contains three β-barrels, but in this case each is contributed by a different coat protein (labeled viral protein VP1, viral protein VP2, and viral protein VP3). The comovirus capsid is similar to that of a picornavirus except that two of the β-barrels (corresponding to viral protein VP2 and viral protein VP3) are fused to give the L protein. Reproduced from Lomonossoff GP, Shanks M, *et al*. (1991) Comovirus capsid proteins: Synthesis, structure and evolutionary implications. *Proceedings of the Phytochemical Society of Europe* 32: 76.

constructed, allowing the genome to be manipulated. This was an important development since it allowed both reverse genetic experiments to be undertaken and for the virus to be used for biotechnological applications.

Expression of the Viral Genome

Both genomic RNAs contain a single long open reading frame, which occupies over 80% of the length of the RNA. A combination of *in vitro* translation and protoplast studies has unraveled the basic mechanism of gene expression of the virus. Both RNAs of CPMV are expressed through the synthesis and subsequent cleavage of large precursor polyproteins. This was the first example of a plant virus using this strategy for the expression of its genome, a strategy that was subsequently shown to be used by a number of other plant viruses. On RNA-1, initiation of translation occurs at the first AUG encountered on the sequence (at position 207) and results in the synthesis of a protein of approximately 200 kDa (the 200K protein). This initial product undergoes rapid cotranslational autoproteolysis to give proteins with apparent sizes of 32 and 170 kDa (the 32K and 170K proteins). The 170K protein undergoes further cleavages to give the range of virus-specific proteins shown in **Figure 3**. *In vitro* translation studies using mutant RNA-1 molecules have shown that all the cleavages occur most efficiently in *cis*. The 170K product can initially be cleaved at three different sites to give three different combinations of secondary cleavage products, 58K + 112K, 60K + 110K, and 84K + 87K. *In vitro*, and probably also *in vivo*, the 60K and 110K are stable and do not undergo further cleavage reactions. This is particularly curious in the case of the 110K protein as it contains both the 24K proteinase domain and a cleavage site. By contrast, the 112K and 84K proteins do undergo further cleavages. The end products of the cleavage pathway of the 170K protein are, from N- to C-terminus, the 58K protein, the VPg, the 24K proteinase, and the 87K protein.

Initiation of translation of RNA-2 occurs at two different positions on the RNA and results in the synthesis of two carboxy coterminal proteins, the 105K and 95K proteins (**Figure 3**). This double initiation phenomenon, which occurs as a result of 'leaky scanning', is found with the RNA-2 molecules of all comoviruses. In the case of CPMV, synthesis of the 105K protein is initiated from an AUG at position 161 while initiation from an AUG at position 512 directs the synthesis of the 95K protein. CPMV RNA-2 has an additional AUG (position 115) upstream of both these initiation sites but this feature is not conserved in the RNA-2 molecules of other comoviruses. Both RNA-2-encoded primary translation products are cleaved by the RNA-1-encoded proteolytic activity to give either the 58K or the 48K protein (depending on whether it is the 105K or 95K protein that is being processed) and the two viral coat proteins. Processing of the RNA-2-encoded polyproteins, at least at the site between the 48K and L coat protein, has been shown to require the presence of the 32K protein as well as the 24K proteinase.

Functions of the Viral Proteins

Functions have been ascribed to most of the regions of the polyproteins encoded by both RNA-1 and RNA-2 of CPMV. In most cases, however, it is not certain at what stage(s) in the cleavage pathway they manifest their activity.

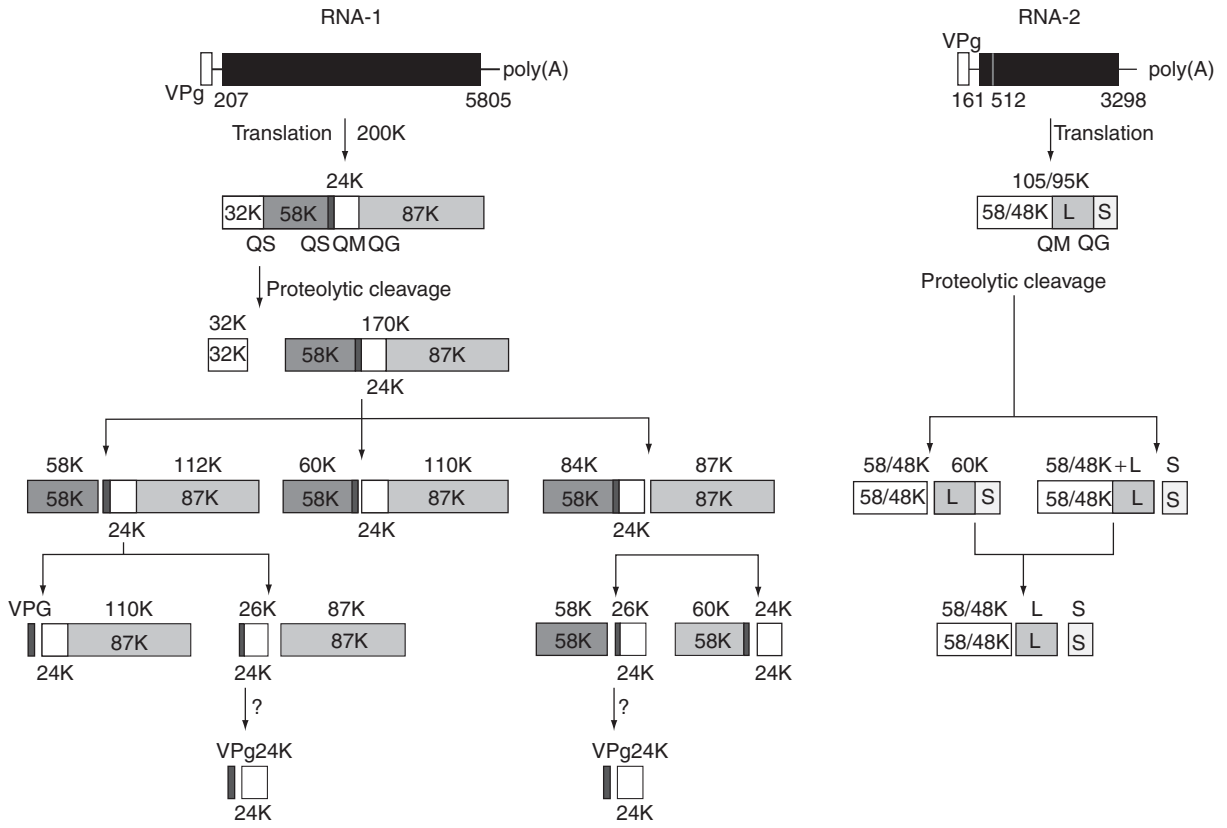

Figure 3 Expression of CPMV RNA-1 and RNA-2. Both RNAs contain a single long open reading frame, which is processed to yield a series of proteins. The positions of the initiation and termination codons and the dipeptides at the proteolytic processing sites are shown.

In the case of RNA-1, the 32K protein, which is rapidly cleaved from the N-terminus of the 200K primary translation product, is a cofactor which modulates the activity of the virus-encoded protease. As described earlier, the presence of the 32K protein is required for the cleavage of the RNA-2-encoded 105K and 95K proteins but is not essential for the cleavage of the RNA-1-encoded 170K protein. It does, however, seem to play a role in determining the rate at which cleavage of the 170K protein occurs. When mutant RNA-1 molecules carrying deletions in the region encoding the 32K protein are translated *in vitro*, the rate of processing of the 170K protein is greatly increased, indicating that the 32K protein acts as an inhibitor of processing. This inhibition may be achieved through the interaction of the 32K with the 58K domain of the 170K protein. The mechanism by which the 32K protein enables the 24K proteinase to cleave in *trans* is unclear.

The RNA-1-encoded 58K protein is associated with cell membranes and contains a nucleotide-binding motif. The 60K protein (**Figure 3**), containing the amino acid sequence of the 58K protein linked to VPg, is involved in rearrangements in the endoplasmic reticulum of CPMV-infected cells and acts in concert with the 32K protein. The 24K protein is the virus-encoded proteinase that carries out all the cleavages on both the RNA-1- and RNA-2-encoded polyproteins. Its proteolytic activity has been shown to be expressed in a number of the processing intermediates that contain its sequence. Indeed, it is not known whether the free form of the protein has any biological significance. Although the proteinase contains a cysteine at its active site, it is structurally related to serine proteases, such as trypsin, rather than cellular thiol proteases, such as papain. In this regard, it is similar to the 3C proteinases of picornaviruses. All comoviral cleavage sites identified so far have glutamine (Q) residue at the −1 position. The enzyme encoded by a given comovirus is specific for the polyproteins encoded by that virus and is unable to cleave the polyproteins from other comoviruses either in *cis* or in *trans*.

The 87K protein is believed to contain the virus-encoded RNA-dependent RNA polymerase (RdRp) activity since it contains the G-D-D sequence motif found in all such enzymes. It also has amino acid sequence

homology to the $3D^{Pol}$ polymerases encoded by picornaviruses. However, when replication complexes capable of elongating nascent RNA chains were isolated from CPMV-infected cowpea plants, they were found to contain the 110K protein (**Figure 3**), consisting of the sequence of 87K protein linked to the 24K proteinase, rather than the free 87K protein.

In the case of RNA-2, the 48K protein, derived from processing of the 95K protein, is involved in potentiating the spread of the virus from cell to cell. This protein is found in tubular structures that are formed in the plasmodesmata of infected cells. Tubules extending into the culture medium can also be seen in protoplasts either infected with CPMV or transiently expressing the 48K protein. Virus particles can be seen within these tubules when protoplasts are infected with CPMV but not when only 48K protein is expressed. At present, no definite role has been assigned to the 58K protein, which is produced by processing of the 105K protein. Mutants in which translation of the 105K protein is disrupted replicate poorly, if at all. In light of these observations, it has been suggested that the 105K protein may play a role in the replication of RNA-2. Apart from containing many hydrophobic and aromatic amino acids, the approximately 10 kDa of protein present in the 58K but absent from the 48K protein is not conserved between comoviruses. The viral coat proteins are required to enable capsids to be formed. As well as protecting the genomic RNAs, capsid formation is essential for the virus to be able to spread from cell to cell through modified plasmodesmata and long-distance movement also requires capsid formation. An additional function in suppressing gene silencing is also provided by the C-terminal region of the S protein.

Replication

CPMV replicates to high level in infected cells. Replication is believed to involve the initial transcription of the incoming positive-sense RNA into minus-strands followed by initiation and synthesis of new plus-strands from the recently formed minus-strands. It has been shown that the 5′ends of both the plus- and minus-strands are covalently linked to the VPg, suggesting that this protein has an essential role in the initiation of RNA synthesis. There also appears to be a tight linkage between the translation of the viral RNAs and their replication.

Replication of the viral RNAs has been shown to occur in the membraneous cytopathological structures, which are formed in the cytoplasm of cells during infection through the action of the RNA-1-encoded 32 and 60K proteins. Both CPMV-specific double-stranded replicative form (RF) RNA and an enzyme activity capable of completing nascent RNA strands can be isolated from such structures. Purified preparations of the enzyme activity contain the RNA-1-encoded 110K protein and two host-encoded proteins of 68 and 57 kDa. However, at present, no enzymatic activity capable of initiating RNA synthesis *in vitro* has been described.

Relationships with Other Viruses

Together with the genera *Nepovirus* and *Fabavirus*, the genus *Comovirus* belongs to the family *Comoviridae*. Within the family, the greatest affinity is between the genera *Comovirus* and *Fabavirus*. On a wider scale, consideration of genome structure and organization, translational strategy, and amino acid homologies between the virus-encoded proteins has led to grouping the family *Comoviridae* with the families *Potyviridae* and *Picornaviridae* as members of picorna-like superfamily of viruses. Members of this superfamily are all nonenveloped positive-strand RNA viruses with 3′ polydenylated genomic RNAs, which have a protein (VPg) covalently linked to their 5′ ends. All members of the supergroup have a similar mode of gene expression, which involves the synthesis of large precursor polyproteins and their subsequent cleavage by a virus-encoded proteinase. The members of the superfamily all contain similar gene order, membrane-bound protein-VPg-proteinase-polymerase (see **Figure 3**) and share significant amino acid sequence homology in the membrane-bound proteins, the proteinases, and polymerase coding regions. Comovirus capsids are also clearly structurally related to those of picornaviruses (**Figure 2**).

Use in Biotechnology

CPMV has been extensively used as a vector for the expression of foreign peptides and proteins in plants. To date, all vectors have involved modifications to RNA-2 (**Figure 4**). In the first instance, antigenic peptides (epitopes) were genetically fused to exposed loops on the surface of the viral capsids. The resulting chimeric virus

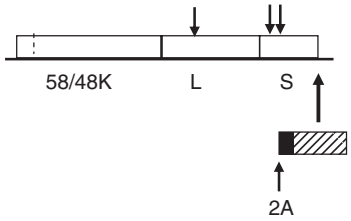

Figure 4 Structure of CPMV RNA-2-based vectors used to express heterologous peptides and proteins in plants. Positions where epitopes have been inserted into the sequence of the coat proteins are shown by black arrows. The position where foreign proteins (shown hatched) have been inserted into RNA-2 is indicated. The FMDV 2A sequence is shown as a black box at the N-terminus of the foreign protein.

particles (CVPs) could be propagated in plants and the modified virions purified. When injected into experimental animals, CVPs can elicit the production of antibodies against the inserted epitope and in a number of instances can confer protective immunity against the pathogen from which the epitope was derived. This was a significant breakthrough as it represented the first instance where protection against an animal pathogen was conferred by material produced from a plant virus-based vector.

In an alternative approach, the sequence encoding an entire heterologous polypeptide has been fused to the C-terminus of the RNA-2-encoded polyprotein via a 2A catalytic peptide derived from foot-and-mouth disease virus (FMDV). The inclusion of the 2A sequence promotes efficient release of the foreign polypeptide from the polyprotein (**Figure 4**). This system has been used to express antibody derivatives in cowpea plants and crude plant extracts containing the antibodies have been shown to be capable of passively immunizing newborn pigs against challenge with the porcine coronavirus, transmissible gastroenteritis virus.

Recent developments in the use of comoviruses in biotechnology include the creation of combined transgene/viral vector systems based on CPMV, and the use of CPMV particles in bionanotechnology.

History

The first published account of cowpox in man and cattle is probably that of Edward Jenner in his *Inquiry* published in 1798, although others, such as Benjamin Jesty, performed immunization of humans with cowpox material earlier. Jenner described the clinical signs of cowpox in both hosts, and how infection in man with *Variolae vaccinae* ('known by the name of the cowpox') provided protection against smallpox. At that time, smallpox was responsible for between 200 000 and 600 000 deaths each year in Europe and about 10% of all deaths in children. Jenner's discovery, despite the concern of some over the consequences of inoculating bovine material into man, soon led to the establishment of smallpox vaccination schemes around the world. However, not until Pasteur's work *c.* 100 years later was the principle of immunization used again. In fact, it was Pasteur who suggested that all such immunizations be called vaccines in honor of Jenner's work.

Although Jenner's first vaccines probably came indirectly from cattle, later vaccine material was often derived from horses, and the origin(s) of modern vaccinia virus (VACV) the smallpox vaccine, remain unknown. That cowpox virus (CPXV) and VACV are different was first published in 1939, since when further biological and genetic studies have confirmed that VACV represents a species in its own right, and is not simply a mutant of CPXV or a recombinant of variola virus (VARV) and CPVX.

Even Jenner seems to have had difficulty finding cowpox cases, and CPXV is not endemic in cattle. Rather, it is endemic in rodents, and cattle and man are merely accidental hosts. The domestic cat is the animal diagnosed most frequently with clinical cowpox in Europe.

Taxonomy and Classification

CPXV represents the species *Cowpox virus*, a member of the genus *Orthopoxvirus* in the family *Poxviridae*, and the international reference strain, Brighton Red, was isolated from farm workers in contact with infected cattle in 1937. CPXV can be differentiated from other orthopoxviruses

(OPVs) by a combination of biological tests, including the ability to produce hemorrhagic pocks on chorioallantoic membranes, the production of A-type inclusions (ATIs) in infected cells, and its ceiling temperature for growth (40 °C, the highest temperature at which the virus will replicate), by minor antigenic differences, by restriction enzyme digestion of the entire genome, particularly with *Hin*dIII, by sequencing of certain genes, and by polymerase chain reaction (PCR). There is considerably more variation between some CPXV isolates than between strains of other OPV species, such that some CPXV strains might be reclassified as separate species rather than strains of the same species. This variation is seen in biological properties (e.g., ceiling temperature of growth, and possibly virulence in different hosts) and genome (restriction enzyme fragment polymorphism, gene content, and nucleotide sequence). It is not yet known whether these differences reflect variation in geographic range or reservoir host.

Properties of the Virion

CPXV has a typical OPV morphology, and is indistinguishable from VACV by electron microscopy. Virions are brick shaped, approximately 300 nm × 200 nm × 200 nm in size, and are enveloped. There are two types of virion. The simpler form, termed intracellular mature virus (IMV), consists of a biconcave core, and within each concavity lies a lateral body. The whole is surrounded by a lipid membrane, and an outer layer of protein. The core contains DNA and proteins, many of which are virus-encoded enzymes. The second form is called extracellular enveloped virus (EEV), and these virions are surrounded by an additional lipid envelope that is fragile and is derived from either the *trans*-Golgi network or endosomes.

The life history of CPXV within the cell is very similar to that of VACV, except that intracellular nonenveloped, yet infectious, virions can become incorporated into large intracytoplasmic ATIs (**Figure 1**). It is thought that these inclusions help protect the virus after cell lysis, and so are important in survival in the environment and spread from animal to animal. In contrast, EEV is more important for spread within individual hosts.

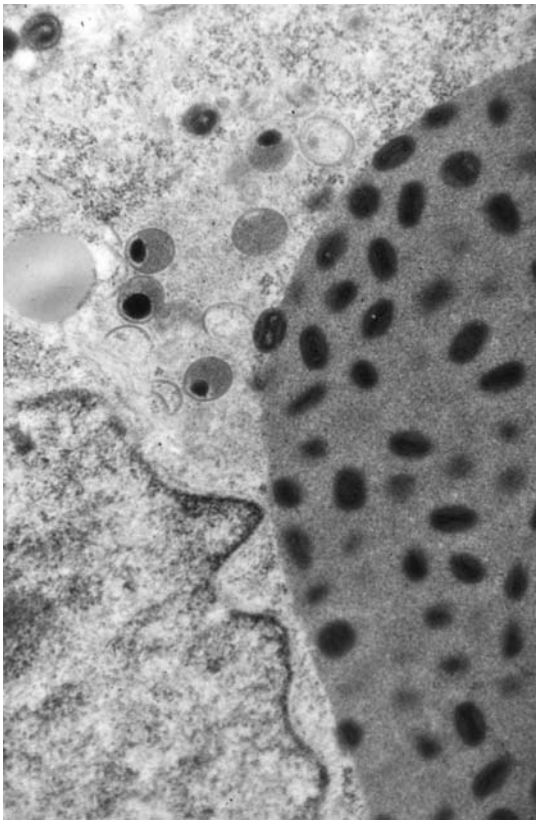

Figure 1 A CPXV-infected cell, showing intracytoplasmic virion synthesis and an ATI containing intracellular mature virions.

Properties of the Genome

The genome consists of linear, double-stranded DNA with covalently linked inverted repeats at the termini. The CPXV genome is the largest of all the OPV genomes and for strain Brighton Red is 224 501 bp. Restriction endonuclease mapping and nucleotide sequencing demonstrated that the middle portion of the CPXV genome (approximately 100 kbp) is highly conserved between OPVs, but more variation occurs toward either end. Digestion with *Hin*dIII usually differentiates CPXVs from other known OPVs, but isolates, particularly geographically distinct strains, do vary in profile, and digestion of genomic DNA with other enzymes often reveals much greater differences between strains. However, overall the genome is fundamentally very stable. The main exception to this is the deletion of 32–39 kbp of DNA from the right end of the genome and its replacement by DNA from the left end: these terminal transpositions are the cause of the 1% white pocks observed on infected chorioallantoic membranes. The size of the transposed fragment varies (5–50 kbp) but the net effect is a change in the length of the inverted terminal repeat (ITR), the duplication of some genes, and the loss of others.

The nucleotide sequences of two CPXV genomes, and of particular genes for a much greater number of isolates, have been determined. CPXV not only has the largest OPV genome, but it also encodes the greatest number of complete protein-coding open reading frames (ORFs) and has relatively few genes that are broken by mutation into fragments. Such broken ORFs are more common in other OPVs such as VARV, camelpox virus (CMLV), and taterapox virus (TAPV). These observations suggest that CPXV might be closest in its genetic complement to the

ancestral poxvirus from which OPVs have evolved. PCR-based diagnostic methods are now used to distinguish CPXV from other OPVs.

Properties of Proteins

The genome of CPXV Brighton Red is predicted to encode more than 200 proteins. Like other OPVs, the proteins encoded in the central part of the genome are mostly essential for virus replication, and in this region 89 genes have counterparts in all sequenced chordopoxviruses. Generally, these CPXV proteins are very closely related to their counterparts in VACV, VARV, and other OPVs. This is certainly true for the proteins that are present in the infectious virion, and the finding that the proteins on the surface of IMV and EEV are very closely related provides a plausible explanation why VACV and CPXV were effective vaccines against smallpox. In contrast, genes located toward the genome termini are nonessential for virus replication in cell culture and these include approximately half of all CPXV genes. Notably, CPXV encodes many genes that are not found in VACV strains.

Interest has focused on proteins concerned with immune modulation, and these are encoded mostly near the left and right ends of the genome. Experimentation has demonstrated that several of these genes (or their orthologs in VACV) are associated with virulence in accidental hosts, but their functions in natural rodent hosts may be more subtle. Possibly their role in natural infection, where clinical disease is not seen and presumably not relevant to transmission, is to moderate the host's immune response, ensuring efficient contact between individuals and therefore transmission.

Other proteins expressed by CPXV but not VACV have been studied, such as those affecting the ability to grow on Chinese hamster ovary (CHO) cells and produce ATIs. Growth of CPXV in CHO cells is dependent on production of a 77 kDa protein and the insertion of the gene encoding this protein into VACV enables that virus to replicate in CHO cells. Formation of ATIs involves the production of two late proteins. One, of 160 kDa, is the major component of the inclusion itself. The other is required for occlusion of virions into the ATI.

A red pock character is associated with the *crmA* gene, which encodes a 38 kDa protein that is one of the most abundant early gene products and a serine protease inhibitor that inhibits apoptosis and the cleavage of pro-interleukin (IL)-1β to IL-1β. This gene is lost in the frequent deletion mutants referred to above. The essential difference between the wild-type and mutant white pock is the greater hemorrhage in the former and the massive leukocyte infiltration in the latter. Although a protein with 93% amino acid sequence identity is encoded by VACV strain Western Reserve, pocks formed by this virus are white irrespective of whether or not the protein (B13) is expressed.

Physical Properties

Little work has been done directly on the physical properties of CPXV, which are usually assumed to be similar to those of VACV and ectromelia virus (ECTV). The outer lipid envelope of extracellular forms of CPXV is labile and readily lost by mechanical stress, but is not essential for virus infectivity because its removal releases an infectious IMV particle. The virus is generally very hardy, and can survive for months in dry scab material at room temperature, and indefinitely at −70 °C. It is inactivated by moist heat at 60 °C for 10 min, and by hypochlorites, phenolics, and detergents, but less effectively by alcohols. The significance of survival in the environment to the epidemiology of cowpox is unknown. The transmission dynamics of natural infections suggest that most transmission is direct. However, in populations of rodents on small islands, infection occurs as small epidemics followed by apparent extinction: whether these epidemics result from immigration of infected individuals, or survival of the virus in the environment with rare reintroduction into naive populations, has not been resolved.

Replication

The mechanisms of DNA replication and temporally regulated transcription and translation of CPXV mRNA are assumed to be very similar to those in VACV. Virus replication takes place in the cytoplasm, and virus assembly occurs in areas known as B-type inclusions. Like VACV, CPXV virions can leave the cell as IMV by lysis of the cell membrane, or as EEV by exocytosis following fusion between the outer membrane of intracellular enveloped virus (IEV) and the plasma membrane. CPXV differs from VACV in that its genome also encodes for large proteinaceous inclusions known as ATIs, into which virions are incorporated (**Figure 1**). These inclusions are released by cell lysis, and are thought to act as protective packets that aid survival of the virus outside of the animal and therefore increase the chance of spread to another host on fomites.

Geographic and Seasonal Distribution

CPXV has been isolated, or detected by PCR and sequencing, throughout much of Northern Europe and as far east as Kazakhstan. Although cases of human and feline cowpox may be seen at any time of year, infection is most common

in the late summer and autumn, which probably reflects increased infection in the reservoir hosts, which in turn reflects increased numbers of hosts at that time of year.

Host Range and Propagation

CPXV has a wide host range both *in vivo* and *in vitro*. It has been isolated from cattle, humans, domestic cats (perhaps the most common source of human infection), dogs, a horse, and a variety of zoo animals including cheetahs, ocelots, panthers, lynx, lions, pumas, jaguars, anteaters, elephants, rhinoceroses, and okapis. All of these are, however, accidental hosts, and the virus circulates mainly in wild rodents. The main reservoir hosts appear to be voles (*Clethrionomys* spp. and *Microtus* spp.) and wood mice (*Apodemus* spp.) throughout the virus' range. House mice (*Mus musculus*) and rats (*Rattus norvegicus*) are infected rarely and are probably accidental hosts (explaining the limited geographic range of the virus), although they may, like cats, act as liaison hosts and transmit the infection onward to man. Other rodents may also act as reservoirs toward the eastern range of the virus. CPXV has been isolated from wild susliks and gerbils (*Rhombomys* spp., *Citellus* spp., and *Meriones* spp.) in Turkmenia. Guinea pigs and rabbits have been infected experimentally with CPXV.

CPXV can be isolated and propagated on the chorioallantoic membrane of hens' eggs, but, unlike VACV, it does not grow in feather follicles of adult chickens. It can be propagated in a variety of cell cultures derived from human, simian, bovine, feline, murine, and rabbit tissues.

Genetics

CPXV produces red hemorrhagic pocks on the chorioallantoic membrane with about 1% white pock mutants. The virus that produces the white pocks breeds true and the change in pock character reflects deletion and transposition events near the termini of the genome. White pock mutants are better able to grow on arginine-deprived cells than is the parent virus. Other properties that are inherited independently, and vary between individual strains, include production of the hemagglutinin, incorporation of virions into ATIs, resistance to heat inactivation, ceiling temperature for growth, and virulence for newborn mice and chick embryos. OPVs undergo genetic recombination in dual-infected cells, for example producing hybrids of CPXV and VARV.

Evolution

The genetic relationships of CPXV and other OPVs have been studied by bioinformatics. Nucleotide sequencing demonstrated that the OPVs are very closely related as a whole (although the North American OPVs appear more distantly related), but each species can be readily differentiated by biological properties and genome structure. Bioinformatic analyses demonstrated that the two CPXV genomes sequenced are quite divergent and it was proposed they should be reclassified as separate species. As noted above, the presence of the greatest number of intact genes and fewest broken genes suggests that CPXV is closest to the ancestral OPV. With the exception of terminal transposition events (see above), CPXV isolates are genetically stable *in vitro* and *in vivo*. Modern isolates often have near-identical restriction enzyme profiles to isolates made many years ago, and the Brighton Red strain behaves the same now as when first isolated over 60 years ago. However, isolates of CPXV do differ in restriction enzyme pattern and minor biological characteristics, and generally greater differences occur between geographically distinct isolates. Furthermore, the greatest variation appears to be seen among isolates in central Europe, and this may reflect a central European origin for CPXV and divergence as individual strains spread out into different host reservoirs and different geographical areas.

CPXV isolates are all clearly different from other OPVs, such as VACV and VARV, but the genome sequence of horsepox virus (from Central Asia) shows that it is intermediate between VACV and CPXV and shares some properties of each virus.

Serologic Relationships and Variability

Within the genus *Orthopoxvirus*, there is extensive antigenic cross-reactivity in all serologic tests, although minor differences can allow differentiation of species using monoclonal antibodies. No significant serologic differences have been reported among CPXV strains.

Epidemiology

CPXV is rarely isolated from cattle, and serologic surveys show that cattle are not the reservoir host. Most human infection cannot be traced to contact with infected cattle, but about half of the recent human cases in Britain were traced to contact with an infected cat. The domestic cat, although the species in which clinical cowpox is most frequently diagnosed in Europe, is not the reservoir host of CPXV either. Although cat-to-cat transmission can occur, antibody to CPXV is uncommon in surveys of healthy cats. There is no evidence that CPXV can become endemic in any of the zoo animals that have been infected, but with increasing reliance on zoo populations for the survival of many species, these outbreaks may cause conservation problems.

Rather, CPXV is endemic in rodent populations. Transmission has been studied in most detail in several populations of voles (*Clethrionomys glareolus* and *Microtus agrestis*) and wood mice (*Apodemus sylvaticus*) in northern England, where it has been used as a model system for investigating the ecology of endemic infections in wildlife populations. Transmission dynamics appear linked to host population dynamics, with the highest incidence of infections occurring in the autumn when population sizes are at their greatest. This is reflected in the highest incidence of infection in cats and human beings also at this time of year. Although cross-species transmission may occur, empirical evidence combined with mathematical models suggests that most transmission occurs among members of the same rodent species, even where two rodent host species share the same habitat.

Transmission and Tissue Tropism

Both natural rodent hosts and laboratory rodents can be infected with CPXV by the oral and respiratory routes as well as skin inoculation: natural hosts can often be infected with less virus than is required to infect cell culture, as is the case with ECTV where the lethal dose for some strains of mice may be less than one plaque-forming unit. However, it is not known how the virus is transmitted in the wild, and transmission has not occurred among laboratory-housed rodent hosts. This may be because a particular behavior, not elicited in the laboratory, is involved in transmission. Transmission rates in the wild can be very high, and longitudinal studies of naturally infected populations suggest that much transmission, although not all, is frequency, rather than density, dependent, which might itself suggest an important role for particular behaviors in transmission.

Among the occasional hosts of CPXV, the most frequent route of infection appears to be through the skin, probably through a cut or abrasion. Domestic cats, however, can be infected experimentally by oronasal inoculation, and limited respiratory spread sometimes occurs in domestic or zoo cat colonies.

Virus replication in cattle and man is mainly limited to the epidermis at the site of entry, and possibly also to draining lymph nodes. In cats, virus can be isolated not only from skin lesions but also from lymphoid, lung, and turbinate tissue. Skin inoculation of cats is followed by virus replication both at the site of entry and in draining lymph nodes, which leads to the development of a viremia, and virus can be isolated from the white cell fraction of blood, from the spleen, and other lymphoid organs. After about 7–10 days, virus can be detected in the epidermis, leading to the development of secondary skin lesions. The viremia in cats appears to last 1–8 days, and no virus has been isolated from cats after the skin lesions have healed, which may take 5–6 weeks.

Oral, nasal, and skin inoculation of various rodents with CPXV also causes systemic infection. Virus has been isolated from lung, kidney, liver, and lymph nodes of susliks and gerbils, and detected by PCR in a similar range of tissues, and the cellular fraction of blood from naturally and experimentally infected British wild rodents. Laboratory infection and studies of naturally infected wild voles and wood mice suggest that they remain infected for around 4 weeks before clearing the infection.

Virulence

It is not known whether different strains of CPXV vary in virulence for most accidental hosts, including man. In a small-scale experiment, no differences in the ability to cause infection or a primary lesion in domestic cats could be detected between the Brighton Red strain and isolates from a cheetah and a domestic cat. Differences in virulence of different strains do exist for newborn laboratory mice and chick embryos, but these differences are not associated with the ability to infect various accidental hosts and it is not known whether they have any significance in the maintenance of different strains of CPXV in different reservoir tests.

Wild-type CPXV outgrows the white pock mutants and is more virulent for laboratory animals.

Clinical Features of Infection

In cattle, CPXV causes teat lesions, but little apparent systemic disease. Human infection is characterized usually by a single skin lesion, often on a hand or the face. Spread of skin lesions in man is usually the result of direct transmission, for example, from hand to face, but multiple lesions may also occur if there is a preexisting skin condition. Cowpox in man is often accompanied by systemic signs such as nausea, fever, and lymphadenopathy, and children are often hospitalized. Death is rare, and usually the result of an underlying condition, such as immunodeficiency, which increases the severity of disease.

CPXV infection in domestic cats is usually a more severe disease than in cattle or man. There is often a history of a single primary lesion, especially on the head or a forelimb, but by the time the cat is presented for veterinary attention widespread skin lesions have usually developed. The primary lesions vary enormously in character, and secondary bacterial infection is common. The widespread secondary lesions first appear as small erythematous macules, which develop into papules and ulcers over several days. These scab over, and the cat

usually recovers within 6–8 weeks. Cats may be slightly pyrexic in the early stages of the disease and some show signs of mild upper respiratory disease. More severe illness such as large nonhealing lesions or pneumonia usually, but not always, results from secondary bacterial infection or immunosuppression. In some zoo-kept cats, such as cheetahs, pneumonia is more common and is associated with a high mortality rate.

No obvious clinical signs are observed in either naturally or experimentally infected rodents (unless the experimental dose used is high). However, longitudinal studies of naturally infected wild voles and wood mice, at both the individual and population levels, as well as experimental infections, have shown an effect on rodent fecundity. Infected voles and mice delay reproduction compared to uninfected animals in the wild by perhaps a whole season.

Pathology and Histopathology

Skin lesions associated with cowpox in most accidental hosts are typical of those expected of an OPV infection, developing through papule, vesicle, pustule, ulcer, and healing stages, although macroscopic vesicles often ulcerate quickly because of abrasion or, in the case of domestic cats, because the epidermis is too thin in most areas to support a vesicle. Microscopic examination reveals hypertrophy and hyperplasia of infected cells, multilocular vesicle formation, large, intracytoplasmic eosinophilic inclusion bodies (ATIs) (**Figure 1**) in epithelial cells, and a vigorous polymorph infiltration of the dermis. Immunostaining demonstrates virus antigen in epithelial cells of the skin, hair follicles, and sebaceous glands, and in dermal macrophages.

Even in lungs and turbinates of cats from which large amounts of virus can be isolated, there are often no gross lesions, and microscopic lesions may be difficult to find. In cats showing clinical signs of pneumonia, there is often an interstitial pneumonia, and, again, eosinophilic inclusions can be seen in infected cells. The tonsils and lymph nodes of infected cats contain many large reactive follicles, and immunostaining may demonstrate antigen in macrophage-like cells. Some follicles have large necrotic centers, suggesting that virus replication is occurring here.

After 3 days of growth on the chorioallantoic membrane of 12 day chick embryos, CPXV causes hemorrhagic pocks approximately 2 mm in diameter, with a few (usually 1%) white pocks. Microscopically, the red pocks consist of ectodermal proliferation and hypertrophy with many cells containing ATIs, and extensive edema and hemorrhage into the mesoderm. The histopathology of white pocks is similar but consists of more inflammatory infiltration and no hemorrhage.

Immune Response

Relatively little is known about the immune response to CPXV in naturally infected hosts. Antibody can be detected by enzyme-linked immunosorbent assay (ELISA), immunofluorescence, virus neutralization (VN) (usually done with the IMV form of virus) with or without complement, complement-fixation, and hemagglutination-inhibition (HAI) tests. HAI antibody can be detected before VN antibody, and in cattle and cats begins to decline after about 6 months. HAI antibody is therefore more useful for the diagnosis of acute infections than VN antibody, and in epidemiological studies indicates more recent infection than VN antibody alone.

As in VACV and ECTV infections, cell-mediated immunity plays an important role in protection against CPXV disease, but less work has been published specifically on the cell-mediated immunity to CPXV. A possible delayed-type hypersensitivity response has been reported in cats.

Prevention and Control

Infection in man and domestic animals is relatively uncommon and so measures to prevent infection are generally not warranted. Vaccination against smallpox is no longer routine, and might not protect against the development of a skin lesion, but would reduce the severity of any systemic illness. VACV infection of cattle and man often causes lesions and disease similar to cowpox. VACV does not grow well in cats, and its efficacy as a vaccine (although not necessarily as a vaccine vector) in felids is uncertain, although it has been recommended for some zoo animals.

Although CPXV can cause quite severe disease in man, it does not appear to be very infectious. Human-to-human spread of cowpox has not been reported (in contrast to VACV). Many human cases of cowpox have been traced to contact with infected cats, but we know of no cases of cat-to-human transmission after cowpox was diagnosed in the cat. Simple hygiene – washing hands after handling the cat, keeping the cat or scab material away from cuts and the eyes – seems adequate to prevent transmission to man, although special measures might be taken for the very young, elderly, or immunosuppressed. Similarly, if an outbreak occurs in cattle, the main route of spread among the cows is through milking equipment, and simple hygiene should suffice to control spread.

Future Perspectives

CPXV is one of several OPVs that have wildlife reservoirs; others include monkeypox virus, raccoonpox virus,

and Californian volepox virus. Buffalopox virus is now regarded as a variant of VACV and may also have a wild animal reservoir in India. Occasionally, these and other OPVs may infect other, accidental, hosts, such as domestic animals: there are reports of uncharacterized OPVs being isolated from horses, for example, in Africa, North America, and Australia, and a recent report of raccoonpox virus infection in a cat in Canada. Study of the ecology of CPXV is therefore useful as a model for OPV maintenance in a wildlife reservoir host and the mechanisms of transmission from animals to man. It is also being studied in wild rodents as an ecological model of transmission of endemic infections, and the interactions between host and parasite dynamics.

Coxsackieviruses

M S Oberste and M A Pallansch, Centers for Disease Control and Prevention, Atlanta, GA, USA

Published by Elsevier Ltd.

Glossary

Chemosis Edema of the bulbar conjunctiva.
Conjunctival hyperemia Increased blood flow to the conjunctiva.
Cytopathic effect Degeneration of cultured cells due to virus infection and replication, often characteristic of a given virus.
Exanthem Illness characterized by skin eruption (rash).
Myalgia Nonspecific muscle pain or tenderness.
Nuclear pyknosis Condensation and reduction in size of the nucleus, often the result of a pathogenic process.
Pleurodynia Illness characterized by chest pain due to inflammation of the pleura, the membrane surrounding the lungs and chest cavity.
Protomer Basic unit of a virus capsid, containing one or more viral proteins.

History

The coxsackieviruses (genus *Enterovirus*, family *Picornaviridae*) were discovered in the late 1940s, as a result of intense efforts to develop better systems to propagate and study poliovirus. At the time, nonhuman primates were

the model system for poliovirus and poliomyelitis, as cell culture and inoculation of suckling mice were just being introduced. Investigators at the New York State Department of Health inoculated suckling mice with fecal suspensions from two suspected poliomyelitis cases. The mice became paralyzed, but the viruses were not polioviruses – the virus was later named 'coxsackievirus' (CV) for the patient's home town, Coxsackie, New York. Subsequent studies identified related viruses, some causing spastic paralysis rather than the flaccid paralysis observed with the initial isolates. Based on these differences in pathogenicity, the viruses were classified as group A coxsackieviruses (flaccid paralysis) or group B coxsackieviruses (spastic paralysis), with the individual virus types being numbered sequentially within each group (e.g., coxsackievirus A2 or coxsackievirus B5). Once cell culture became established as a standard laboratory technique, additional viruses were discovered that were able to replicate in culture but caused no disease in mice. Since many of these were derived from stools of healthy individuals and they were not yet known to cause disease in humans, they were termed enteric cytopathic human orphan viruses or 'echoviruses' – these were also named using consecutive numbers (e.g., echovirus 9). The early coxsackieviruses had been isolated from cases of 'nonparalytic poliomyelitis' (aseptic meningitis), showing that this disease was not necessarily caused by polioviruses. Other illnesses, including herpangina, rash, pleurodynia, and myocarditis, were also shown to be associated with coxsackievirus infection; later, the echoviruses were later shown to be associated with many of these same illnesses.

Taxonomy and Classification

As mentioned, the term 'coxsackievirus' was applied to enteroviruses that caused paralysis upon intracerebral inoculation in suckling mice, with the type of paralysis – flaccid versus spastic – being used to place strains in group A or group B. When it was discovered that antigenically related viruses could have varying degrees of pathogenicity in mice, the original naming convention was abandoned and since 1967 all new enteroviruses (whether coxsackievirus-like or echovirus-like) have been named 'enterovirus' followed by a sequential number, starting with enterovirus 68. Enteroviruses have traditionally been classified antigenically, using well-characterized, standardized antisera in a neutralization assay, either in cell culture or in suckling mice (for viruses that replicate poorly in culture). Using this approach, 30 coxsackievirus serotypes were defined, with 24 in group A and six in group B. Coxsackievirus A23 was later discovered to be antigenically identical to echovirus 9, so CVA23 was dropped as a distinct serotype.

It was recognized early on that there were many limitations to the antigenic typing approach. In addition to the labor-intensive nature of the neutralization assay and the requirement for extensive characterization of new antisera, different serotypes may cross-react in complex combinations and individual strains of a given type may react differently with different preparations of homotypic antisera. Once nucleotide sequences became available for a large number of serotypes, it became clear that the sequences of certain parts of the capsid-coding region could serve as a surrogate for antigenic type. In the late 1990s and early 2000s, several investigators developed typing systems based on polymerase chain reaction (PCR) amplification of a portion of the capsid region, followed by sequencing and analysis of the sequence to determine type. Eventually, VP1 was settled upon as the most reliable region for molecular virus typing. Sequence comparisons have shown that CVA15 is a strain of CVA11 and CVA18 is a strain of CVA13.

Sequence relationships are now recognized as a primary discriminating characteristic in enterovirus taxonomy. There are currently eight species in the genus *Enterovirus*: *human enterovirus* (HEV) A–D, *Poliovirus*, *Bovine enterovirus*, *Porcine enterovirus*, and *Simian enterovirus A*. There are current proposals to merge *Poliovirus* with HEV-C and to move the two human rhinovirus species from their own genus into *Enterovirus*. The coxsackieviruses are distributed among three species: HEV-A (CVA2–8, CVA10, CVA12, CVA14, and CVA16), HEV-B (CVA9, CVB1–6), and HEV-C (CVA1, CVA11, CVA13, CVA17, CVA19–22, and CVA24) (**Table 1**).

Host Range and Virus Propagation

Coxsackieviruses are primarily human pathogens but many can also infect certain nonhuman primate species and all serotypes are able to infect and cause disease in mice (by definition), though there is some variability among strains of any given type. Infection of nonhuman primates often fails to induce clinical disease, but CVA7

Table 1 Coxsackievirus taxonomy

Species	*Serotype*
Human enterovirus A[a]	CVA2–8, CVA10, CVA12, CVA14, CVA16
Human enterovirus B[b]	CVA9, CVB1–6
Human enterovirus C[c]	CVA1, CVA11, CVA13, CVA17, CVA19–22, CVA24

[a]Also includes EV71, EV76, EV89–92.
[b]Also includes all echoviruses, EV69, EV73–75, EV77–88, EV93, EV97–98, EV100–101.
[c]Also includes polioviruses, EV95–96, EV99, and EV102.

can induce polio-like paralysis in monkeys. Swine vesicular disease virus, an important livestock pathogen because symptoms of illness are similar to those of foot and mouth disease, is closely related genetically and antigenically to CVB5. Genetic and epidemiologic studies strongly suggest that human CVB5 was introduced into swine decades ago, with subsequent adaptation and diversification in the new host species.

The best specimens for virus isolation are stool specimens or rectal swabs, throat swabs or washings, and cerebrospinal fluid, in that order. Isolation from stool is most sensitive because virus is usually present at higher titer and it is present in stool longer than in any other specimen. Nonfecal specimens are most likely to yield virus isolates if they are obtained early in the acute phase of illness. For cases of acute hemorrhagic conjunctivitis, the best specimens are conjunctival swabs and tears. A number of different primary cell cultures and continuous cell lines, both generally of human or monkey origin, have been used for isolation and propagation of coxsackieviruses. These cell systems include primary monkey kidney cells; monkey kidney cell lines such as BGM, Vero, and LLC-MK2; and human cell lines such as HeLa, Hep2, KB, and RD. Virus infection and replication results in a characteristic cytopathic effect which is observed microscopically 1–7 days after inoculation. The cells become rounded and refractile, with nuclear pyknosis and cell degeneration. Ultimately, the cells are lysed and become detached from the surface of the culture vessel.

Attempts at virus isolation in cell culture may sometimes be unsuccessful, necessitating the inoculation of suckling mice. For example, CVA1, CVA19, and CVA22 are rarely, if ever, isolated in culture, but grow readily in suckling mice. If the virus titer is extremely low, blind passage in mice may be necessary; blind passage may also be needed to allow the virus to adapt to growth in mice. The two groups of coxsackieviruses can be distinguished by the distinct pathology that they cause in mice. With CVA infection, newborn mice develop flaccid paralysis and severe, extensive degeneration of skeletal muscle (sparing the tongue, heart, and CNS), and they may have renal lesions. Death usually occurs within a week. CVB infection proceeds more slowly and is characterized by spastic paralysis and tremors associated with encephalomyelitis, focal myositis, brown fat necrosis, myocarditis, hepatitis, and acinar cell pancreatitis.

Epidemiology, Geographic Distribution, and Seasonality

The coxsackieviruses are distributed worldwide, but there can be significant geographic and temporal variation in prevalence of individual serotypes. These differences are attributed to differences in climate and public hygiene, overall population immunity (e.g., an increase in the number of susceptible individuals in the years following an outbreak), and other factors. In the United States, for example, CVA9 is among the most commonly reported enteroviruses, but circulation tends to peak every 3–5 years. CVB2, CVB4, and CVB5 are also common, with cyclic peaks of activity, and CVB5 has been associated with large outbreaks, while CVB1 and CVB3 circulate at low, relatively constant levels, and CVB6 is rarely reported. Like the other enteroviruses, most coxsackievirus infections tend to occur during the warmer months in areas with a temperate climate, peaking in late summer or fall. In the tropics, peak activity generally correlates with the rainy season.

Coxsackieviruses are isolated in the highest titer and for the longest time in stool specimens but can also be isolated from respiratory secretions. Fecal-oral transmission and spread by contact with respiratory secretions (person-to-person, fomites, and possibly large particle aerosol) are the most important modes of transmission. The relative importance of the different mode probably varies with the virus and the environmental setting. Viruses that cause a vesicular exanthem are also presumably spread by direct or indirect contact with vesicular fluid, which contains infectious virus. Exceptions to the usual modes of enterovirus transmission are the agents of acute hemorrhagic conjunctivitis, coxsackievirus A24 variant (CA24v), and enterovirus 70 (a member of HEV-D). These two viruses are seldom isolated from respiratory or fecal specimens and are probably transmitted primarily by direct or indirect contact with eye secretions.

Virion Structure and Host Cell Receptors

Coxsackievirus virions, like those of other picornaviruses, are approximately 30 nm in diameter, with little discernable fine-scale structure (**Figure 1**). Sixty copies of each of the mature virion proteins, VP1–VP4, form an icosahedral virion particle with pseudo $T = 3$ symmetry. The proteins VP1–VP3 combine to form the virion protomer, with VP4 internal to the particle.

Virus infection is dependent on the presence of specific receptors. At least four distinct receptors are used by coxsackieviruses for entry into human cells. CVA9 uses integrin $\alpha_v\beta_3$, CVB1–6 use the 'coxsackievirus–adenovirus receptor' (CAR) and some may also use decay-accelerating factor (DAF), and some of the HEV-C coxsackieviruses use intracellular adhesion molecule 1 (ICAM-1). The receptor (s) used by most viruses in HEV-A, and by many of the viruses in HEV-C remain unknown.

Genetics, Genetic Diversity, and Evolution

Like the other enteroviruses, the coxsackievirus genome is a single-stranded, polyadenylated, positive-sense RNA of approximately 7.4 kbp, with a 22-amino-acid virus-encoded protein ($3B^{VPg}$) covalently linked to the 5′ end. Flanked by 5′- and 3′-nontranslated regions (NTRs), the single long open reading frame encodes a polyprotein of approximately 2200 amino acids that is processed during and following translation by viral proteases to yield the mature viral polypeptides (**Figure 2**). The P1 region encodes the capsid proteins 1A-1D (VP4, VP2, VP3, and VP1, respectively). The P2 and P3 regions encode proteins involved in polyprotein processing, RNA replication, and shutdown of host cell protein synthesis.

Coxsackieviruses, like other picornaviruses, evolve extremely rapidly, because the viral RNA-dependent RNA polymerase is error-prone and lacks a proofreading function (like other RNA virus replicases). Most of the nucleotide substitutions are translationally silent, because most substitutions that become fixed in a virus population are in the third ('wobble') position of codons. This phenomenon is likely due to intense selection against amino acid substitutions, especially in the proteins that are required for replication, protein processing, and shutdown of host cell synthesis. Most viable amino acid substitutions occur in surface loops of the external capsid proteins, VP1, VP2, and VP3, while residues that contribute to the proteins' beta-barrel structure tend to be highly conserved within a serotype and, to a large extent, within a species. Within a serotype, VP1 nucleotide sequence can vary by up to 25%, representing near-saturation of synonymous sites, as well as multiple nonsynonymous substitutions – the amino acid sequence can vary by as much as 15% with a type.

The different enterovirus species each form a distinct phylogenetic group throughout the coding region, as well as in the 3′-NTR. In the 5′-NTR, the human enteroviruses form only two clusters: cluster I contains HEV-C and HEV-D, while cluster II contains HEV-A and HEV-B. The nonhuman species each form distinct 5′-NTR clusters. The coxsackie B virus capsid sequences cluster together as a group, probably reflecting their shared, but unique, use of CAR as a receptor. In other parts of the coding region, the CVB are not phylogenetically coherent; rather, they interdigitate with other viruses in HEV-B, due to the high frequency of RNA recombination within any given enterovirus species.

Pathogenesis and Immunity

Much of the disease associated with coxsackievirus infection is thought to be a direct result of tissue-specific cell destruction, analogous to the cytopathic effect in cultured cells (**Figure 3**). For the most part, the detailed mechanisms of virus-induced disease have not been well-characterized. The primary site of infection is typically the respiratory or gastrointestinal epithelium, leading to viremia that may result in a secondary site of tissue infection. Such secondary spread of virus to the CNS can result in aseptic meningitis or, rarely, encephalitis or paralysis. Other tissue-specific infection can result in pleurodynia or myocarditis. Disseminated infection can lead to exanthems, nonspecific myalgias, or severe multiple-organ disease in neonates. Some disease manifestations, enteroviral exanthems and myocarditis, for example, are thought to result from the host immune response to the infection.

Enterovirus infection elicits a strong humoral immune response. Often the response is heterotypic; that is, infection with one serotype induces a broad immune response

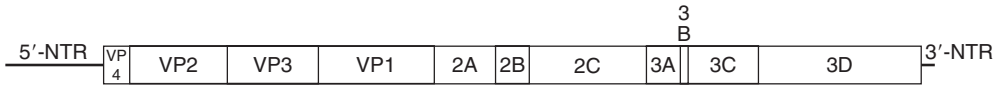

Figure 2 Coxsackievirus genome, indicating the locations of the mature viral proteins, 1A-1D (VP4, VP2, VP3, and VP1, respectively), 2A–2C, and 3A–3D, flanked by the 5′- and 3′-nontranslated regions (NTRs).

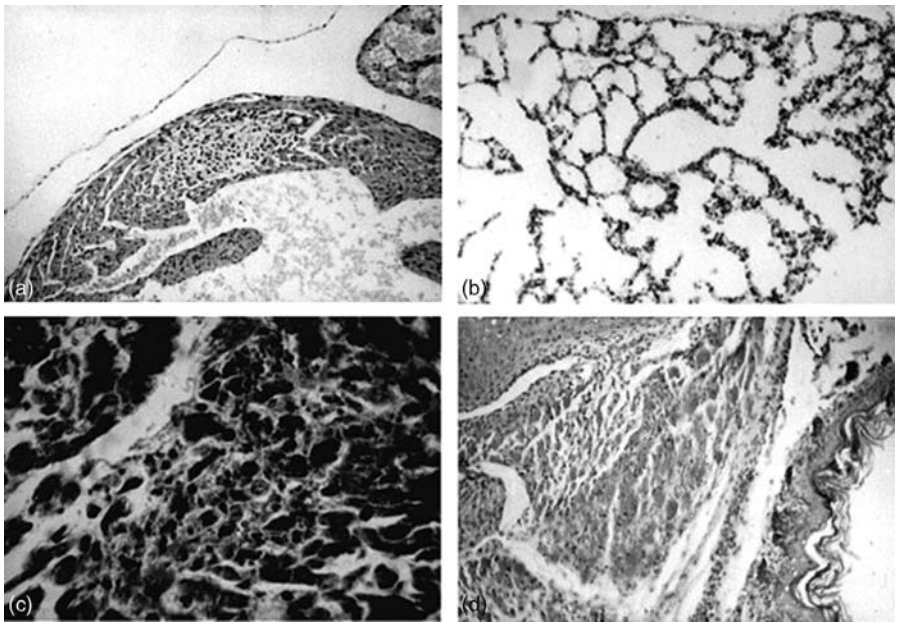

Figure 3 Tissue damage caused in baby mice by a freshly isolated strain of coxsackievirus B (a–c) or coxsackievirus A (d). (a) A large necrotic focus in the atrial myocardium (× 100); (b) steatitis in the interscapular brown fat pad (× 250); (c) a ventricular focus of necrotic cardiomyocytes (× 450); (d) intercostal muscles with diffuse hyalinization of myocytes and mild inflammatory infiltrate (×250). San Diego: Academic Press, with permission from Elsevier.

that cross-reacts with several other serotypes. Young children develop a more homotypic response, whereas older children and adults tend to develop a more heterotypic response. This age difference in the specificity of the antibody response probably reflects exposure to a greater number of serotypes with increasing age. The heterotypic response may reflect the presence of epitopes that are shared among multiple serotypes, but the actual mechanism is unknown. The presence of antibody does not prevent infection or primary virus replication, but it is sufficient to protect from disease, probably by limiting spread of the virus to secondary sites such as the CNS. Infection also elicits a T-cell response which helps clear the virus, but the cell-mediated immune response is not required for protection from disease.

Clinical Manifestations

Coxsackievirus infections can result in a wide variety of disease syndromes (**Table 2**). Most infections are asymptomatic or result in only mild upper respiratory tract symptoms (common cold). Other mild enteroviral illness, such as fever, headache, malaise, and mild gastrointestinal symptoms, may also occur. Serious illness that brings the patient to the attention of a physician is much less frequent. Inapparent infections and prolonged excretion of virus, especially in stools, are common. These properties of enterovirus infection, and the fact that enterovirus infection is extremely common, make it difficult to establish a definitive link between infection and specific disease unless the virus can be isolated from a nonsterile site that is linked to the observed pathology (e.g., isolation from cerebrospinal fluid in the case of aseptic meningitis). Often, the association between infection and disease is based on studies of outbreaks in which a large number of persons with the same clinical signs and symptoms have evidence of infection with the same serotype. Such studies have clearly demonstrated that enterovirus infection can cause aseptic meningitis, pericarditis, pleurodynia, myocarditis, and encephalitis.

Table 2 Diseases commonly associated with coxsackievirus infection

Illness or syndrome	*Group A*	*Group B*
Acute hemorrhagic conjunctivitis	X[a]	
Aseptic meningitis	X	X
Encephalitis[b]	X	X
Exanthema	X	X
Hand, foot, and mouth disease	X[c]	
Hepatitis	X	X
Herpangina	X	
Infantile diarrhea	X	
Myocarditis/pericarditis		X
Paralysis[b]	X	X
Pleurodynia		X
Respiratory illness	X	X
Severe systemic infection in infants		X
Undifferentiated febrile illness	X	X

[a]CVA24 variant.
[b]Rare.
[c]Primarily CVA16 and EV71; also CVA6, CVA10.

Central Nervous System Disease

The most commonly recognized serious manifestation of enterovirus infection is CNS disease, usually aseptic meningitis, but sometimes, encephalitis or paralysis. Aseptic meningitis is the most common CNS infection in the United States, and enteroviruses are the main recognized cause of aseptic meningitis in both children and adults in developed countries. Other than poliovirus, echoviruses and group B coxsackieviruses are most commonly isolated from cases of enterovirus-associated CNS disease, but this may be largely an artifact of low-efficiency isolation of group A coxsackieviruses in culture.

Febrile Rash Illnesses

Herpangina is a common illness in school-age children, characterized by vesicular inflammation of the oral mucosa, including throat, tonsils, soft palate, and tongue. Herpangina has commonly been associated with CVA2–6, CVA8, and CVA10, as well as with some of the echoviruses. Hand, foot, and mouth disease (HFMD) is characterized by vesicular rash on the palms, soles, and oral mucosa, with frequent involvement of the limbs and trunk. CVA 16 and EV71 are the most common viruses isolated from HFMD cases, but CVA4, CVA6, and CVA10 are also frequent causes. Many of the coxsackieviruses (both groups A and B) may also be associated with undifferentiated rash, often in connection with other symptoms such as meningitis.

Prenatal, Perinatal, and Neonatal Infection

A number of enterovirus serotypes have been associated with severe illness in neonates, including generalized disseminated infection that can mimic some aspects of bacterial sepsis. CVB4 infection is associated with a higher risk for severe disease in infants less than 1 month old, but other CVB serotypes and other enteroviruses can also cause similarly severe disease in this age group. Neonatal disease can also include other typical enterovirus syndromes, such as meningitis, encephalitis, pneumonia, hepatitis, myocarditis, and pancreatitis. One systematic study in Nassau County, New York, estimated that one of every 2000 infants in that area was hospitalized during the first 3 months of life for CVB sepsis-like disease, with significant mortality. This probably underestimates the true rate, since virus isolation studies may be insensitive and other enteroviruses were not included in the estimate.

Although there are few studies that examine the relationship between enterovirus infection and adverse effects on the fetus, one study found serologic evidence of CNS infection with CVB in ventricular fluid from 4 of 28 newborns with congenital neural tube defects. The infants had neutralizing antibody to only one CVB serotype in the ventricular fluid, but to several in serum. The unique distribution of antibodies in the ventricular fluid compared to that in serum supports the purported association. The mothers had antibodies to the same serotype as well as some other CVB serotypes. No virus was isolated from infants or mothers. Two other studies have documented an association between enterovirus infection and miscarriages and stillbirths. Further studies are needed to assess the possibility of enterovirus infection of the fetus.

Acute Hemorrhagic Conjunctivitis

Coxsackievirus A24 variant and enterovirus 70 are associated with acute hemorrhagic conjunctivitis. This disease is different from other enteroviral illnesses, having occurred in global pandemics since its introduction around 1969. The incubation period for these agents is shorter than for other enteroviruses (24–72 h); systemic illness is much less common and conjunctival replication the rule. The disease is characterized by acute onset of lacrimation, severe pain, chemosis and periorbital edema, photophobia, conjunctival hyperemia, and mild-to-severe subconjunctival hemorrhages. The disease is usually bilateral. It is generally self-limiting, but may lead to secondary bacterial infection.

Other Acute Illnesses

Group B viruses have been associated with pleurodynia, also known as 'Bornholm disease' or 'epidemic myalgia'. Pleurodynia is characterized by sudden onset of chest pain, due to inflammation of the diaphragm, accompanied by general malaise, headache, fever, and sore throat. Enteroviruses, primarily the coxsackieviruses, are also

a common cause of respiratory illness. Most of these infections are relatively mild – even subclinical – and restricted to the upper respiratory tract (e.g., common cold, croup, and epiglottitis). Occasionally, the lower respiratory tract becomes infected, resulting in more serious illness, such as bronchiolitis or pneumonia, especially in very young children.

Cardiac Disease

Although the association between myocarditis and pericarditis and enterovirus infection is clearly established, it is not yet clear how often enterovirus infections are responsible for the disease syndromes. One study has shown that CVB IgM in a group of patients with acute myocarditis is significantly higher than in controls. Enterovirus RNA has also been detected in myocardial biopsy specimens from patients with myocarditis. These and other studies suggest, but do not clearly show, that CVB infection may be associated with a large fraction of cases of acute myocarditis. By contrast, different studies have failed to show conclusive evidence for the involvement of enterovirus infection in idiopathic dilated cardiomyopathies.

Diabetes

As with myocarditis, numerous studies have suggested a link between enterovirus infection and the onset of type I diabetes mellitus. In some cases, enteroviruses, such as CVB4, have been isolated from pancreas of fulminant diabetes cases, but most of the evidence is indirect, through serologic studies. Several mechanisms have been hypothesized to explain the possible link between infection and diabetes onset, including direct, lytic destruction of insulin-producing beta cells in the pancreas; molecular mimicry of self-antigens, resulting in induction of prediabetic autoimmunity that eventually leads to beta-cell destruction; and indirect damage mediated through activation of a nonspecific inflammatory response in the pancreas ('bystander effect'). A number of studies are attempting to address various steps in virus-induced diabetes pathogenesis, in human patients and in animal model systems.

Treatment and Prevention

Antiviral therapy is not presently available for enterovirus infections, so treatment is directed toward ameliorating symptoms. Drugs have been identified that exhibit antiviral activity against several enteroviruses in tissue culture and experimental animals, and some have been tested in human clinical trials; however, no enterovirus drugs are currently licensed in the United States or elsewhere. Interferon has been proposed for treatment of acute hemorrhagic conjunctivitis, but further studies are needed to evaluate its effectiveness. Chronic enterovirus infections in patients with agammaglobulinemia have been treated with γ-globulin, and in some cases this has controlled the infection.

No vaccines are available to prevent coxsackievirus infection or disease. General preventive measures include enteric precautions and good personal hygiene. Nosocomial infections are most serious in newborns and persons with compromised immune systems, but others may also be affected. Hospital staff can inadvertently carry the virus between patients or become infected themselves and spread the virus. The main strategy to prevent nosocomial infections is to manage patients with suspected enterovirus infection using enteric precautions. During outbreaks, patients and staff can be cohorted. In some cases, neonatal nurseries were closed to new admissions during newborn outbreaks to prevent further spread of the virus.

Glossary

Hyperthermophile An organism that grows optimally at temperature of 80 °C or higher.

Introduction

The susceptibility to viral infection is as common for the domain Archaea as it is for the other two domains of life, the Bacteria and the Eukarya. Initially, the knowledge about archaeal viruses was restricted to head–tail viruses infecting members of the kingdom Euryarchaeota. However, the isolation of viruses from the other archaeal kingdom, the Crenarchaeota, has demonstrated that head–tail phages constitute only a part of viral diversity associated with this domain.

The double-stranded (ds) DNA viruses of Crenarchaeota isolated by Wolfram Zillig and colleagues were so unusual in their morphotypes that for their classification four novel viral families had to be introduced: *Fuselloviridaae, Lipothrixviridae, Rudiviridae,* and *Guttaviridae.*

Further studies on viral diversity in geothermally heated hot habitats, where Crenarchaeota predominate demonstrated that unusual morphotypes are a general feature of crenarcheal viruses and resulted in isolation of more viruses with unique morphologies. They have been classified into three novel viral families the approval of which is pending at the ICTV: Globuloviridae, Ampullaviridae, and Bicaudaviridae.

In this article we summarize our present knowledge on viruses infecting hyperthermophilic crenarchaea (**Table 1**). Virion morphotypes and constituents are described and data regarding different stages of replication cycle presented. Sequences of dsDNA genomes of all viruses are discussed jointly, in accord with the idea that crenarchaeal viruses form a distinctive group, unrelated to any other viruses, with a small pool of shared genes and a unique origin, or more likely, multiple origins.

Morphotypes

The vast majority of the viruses replicated by Crenarchaeota have morphotypes that have not been observed among dsDNA viruses infecting Bacteria and Eukarya. In this section we describe different morphotypes of crenarchaeal viruses grouped according to their gross shape features.

Spindle-Shaped Viruses

Spindle-shaped virions, single or two-tailed, constitute a large fraction of the known archaeal viruses and are abundant in hot acidic springs where crenarchaea predominate.

Virions of the family *Fuselloviridae*, represented by *sulfolobus* spindle-shaped viruses (SSVs), are enveloped with a short tail attached to one of the two pointed ends and measure about (55–60) × (80–100) nm (**Figure 1**(**a**)). The tail carries fibers which serve for adsorption to the host membrane. The structure of the inner core of the enveloped virions which generates the unusual shape is unknown. The mature virions were observed intracellulary (**Figure 1**(**a**)) indicating that the budding process is not required for the coating by a lipid-containing membrane.

The virions of *Acidianus* two-tailed virus (ATV) are most unusual because they undergo extensive morphological changes outside the host cell (**Figures 1**(**c**)–**1**(**g**)). When released from the host cell, the particles are spindle-shaped with an overall length of 250–300 nm and a diameter of 110–120 nm (**Figure 1**(**c**)). Then, specifically at temperatures above 75 °C, a tail-like appendage protrudes from each of the pointed ends (**Figures 1**(**d**)–**1**(**g**)). The particles with fully developed tails are about 1 μm in length. This process is linked with a reduction of the volume of the virion by a factor of 2, concurrent with a slight expansion of its surface area.

The tails are tube-like and terminate with an anchor-like structure formed by two furled filaments (**Figure 1**(**g**)). This structure is employed for adsorption on the host cell surface. The tube contains a filament of an unknown nature,

which exhibits a structural periodicity. Protrusion of tails does not require the presence of host cells, an exogenous energy source or any cofactors. The only requirement is temperature in the range of host growth, above 75 °C.

The virus *Sulfolobus tengchongensis* spindle-shaped virus 1 (STSV1) is the largest of the known spindle-shaped viruses (107 × 230 nm) and has a single short tail (**Figure 1**(**b**)). The tail length varies in the range from 0 to 133 nm suggesting that the virus may also undergo an extracellular morphogenesis similar to ATV.

Rod-Shaped and Filamentous Viruses

The combination of rod or filamentous shape and dsDNA genome occurring among members of *Rudiviridae* and the *Lipothrixviridae* is unique in the viral world.

The three characterized rudiviruses *Sulfolobus* rod-shaped virus 1 (SIRV1), *Sulfolobus* rod-shaped virus 2 (SIRV2), and Acidianus rod-shaped virus 1 (ARV1) are nonenveloped stiff rods about 23 nm wide and 610–900 nm long (**Figure 2**(**a**)). The particle length is proportional to the size of the dsDNA genome (**Table 1**). The rods are formed by a tube-like superhelical nucleoprotein complex that consists of linear dsDNA and copies of a single DNA-binding protein. The tubes are closed at each end by plug-like structures about 50 nm in length. Each plug carries three tail fibers (**Figure 2**(**a**), inset) that are probably involved in adsorption to host cell membranes.

The lipothrixviruses include the highest number of known species among the crenarchaeal viral families. Virions are filamentous and mostly flexible, except for *Thermoproteus tenax* virus 1 (TTV1), and enveloped (**Figure 2**(**b**)).

The structures of the virion termini, as well as of the inner core are diverse, and owing to this diversity, as well as to presumed different replication strategies, four genera have been established in the family.

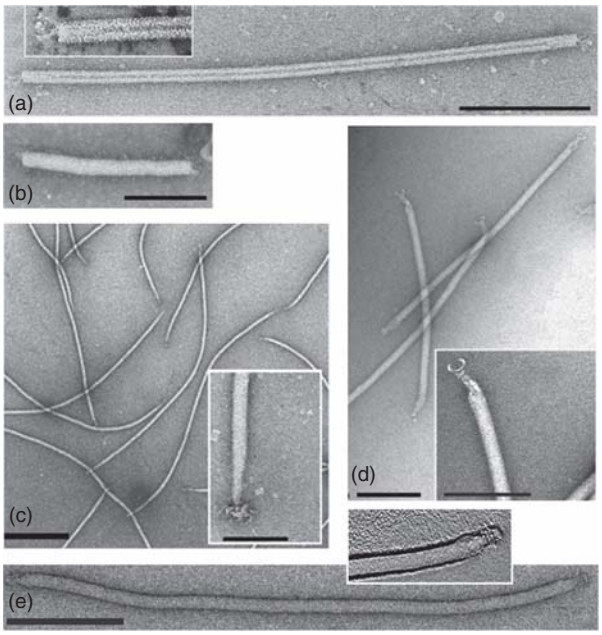

Figure 2 Electron micrographs of linear viruses. (a) SIRV1; (b) TTV1; (c) SIFV; (d) AFV1; (e) AFV2; terminal structures are shown in inserts. Negative stain with 3% uranyl acetate. Scale: 200 nm (a–e) (in insets, 100 nm).

The body of *Sulfolobus islandicus* filamentous virus (SIFV) particles tapers and ends in identical mop-like structures (**Figure 2**(**c**)), the *Acidianus* filamentous virus 1 (AFV1) has claw-like terminal structures (**Figure 2**(**d**)), and *Acidianus* filamentous virus 2 (AFV2) carries a complex collar with

two sets of filaments, resembling a bottle brush with a solid round cap at each end (**Figure 2**(**e**), inset). The virion termini of TTV1 have not been analyzed in detail.

The terminal structures of lipothrixviruses serve for the adsorption onto the host cell. Both termini of a given virus may be involved in this process. The mop-like terminal structures of SIFV have been shown to unfold like spiders legs prior to attachment to cell membranes. Most lipothrixviruses adsorb to host cell membrane with exception of AFV1 which uses the claw-like ends for attachment to host pili.

The architecture of virion cores differs between the lipothrixviruses although they all carry linear dsDNA genomes. The cores of AFV1 and TTV1 are helical, and the latter was shown to contain equimolar amounts of two DNA-binding proteins. The DNA of SIFV is wound around a zipper-like array of subunits of a single protein. Such a core arrangement is reminiscent of nucleosomes. In contrast, no regular structure was detected in the core of AFV2.

Spherical Viruses

The spherical viruses infecting hyperthermophilic Crenarchaeota encompass *Pyrobaculum* spherical virus, PSV, *Thermoproteus tenax* spherical virus 1, TTSV1, and *Sulfolobus* turreted icosahedral virus, STIV (**Figure 3**). This is the only morphotype of crenarchaeal viruses that is also observed in the domains Bacteria and Eukarya.

Virions of PSV are around 100 nm in diameter and they carry an envelope which encases tightly packed nucleoprotein in a superhelical conformation (**Figures 3**(**a**) and **3**(**b**)). Such core structure is unique for a DNA virus but resembles the core structure of single-stranded RNA viruses of the family *Paramyxoviridae*. The virion surface is covered by a variable number of spherical protrusions, about 15 nm in diameter, most likely involved in adsorption to the host cell.

The properties of the virion structure and genome of TTSV1 are very similar to those of PSV suggesting that these viruses belong to the same family.

The virions of the STIV are nonenveloped icosahedra with a diameter of about 74 nm (**Figure 3**(**c**)). The capsid most likely contains an internal lipid envelope. Single-particle reconstruction revealed a unique virus architecture including complex, turret-like appendages at the virion surface. The crystal structure of the major capsid protein of STIV is very similar to those of the bacterial tectivirus PRD1 and the eukaryal phycondnavirus PBCV-1, suggesting a common ancestry, despite the fact that the corresponding protein sequences show no significant similarity.

Bottle- and Droplet-Shaped Viruses

The extraordinary shapes of crenarchaeal viruses are exemplified by two viruses with most unusual virion structures, *Acidianus* bottle-shaped virus, ABV, and *Sulfolobus neozealandicus* droplet-shaped virus, SNDV (**Figure 4**).

The virions of ABV resemble in their shape a bottle with an overall length of 230 nm and a width varying from 75, at the broad end, to 4 nm, at the pointed end (**Figure 4**(**a**)). The broad end of the virion exhibits 20 (± 2) thin rigid filaments, which appear to be inserted into a disk, or ring, and are interconnected at their bases. The 9-nm-thick envelope encases cone-shaped core that is formed by a torroidally supercoiled nucleoprotein filament (**Figures 4**(**b**) and **4**(**c**)). The narrow end of virions is likely involved in cellular adsorption and in channeling of viral DNA into a host cell. The function of filaments at the opposite end remains unclear.

The SNDV virions are droplet-shaped, 110–185 nm long and 70–95 nm wide. The pointed end is densely covered by thin fibers (**Figure 4**(**d**)). The core is protected by a beehive-like structure, the surface of which appears to be built up of components stacked in a helical manner.

Virion Constituents

The protein content of particles of crenarchaeal viruses is often complex. The number of the major protein components present in the virions varies from two proteins for rudiviruses, fuselloviruses, and lipothrixviruses up to 11 proteins for the ATV. Moreover, in the majority

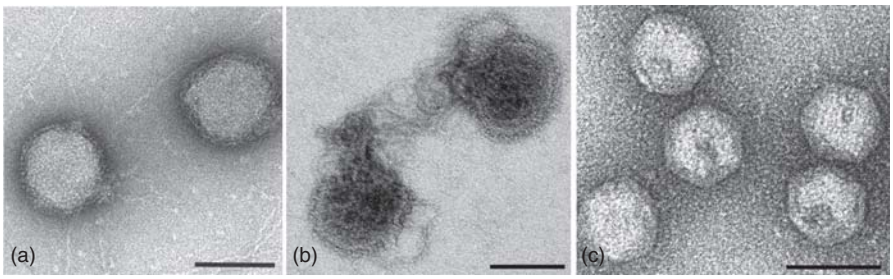

Figure 3 Electron micrographs of spherical viruses. (a) PSV; (b) partially disrupted virions of PSV releasing helical nucleoprotein filament; (c) STIV. Negative stain with 3% uranyl acetate. Scale = 100 nm.

Scale: 50 nm (a); 100 nm (b, c); 200 nm (d).

of viruses a few minor protein components are also present. Several structural proteins have been identified (**Figure 5**).

Virion proteins have an important role in protecting the viral DNA from the harsh conditions of the host's habitat. For example, the single DNA-binding protein of nonenveloped rudiviruses can partially protect the virion structure during autoclaving at 120 °C for 10 min. The particles are completely disrupted only after a further 50 min.

Some of the structural proteins can form structures of higher order. This is exemplified by the 90 kDa protein from ATV that is rich in coiled-coil motifs and can generate long filaments. They may contribute to the protrusion of tail-like appendages during the extracellular development of ATV. The virions of PSV exhibit three major protein components the largest of which can build dimers and higher aggregates. This protein also contains two-thirds of hydrophobic amino acid residues, about 15% of which are aromatic, and no cysteine residues, properties which are likely to contribute to high thermostability.

Almost all crenarchaeal viruses are enveloped. The only exception are the members of the *Rudiviridae*. The envelopes of the PSV, and of all lipothrixviruses, except AFV2, have been shown to contain host lipids that have been modified probably by virus-encoded enzymes. The STIV particles have an internal host lipids-containing envelope. The presence of lipids in virions of other crenarchaeal viruses has not yet been reported.

Virus–Host Interactions

Little is known about the modes of cellular entry and the assembly mechanisms of the crenarchaeal viruses. Presumably, after attachment to the host cell surface either the whole virion is taken up or the viral DNA is injected through the host membrane. The latter mechanism could be employed by the virions of ABV that were shown to release a nucleoprotein complex through the pointed end (**Figure 4**(**c**)). Another mechanism is possible for the AFV1 which attaches with its claw-like terminal structures onto the host pili. The virions could be pulled into the cell by retraction of the pili.

Hosts of cultured crenarchaeal viruses are extreme acidophiles (*Sulfolobus*, *Acidianus*), or neutrophiles and obligate anaerobes (*Pyrobaculum*, *Thermoproteus*). Infectivity of the latter organisms with viruses is unaffected by exposure to oxygen. For all of the hosts which grow optimally at 80 °C or above, viral infection occurs most effectively at the optimal growth temperature of the host such that viruses can also be considered as hyperthermophiles.

Viruses of the Crenarchaeota are rather exceptional with respect to virus–host interactions because they generally do not kill their host during release of progeny virions. Instead, the viruses persist in host cells and are not segregated even after prolonged growth and several dilutions of infected cell cultures. This is the result of an equilibrium that is established between the viral genome replication and cell division. It is usually argued that such inoffensiveness of crenarchaeal viruses is beneficial, helping them to avoid direct, and possibly prolonged, exposure to the harsh environmental conditions of the host habitat.

The only two examples of crenarchaeal viruses that cause lysis of their hosts are TTV1 and ATV.

The ATV exhibits the characteristics of a true temperate virus. At the optimal temperature of host growth, 85 °C, infection with ATV results in integration of the viral genome into the host chromosome and lysogenization of the host cell. The lysogeny can be interrupted by

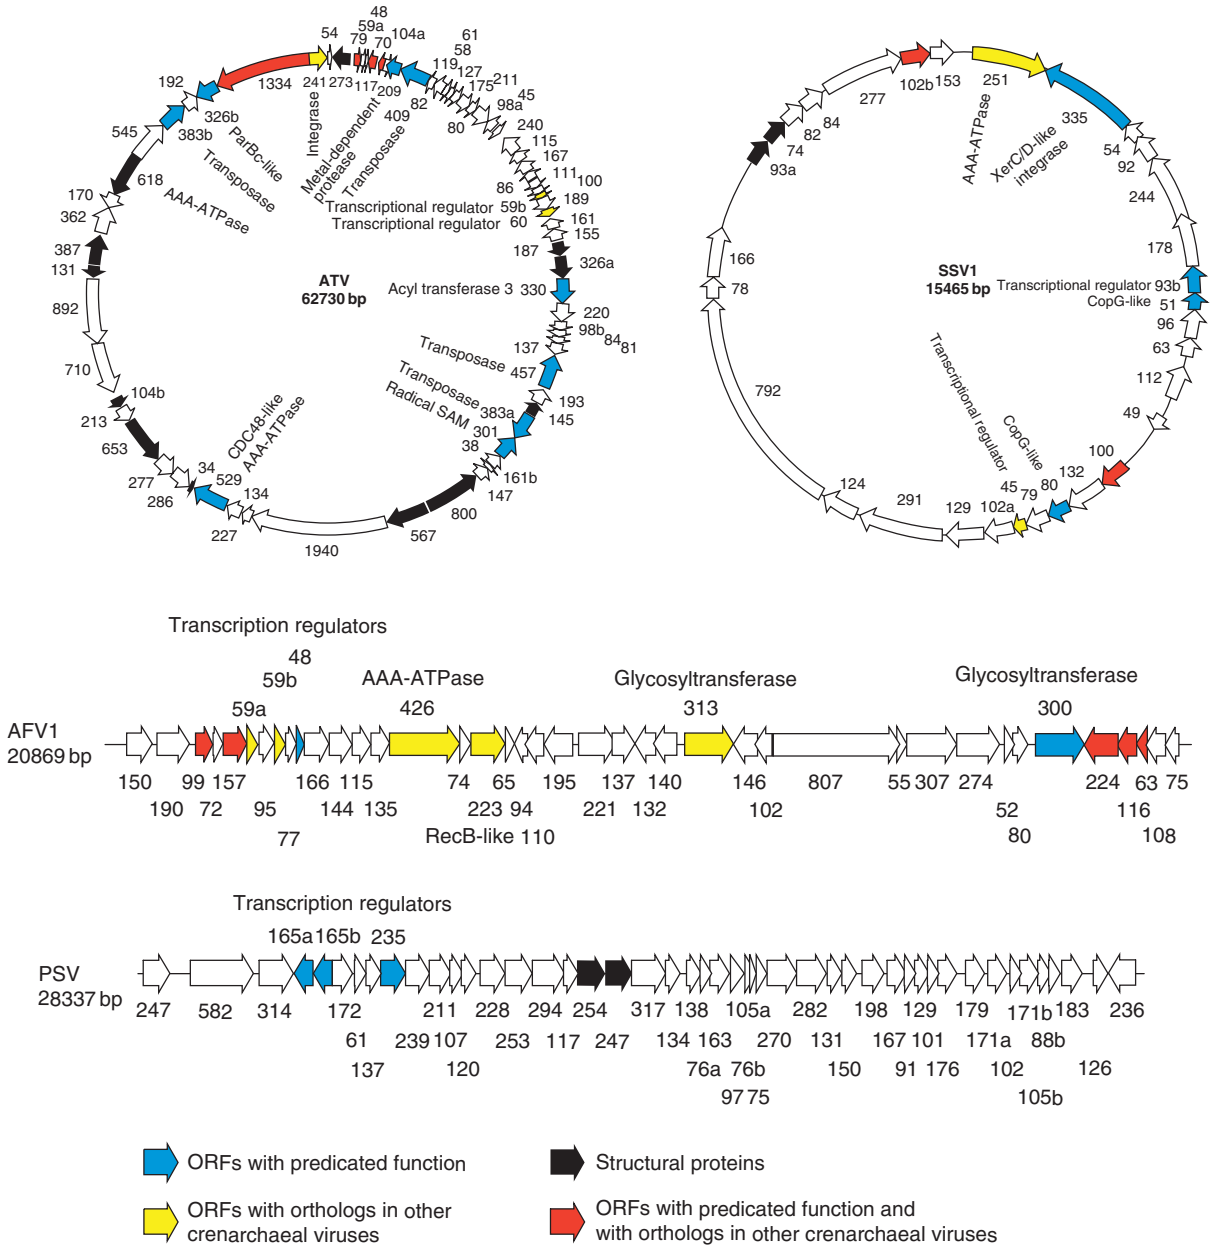

Figure 5 Schematic representation of the genome organizations found in four different crenarchaeal viruses. Arrows represent predicted viral ORFs and their size and orientation. Numbers assigned to the ORFs correspond to number of amino acids in the encoded proteins. The genomes are not in scale to each other. ORFs have been assigned functions according to sequence similarities with genes in public databases.

subjecting the host cell to stress conditions, for example, UV-irradiation, treatment with mytomycin C, freezing–thawing cycles, or host growth at suboptimal temperatures. Induction of virus replication eventually leads to cell lysis.

The integration of the ATV genome into the host chromosome is facilitated by a virus-encoded integrase. The genes encoding these enzymes have been detected also on circular genomes of the fuselloviruses and STSV1. The former insert generally within specific host tRNA genes and the integrated form of the latter has not been detected. The fuselloviruses are present in the infected host cell cultures in episomal and integrated form but it is not known whether the two forms exist in the same cell. The replication of the SSV1 can be induced by ultraviolet irradiation leading to temporary growth inhibition,

but not lysis, of host cells. Subsequently, virus proliferation decreases and the host cells assume their earlier growth rate.

The linear genomes of crenarchaeal viruses do not encode integrases and they have not been detected in chromosomes of their hosts. Moreover, their replication is not affected by UV-irradiation or other stress factors.

Genome Structure

The crenarchaeal viruses investigated so far all carry dsDNA genomes. The genomes of the fuselloviruses ATV and STSV1 are circular, 15–75 kbp in size (**Table 1**). Known rudiviruses, lipothrixviruses, and PSV contain linear genomes in the size range 25–45 kbp.

For the fuselloviruses and some lipothrixviruses, about half of each genome, including genes for viral structural proteins, is always highly conserved in gene content and order with the remainder of the genome being more variable.

Modifications have been detected in two of the viral genomes. The SNDV carries a *dam*-like N(6) methylation of adenine residues in GATC sequences while the DNA of the STSV1, which encodes three putative modifying enzymes, undergoes methylation of specific cytosine residues within the sequence CCGG. The latter modifications are probably absent from the host chromosmal DNA.

Most of the linear genomes carry inverted terminal repeats (ITRs) that can vary significantly in their size between viruses. The rudiviral genomes exhibit large ITRs (600–2000 bp), the PSV carries a 190 bp ITR, and the lipothrixvirus AFV1 has a very short 11 bp ITR.

Genomic termini of some crenarchaeal viruses are modified. In the rudiviruses SIRV1 and SIRV2 the two DNA strands are covalently linked at the ends, generating a 4 bp hairpin loop which can be degraded by *Bal*31 endonuclease. A similar structure may occur at the termini of the PSV genome.

Restriction fragments containing the terminal sequences of the TTV1 and AFV1 produce low molar yields on phenol extraction suggesting the presence of tightly bound proteins at the ends of genomic DNA.

Replication of Viral Genomes

The genome replication of crenarchaeal viruses has not been studied experimentally. Consequently, the knowledge about the replication mechanisms employed and participating enzymes is very scarce. Nevertheless, some clues about possible replication strategies of crenarchaeal viruses could be obtained from the sequences of the genomes and the genome arrangements.

Linear genomes of some lipothrixviruses exhibit an internal, repeat-rich, non-protein-coding region. The AFV2 carries a 1008 bp element bordered by an ITR that is rich in repeat sequences. Such regions could constitute internal origins of replication.

Even more remarkable are the genomic features of the STSV1. Its circular genome is highly asymmetric and divides into equal halves with respect to gene orientation. Between the two halves of the genome was located the 1.4 kbp long intergenic region with an unusually high AT content, including two sets of tandem repeats and two sets of inverted repeats. This region constitutes the putative origin of replication. Most likely, genome replication proceeds bidirectionally in the theta-mode from the proposed origin.

The genomic termini of lipotrixvirus AFV1 do not resemble any other virus. The two very short (11 bp) ITRs are preceded by about a 300 bp region consisting of many direct repeats of the pentanucleotide TTGTT, or close variants thereof. Such structures resemble telomeric ends of eukaryotic chromosomes and raise the possibility of a primitive telomeric mechanism operating in AFV1 genome replication.

Rudivirus SIRV1 replicates its genome via head-to-head and tail-to-tail linked intermediates. This suggested a self-priming mechanism of replication, similar to that proposed for large eukaryotic dsDNA viruses including poxviruses. Consistent with this proposal are the similarities in the structures of linear genomes of these archaeal and eukaryal viruses, including long ITRs and covalently closed termini. Moreover, each of these viruses encodes a Holliday junction resolvase which is likely to resolve the replicative intermediates into single-progeny genomes. The large ITRs of the rudiviruses carry highly conserved sequence located 100–150 bp from the genomic termini that could serve as signal for the initiation of replication.

Transcription of Viral Genes

The studies on transcription of the fusellovirus SSV1 resulted in identification of archaeal promoter sequences and were crucial for our seminal understanding of mechanisms of transcriptional regulation in archaea. SSV1 transcripts were mapped after UV induction of virus production in the lysogenes. Eight constitutive and one UV-inducible transcript were identified.

The first detailed analysis of transcription over the complete replication cycle was performed on rudiviruses SIRV1 and SIRV2. Already 30 min post infection all the ORFs, with one exception, are transcribed. Nevertheless, some ORFs have different transcription patterns during the replication cycle. One example is the ORF coding for coat protein that is initially transcribed as polycistronic

mRNA but its monocistronic transcript was detected in the later stage of virus infection. The rather simple and ordered transcriptional pattern of the rudiviruses fits with fairly unsophisticated virus–host relationship (stable carrier state) which probably does not require much transcriptional control.

SIRV promoters, like those of their hosts, carry a TATA-like box and adjacent to it a purine-rich region, corresponding to the transcription factor B binding site. In addition, virus-specific consensus element, the trinucleotide GTC is located immediately downstream from the TATA-like box. The GTC motif is also present in one-third of the promoter regions of another rudivirus, the ARV1.

Many viral transcripts for single genes and the first genes of SIRV operons are leaderless, and lack the consensus Shine–Dalgarno motif GGTG.

Genomics of Crenarchaeal Viruses

The most prominent feature of genomes of known crenarchaeal viruses is the extremely low number of gene products with homologs in the public sequence databases (**Figure 5**).

Genes with Confirmed Functions

Putative functions of only few genes (with homologs in public databases) have been confirmed experimentally. They encode the dUTPase and the Holliday junction resolvase of the rudiviruses SIRV1 and SIRV2 and the integrase/recombinase of the fusellovirus SSV1. In addition genes for structural proteins were identified.

Genes with Putative Functions Unique for Individual Viruses

A few genes of crenarchaeal viruses have homologs in archaea and/or bacteria. These include DNA-modification methylases of the STSV1, superfamily 2 helicases of the lipothrixvirus SIFV, ABC-class ATPase of the rudivirus ARV1, and thioldisulfide isomerase of the globulovirus TTSV1.

Genes with Putative Functions Shared by Different Viruses

Many crenarchaeal viruses share a repertoire of genes with putative functions including transcription regulators, ATPases, enzymes of DNA precursor metabolism, and RNA modification, and glycosylases.

The most common gene products in crenarchaeal viruses are small proteins containing ribbon–helix–helix (RHH) domain. These proteins are transcription regulators, common in archaea, and are nearly as abundant as classical helix–turn–helix (HTH) domains. The RHH proteins of crenarchaeal viruses are rather heterogeneous, and apparently have a complex history, probably involving multiple independent acquisitions as well as horizontal gene transfers.

Other putative transcription regulators encompass HTH-domains, looped-hinge helix domains, and Zn-fingers. Remarkable is the presence of C2H2 Zn-finger proteins with moderate similarity to a variety of eukaryotic Zn-fingers but no obvious homologs in prokaryotes.

Each of the crenarchaeal viruses encodes at least one of the P-loop ATPases, which are known to be the most abundant protein domain in prokaryotes and the great majority of viruses, and typically are involved in viral replication, transcription, or packaging. Other predicted enzymes with probable functions in DNA replication are the RecB-family nucleases in the *Lipothrixviridae*, *Rudiviridae*, and *Fuselloviridae*, the XerC/D-like integrase/recombinase in the Bicaudaviridae, and the STSV1. As for the Holliday junction resolvases of the *Rudiviridae*, these enzymes may be involved in intermediate resolution during viral genome replication.

The *Rudiviridae* and STSV1 encode a dUTPase and/or the flavin-dependent thymidylate synthase (ThyX) which apparently are involved in DNA precursor metabolism, a function widely represented in DNA viruses of Bacteria and Eukarya. Another function common for bacterial viruses, RNA modification, is also represented in the members of *Rudiviridae*: they encode predicted tRNA-ribosyltransferase and S-adenosylmethionine-dependent methyltransferase. The former enzyme is encoded also by STSV1 and the latter enzyme by the lipothrixvirus SIFV.

All known members of the *Rudiviridae* and *Lipothrixviridae* encode glycosyltransferases that may be involved in modification of virions proteins and/or the host cell wall during viral entry and/or release. In members of other viral families in this process maybe implicated such enzymes as a membrane-associated acyltransferase (in ATV) and nucleoside-diphosphate-sugar epimerase (in STSV1).

The gene pool shared by crenarchaeal viruses includes also two protein families with unknown functions. One of these, exemplified by the AFV1 protein 03 of 99 amino acids, is found exclusively in the *Rudiviridae* and *Lipothrixviridae*. Another family of small proteins has a single bacterial representative, the uncharacterized protein YddF of *Bacillus subtilis*, with all other members found in crenarchaeal viruses: in the *Rudiviridae, Lipothrixviridae, Fuselloviridae*, the ATV, and STIV.

Orthologous Genes

Results of identification of orthologous genes among the genes shared by crenarchaeal viruses are in astounding

accord with evolutionary relationships postulated on the basis of viral morphotypes. (Because of the uncertainty regarding the very existence of a unique common ancestor virus, orthologs were defined only conditionally, as genes that are more closely related to each other in a given set of viruses than they are to any homologs that may exist outside that set of genomes.)

A significant number of orthologs (18–44) are observed among viral species assigned to the same genus, which probably derived from relatively recent common ancestors. These are four members of the *Fuselloviridae*, three members of the *Rudiviridae*, and two members of the Globuloviridae.

A smaller number of orthologous genes (5–9), representing moderately related groups which probably have evolved from a single ancestral virus in a more distant past, were observed for members of different genera in the family *Lipothrixviridae*: the betalipothrixvirus SIFV, gammalipothrixvirus AFV1, and deltalipothrixvirus AFV2. A comparable number of orthologous genes were observed also between some members of different families, the *Rudiviridae* and *Lipothrixviridae*, suggesting a common ancestry for these two families.

In those cases when the viruses share only 1–4 orthologous genes, it remains unclear, whether a common ancestral virus ever existed. The existence of a common viral ancestor is even less likely, when no orthologs are detected among viruses, as it occurs for the two members of the Globuloviridae and the rest of the crenarchaeal viruses.

Conclusions and Future Prospects

Known dsDNA viruses infecting hyperthermophilic crenarchaea represent a remarkable collection of unique morphotypes, not encountered among dsDNA viruses of the Bacteria and Eukarya. It is now clear that crenarcheal viruses are not just an oddity but represent a general picture of viral diversity in hot environments. Therefore, the observed variety of viral morphotypes in hot environments is probably only a tip of an iceberg and the isolation of new viruses should remain an important part of future studies.

Analysis of the sequences of crenarchaeal viral genomes demonstrated that they form a distinct group, evolutionary unrelated to dsDNA viruses of the other two domains of life. Moreover, the majority of predicted genes of crenarchaeal viruses have no homologs in public sequence databases and only a few of the viral genes could be assigned functions. Consequently, this hinders our understanding of the fundamental processes that take place during the replication cycle of the crenarchaeal viruses. It is now time to initiate studies of the mechanisms of these processes, notably attachment, virion assembly and release, transcription, and genome replication. The instrumental discoveries made during studies of bacteriophages in the past argue that the studies of crenarchaeal viruses have potential to provide the archaeal research community with robust genetic tools.

The discovery of the unique group of crenarchaeal viruses provides a new perspective on events related to the origin of diverse groups of DNA viruses and their evolution. It is a challenge for future studies to reveal evolutionary aspects of involvement of sets of nonorthologous genes in establishment of similar lifestyles in the three unrelated groups of dsDNA viruses.

Crimean–Congo Hemorrhagic Fever Virus and Other Nairoviruses

C A Whitehouse, United States Army Medical Research Institute of Infectious Diseases, Frederick, MD, USA

Published by Elsevier Ltd.

Glossary

Argasid ticks Any member of the family *Argasidae*, which are soft-shelled; commonly called soft ticks.
Ecchymosis The escape of blood into the tissues from ruptured blood vessels.
Ixodid ticks Any member of the family *Ixodidae*, which have a hard outer covering called scutum; commonly referred to as hard ticks.
Petechiae Minute reddish or purplish spots containing blood that appear in the skin or mucous membrane, especially in some infectious diseases.

Introduction

The genus *Nairovirus* within the family *Bunyaviridae* includes 34 predominantly tick-borne viruses. These viruses are enveloped, with a tripartite negative-sense, single-stranded RNA genome. Among the members of this genus, the most important pathogens are the Crimean–Congo hemorrhagic fever virus (CCHFV), which causes severe and often fatal hemorrhagic fever in humans, Crimean–Congo hemorrhagic fever (CCHF), and Nairobi sheep disease virus (NSDV), which circulates in Africa and Asia and causes acute hemorrhagic gastroenteritis in sheep and goats.

CCHF was first recognized during a large outbreak among soldiers and agricultural workers in the mid-1940s in the Crimean peninsula but the etiologic agent was not isolated at that time. In 1956 a virus named Congo virus was isolated from a febrile patient in the Belgian Congo (now the Democratic Republic of the Congo) and it was later recognized that Congo virus was the same as Crimean hemorrhagic fever virus, isolated in 1967 from a patient with this disease in (now) Uzbekistan. The disease now occurs sporadically throughout much of Africa, Asia, and Europe and results in an approximately 30% case–fatality rate. CCHF is characterized by a sudden onset of high fever, chills, severe headache, dizziness, and back and abdominal pains. Additional symptoms can include nausea, vomiting, diarrhea, neuropsychiatric disorders, and cardiovascular changes. In severe cases, hemorrhagic manifestations, ranging from petechiae to large areas of ecchymosis, develop. Ixodid ticks of numerous genera serve both as vector and reservoir for CCHFV. Ticks in the genus *Hyalomma* are particularly important in the ecology of this virus and exposure to these ticks represents a major risk factor for contracting disease. Other important risk factors include direct contact with blood and/or body fluids from infected patients or animals. The highly pathogenic nature of CCHFV has restricted research on the virus to biosafety level 4 (BSL-4) laboratories and has led to the fear that it might be used as a bioweapon.

NSDV, which is an important cause of veterinary disease, was originally isolated from sheep from Nairobi, Kenya in 1910. Dugbe virus was originally isolated from adult male *Amblyomma variegatum* ticks collected from cattle in Ibadan, Nigeria in 1964. Both Dugbe and Ganjam viruses (a variant of NSDV) have been isolated repeatedly from ticks removed from domestic animals and have both caused febrile illnesses in humans. Most other nairoviruses have been isolated from ixodid ticks or from argasid ticks, which are ectoparasites of seabirds and other birds, and their medical or veterinary significance is not known.

History

Crimean–Congo Hemorrhagic Fever Virus

A disease now considered to be CCHF was described by a physician in the twelfth century from the region that is presently Tadzhikistan. The description was of a hemorrhagic disease with the presence of blood in the urine, rectum, gums, vomitus, sputum, and abdominal cavity. The disease was said to be caused by a louse or tick, which normally parasitizes a blackbird. The arthropod described may well have been larvae of a species of *Hyalomma* ticks, which are frequently found on blackbirds. CCHF has also been recognized for centuries under at least three names by the indigenous people of southern Uzbekistan: *khungribta* (blood taking), *khunymuny* (nose bleeding), or *karakhalak* (black death). Various other names, including acute infectious capillarotoxicosis and Uzbekistan hemorrhagic fever, have been used for centuries in Central Asia to refer to CCHF.

In modern times, CCHF (then known as Crimean hemorrhagic fever (CHF)) was first described as a clinical entity in 1944–45 when about 200 Soviet military personnel and civilian farmers were infected during an epidemic in war-torn Crimea. Shortly thereafter, a viral etiology was suggested by reproducing a febrile syndrome in psychiatric patients who were inoculated with a filterable agent from the blood of CHF patients. Further evidence of a viral etiology and of a suspected tick-borne route of infection was demonstrated by inducing a mild form of

disease in healthy human volunteers after their inoculation with filtered suspensions of nymphal *H. marginatum* ticks. In 1967, the Russian virologist M. P. Chumakov and his colleagues at the Institute of Poliomyelitis and Viral Encephalitides in Moscow were the first to use newborn white mice for CHF virus isolation.

In 1956, Dr. Ghislaine Courtois at the Provincial Medical Laboratory in what was then Stanleyville, Belgian Congo, isolated a virus, referred to as Congo virus, from the blood of a 13-year-old boy who had fever, headache, nausea, vomiting, and generalized joint pains. Interestingly, a second isolation of the virus was made from the blood of Dr. Courtois, who subsequently became ill with symptoms similar to those of the boy. Subsequent work showed that Crimean hemorrhagic fever virus was antigenically indistinguishable from Congo virus and were in fact, the same virus, leading to the new name, Crimean–Congo hemorrhagic fever virus.

Other Important Members of the Genus *Nairovirus*

NSDV, an important cause of livestock disease, was originally isolated from sheep in Nairobi, Kenya in 1910. Dugbe virus was originally isolated from *A. variegatum* ticks from Ibadan, Nigeria in 1964. Ganjam virus (**Figure 1**), which is now considered to be a strain of NSDV, was originally isolated from *Haemaphysalis intermedia* ticks collected from goats in the Ganjam district of India in 1954. Most other nairoviruses were first isolated in the 1960s or 1970s from ticks parasitizing seabirds and other birds (**Table 1**).

Taxonomy and Classification

According to the Eighth Report of the International Committee on the Taxonomy of Viruses, the species *Crimean–Congo hemorrhagic fever virus* is classified in the genus *Nairovirus*. There are seven recognized species in the genus, containing a total of 34 viruses, most of which are transmitted by either ixodid or argasid ticks (i.e., hard or soft ticks, respectively) (**Table 1**).

Geographical Distribution

The known distribution of CCHFV covers the greatest geographic range of any tick-borne virus and there are reports of viral isolation and/or disease from more than 30 countries in Africa, Asia, southeast Europe, and the Middle East. Evidence for its presence in France, Portugal, Egypt, and India is based only on limited serologic observations. Interestingly, after several decades of only serologic evidence of the existence of CCHFV in Turkey, a large outbreak of disease in that country began in 2002, is ongoing, and has resulted in more than 900 cases. This highlights the ability of CCHF to emerge in geographic regions that have previously been devoid of the disease.

Ecology and Epidemiology

As do other tick-borne zoonotic agents, CCHFV generally circulates in nature unnoticed in an enzootic tick-vertebrate-tick cycle. CCHFV has been isolated from numerous domestic and wild vertebrates, including cattle and goats, sheep, hares, hedgehogs, and even domestic dogs. Sera from wild mammals of several species have been shown to have antibodies to CCHFV and seroepidemiological studies have also detected antibodies to CCHFV in domestic cattle, horses, donkeys, sheep, goats, and pigs from various parts of Europe, Asia, and Africa. Interestingly, there has been only one report of antibody to CCHFV detected from a reptile, a tortoise from Tadzhikistan.

Although many domestic and wild vertebrates are infected with CCHFV, as evidenced by development of viremia and/or antibody response, birds, in general, appear to be refractory to infection with CCHFV. One interesting exception is ostriches, which become infected with CCHFV and have been the source of several cases of CCHF associated with slaughtering ostriches in South Africa.

The natural cycle of CCHFV includes transovarial (i.e., passed through the eggs) and trans-stadial (i.e., passed directly from immature ticks to subsequent life stages) transmission among ticks in a tick–vertebrate–tick cycle. CCHFV has been isolated from ticks in at least 31 species. Viral isolations have been made from ticks of two species

in the family *Argasidae* and from ticks of seven genera of the family *Ixodidae*. However, the virus appears to be most efficiently transmitted by ticks of the genus *Hyalomma* (**Figure 2**) and, in general, the known occurrence of CCHFV in Europe, Asia, and Africa coincides with the geographic distribution of these ticks. Although *Hyalomma* spp. ticks are considered the most important in the epidemiology of CCHF, the virus has been isolated from ticks in other genera (i.e., *Rhipicephalus*, *Boophilus*, *Dermacentor*, and *Ixodes* spp.) as well, which may contribute to its wide geographical distribution.

The principal vector of NSDV is the ixodid tick *Rhipicephalus appendiculatus*, which occurs throughout East and Central Africa. Most other nairoviruses have been isolated from ticks parasitizing birds and their ecology has not been well studied.

Properties of the Virion and Genome

The morphology and structure of the CCHFV virion was first described in the early 1970s from the brains of infected newborn mice. It is now known that CCHFV and nairoviruses in general, are typical of other members of the family *Bunyaviridae* in terms of their basic structure, morphogenesis, replication cycle, and physicochemical

Figure 2 Dorsal view of a *Hyalomma marginatum marginatum* female tick. Photo courtesy of Dr. Zati Vatansever, Ankara University Faculty of Veterinary Medicine, Ankara, Turkey.

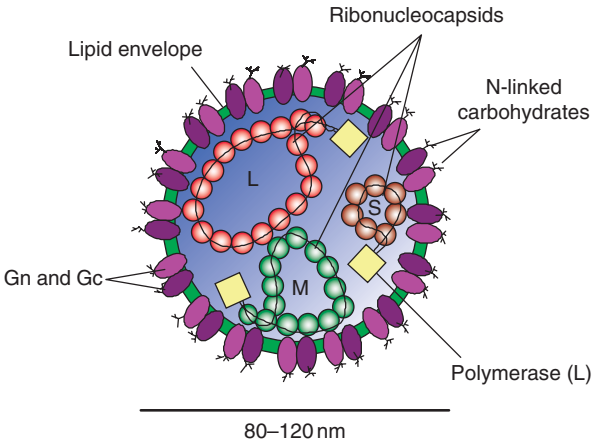

Figure 3 Schematic cross-section of a *Bunyaviridae* virion. The three RNA genome segments (S, M, and L) are complexed with nucleocapsid protein to form the ribonucleocapsids. The nucleocapsids and RNA-dependent RNA polymerase are packaged within a lipid envelope that contains the viral glycoproteins, Gn and Gc. Adapted from Schmaljohn CS and Hooper JW (2001) Bunyaviridae: The viruses and their replication. In: Knipe DM and Howley PM (eds.) *Fields Virology*, 4th edn., pp. 1447–1472. Philadelphia: Lippincott Williams and Wilkins, with permission from Lippincott Williams and Wilkins.

properties. Virions are spherical, approximately 100 nm in diameter, and have a host cell-derived lipid bilayered envelope approximately 5–7 nm thick, through which protrude glycoprotein spikes 8–10 nm in length (**Figure 3**). Virions of members of the family *Bunyaviridae* contain three structural proteins: two envelope glycoproteins (Gn and Gc (previously termed G2 and G1)), named in accordance with their relative proximity to the amino or carboxy terminus of the M segment-encoded polyprotein, respectively, and a nucleocapsid protein (N), plus a large polypeptide (L), which is the viron-associated RNA-dependent RNA polymerase (**Figure 3**).

The genome is typical of those of other members of the family and is composed of three negative-strand RNA segments, S, M, and L, encoding the N nucleocapsid, Gn and Gc glycoproteins, and the L polymerase, respectively. The RNA segments are complexed with N to form individual S, M, and L nucleocapsids, which appear to be circular or loosely helical. The M segment of nairoviruses is 30–50% larger than the M segments of members of other genera in the *Bunyaviridae* family and has a potential coding capacity of up to 240 kDa of protein. At least one of each of the S, M, and L ribonucleocapsids must be contained in a virion for infectivity; however, equal numbers of nucleocapsids may not always be packaged in mature virions. Recent data show that the N protein is targeted to the perinuclear region of infected cells in the absence of native RNA segments and that this targeting is actin filament dependent. The first 8–13 nucleotide bases at the 3′-termini of all three RNA segments have a sequence (3′-AGAGUUUCU-) that is conserved within viruses of the genus, with a complementary consensus sequence at the 5′-termini. Base-pairing of the terminal nucleotides is predicted to form stable panhandle structures and noncovalently closed circular RNAs, which have been directly observed by electron microscopy of RNA extracted from the bunyavirus *Uukuniemi Virus*.

The principal stages of the replication process for viruses in the *Bunyaviridae* are similar to those of many other enveloped viruses. The viral glycoproteins are believed to be responsible for recognition of receptor sites on susceptible cells. Viruses that attach to receptors on susceptible cells are internalized by endocytosis, and replication occurs in the cytoplasm. Virions mature by budding through endoplasmic reticulum into cytoplasmic vesicles in the Golgi region, which are presumed to fuse with the plasma membrane to release virus.

Recently, a reverse genetics system was developed for CCHFV. The development of such a system was a major step forward in efforts to understand the biology of the virus. Developing an infectious clone for CCHFV will allow for more extensive studies of its biology and pathogenesis, and may ultimately lead to better therapeutic and prophylactic measures against CCHFV infections.

Phylogenetic Relationships

Many early studies, based on serological testing, suggested that there are very few significant differences among strains of CCHFV. Recent data based on nucleic acid sequence analyses have revealed extensive genetic diversity. For example, analysis of the S RNA segment reveals

the existence of seven distinct virus groups (i.e., genotypes) (**Figure 4**). These genotypes show a strong correlation with the geographical area of viral isolation. Furthermore, studies have discovered similar genotypes in distant geographical locations. Movement of CCHFV-infected livestock or uninfected livestock carrying infected ticks may explain some of the movement of viral genetic lineages within diverse regions. Other explanations include the movement of virus via migratory animals or birds that are either infected or are carrying virus-infected ticks. It is interesting that the Greek strain AP92 differed greatly from other European strains, and therefore is in a group by itself (**Figure 4**). AP92 strain was originally isolated in Greece from a *Rhipicephalus bursa* tick and has not yet been associated with disease in humans.

Sequence information on the L RNA segment has lagged behind those of the S and M RNA segments; nevertheless, there is evidence that the S and L RNA segments have the same evolutionary history. Thus, essentially identical S and L tree topologies are seen when analyzing all the available segment sequences. This, however, is not the case for the M RNA segment. This is generally taken for evidence of RNA segment reassortment. RNA viruses with segmented genomes have the capacity to reassort their genomic segments into new, genetically distinct viruses if the two or more viruses co-infect the same target cell.

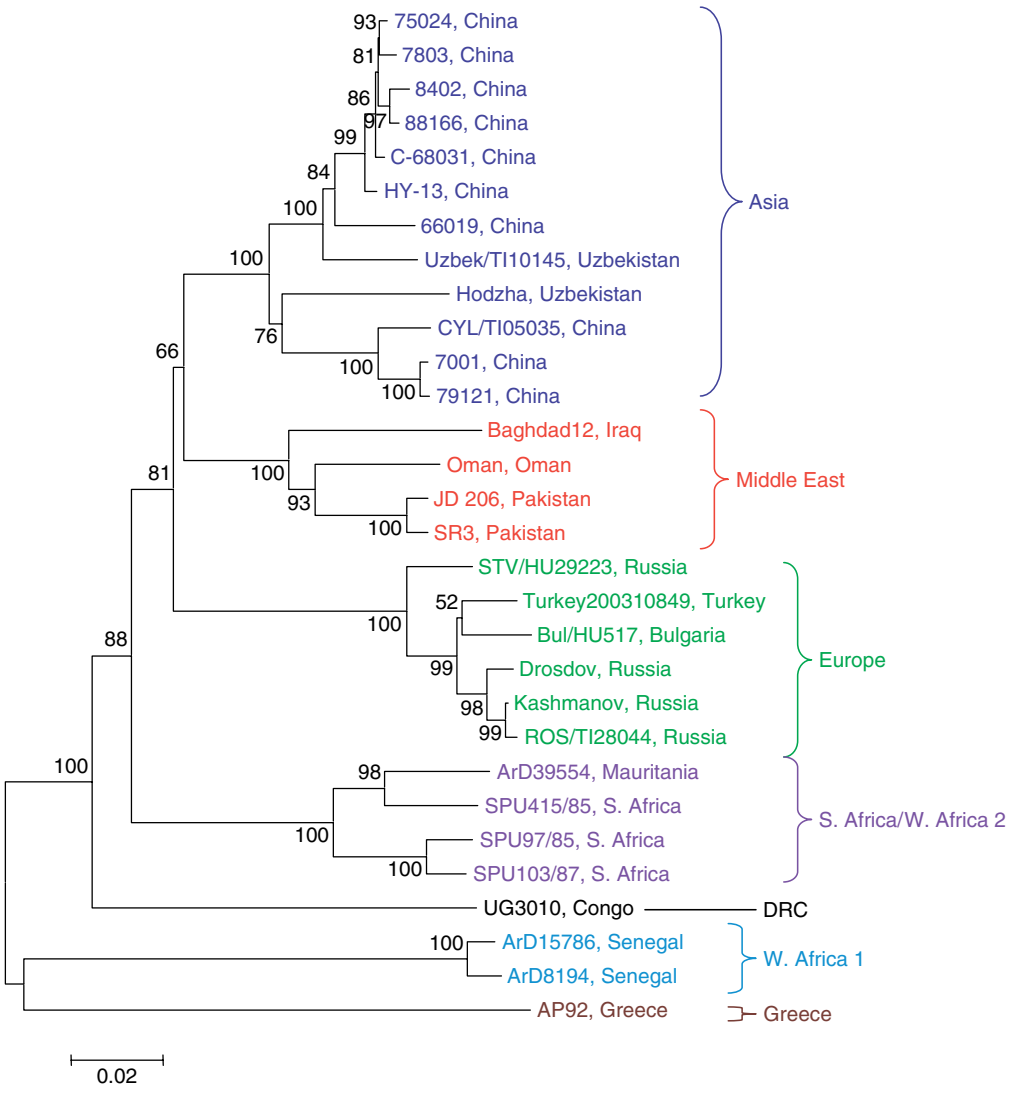

Figure 4 Phylogenetic relationships of the S segment RNA of CCHFV. Complete sequences of S segment RNA were aligned and analyzed by a neighbor-joining method with Kimura two-parameter distances by using MEGA software (version 3.1). The lengths of the horizontal branches are proportional to the number of nucleotide differences between taxa. Bootstrap values above 50%, obtained from 500 replicates of the analysis, are shown at the appropriate branch points. CCHFV strains are described as strain designation, country of origin. Scale = 2% divergence.

Figure 5 Ecchymosis seen on the arm of a CCHF patient. Photo courtesy of Dr. Miro Petrovec, University of Ljubljana, Slovenia.

Indeed, several examples of RNA segment reassortment have been documented among viruses of the family *Bunyaviridae*, including CCHFV. Furthermore, reassortment appears to be much more frequently observed among CCHFV M RNA segments than among S and L RNA segments.

Clinical Features

Except for newborn mice, humans appear to be the only host of CCHFV in which disease is manifested. In contrast to the inapparent infection in most other vertebrate hosts, human infection with CCHFV often results in severe hemorrhagic disease. The typical course of CCHF is noted by some authors as progressing through four distinct phases, that is, 'incubation', 'prehemorrhagic', 'hemorrhagic', and 'convalescence'; it is noteworthy that the duration and associated symptoms of these phases can vary greatly. In general, the incubation period after a tick bite can be as brief as 1–3 days, but can be much longer depending on several factors including route of exposure. After the incubation period, the prehemorrhagic period is characterized by sudden onset of fever, chills, severe headache, dizziness, photophobia, and back and abdominal pains. Additional symptoms such as nausea, vomiting, diarrhea, and an accompanying loss of appetite are common. Fever is often very high (39–41 °C) and can remain continually elevated for 5–12 days or may be biphasic. It is interesting that neuropsychiatric changes have been reported in some CCHF patients. These have included sharp changes in mood, with feelings of confusion and aggression and even some bouts of violent behavior. Cardiovascular changes can also be seen and include bradycardia and low blood pressure. In severe cases, 3–6 days after the onset of disease, hemorrhagic manifestations develop. These can range from petechiae to large areas of ecchymosis and often appear on the mucous membranes and skin, especially on the upper body and/or extremities (**Figure 5**). Bleeding in the form of melena, hematemesis, and epistaxis is also commonly seen by day 4 or 5 and can often be characterized by dark 'coffee grounds' vomitus and tarlike stools resulting from intestinal hemorrhages. Bleeding from other sites including the vagina, gingival bleeding, and, in the most severe cases, cerebral hemorrhage have been reported. About 50% of the patients develop hepatomegaly. Not surprisingly, poor prognosis is associated with cerebral hemorrhage and massive liver necrosis. Mortality rates for the various CCHF epidemics and outbreaks have varied greatly. The average mortality rate is often cited at 30–50%; however, rates as high as 72.7% and 80% have been reported from the United Arab Emirates and China, respectively. During the recent outbreak in Turkey, of the 500 cases reported to the Turkish Ministry of Health, 26 (5.2%) were fatal. Mortality rates of nosocomial infections are often much higher than those acquired naturally through tick bite. The exact reasons for this phenomenon are not known, but may simply relate to viral dose.

Pathogenesis

Because of the difficulties of working with CCHFV (e.g., the need for specialized containment laboratories) and the lack of an animal model of disease, the pathogenesis of CCHF is poorly understood. Capillary fragility is a common feature of CCHF, suggesting infection of the endothelium. This is surely where the alternative term 'capillary toxicosis', given to CCHF by the early Soviet workers, was derived. Localization of CCHFV in tissues by immunohistochemistry has shown that mononuclear phagocytes and endothelial cells are major sites of viral infection. Endothelial damage would account for the characteristic rash and contribute to hemostatic failure

by stimulating platelet aggregation and degranulation, with consequent activation of the intrinsic coagulation cascade. Thrombocytopenia appears to be a consistent feature of CCHF infection and platelet counts can often be extremely low beginning at the early stage of illness in fatal cases.

Some have argued that the characteristic endothelial damage seen in CCHF is not necessarily the result of direct infection of the endothelial cells by CCHFV. Evidence is mounting that for viral hemorrhagic fever, caused by the Ebola virus, much of the cellular damage and resulting coagulopathy results from multiple host-induced mechanisms. These include massive apoptosis of lymphocytes both intravascularly and in lymphoid organs; induction of pro-inflammatory cytokines, including tumor necrosis factor (TNF)-α; and the dysregulation of the coagulation cascade leading to disseminated intravascular coagulation (DIC). Indeed, many of these same features are seen in CCHF, including DIC, vascular dysfunction, and shock. Clearly, more work needs to be done in this area to completely understand the pathogenesis of CCHF.

Diagnosis

A diagnosis of CCHF should be considered when severe flu-like symptoms with a sudden onset are seen in patients with a history of tick bite, travel to an endemic area, and/or exposure to blood or other tissues of livestock or human patients. Early diagnosis is essential, both for the outcome of the patient and because of the potential for nosocomial infections. The differential diagnosis should include rickettsiosis (tick-borne typhus or African tick bite fever caused by *Rickettsia conorii* and *R. africae*, respectively), leptospirosis, and borreliosis (relapsing fever). Additionally, other infections, which present as hemorrhagic disease such as meningococcal infections, hantaviral hemorrhagic fever, malaria, yellow fever, dengue, Omsk hemorrhagic fever, and Kyasanur Forest disease should be considered. In Africa, Lassa fever and infection with the filoviruses, Ebola and Marburg, must also be included in the differential diagnosis.

The diagnosis of CCHF is confirmed by detecting viral nucleic acid by reverse transcription-polymerase chain reaction (RT-PCR), demonstration of viral antigen by enzyme-linked immunosorbent assay (ELISA), or isolation of the virus. Any attempts at isolating and culturing the virus should be performed only under BSL-4 containment. The traditional method and 'gold standard' for CCHFV isolation has been by intracranial or intraperitoneal inoculation of a sample into newborn mice. However, isolation in cell culture is far simpler and safer and provides a more rapid result. Virus can be isolated from blood and organ suspensions in a wide variety of susceptible cell lines including LLC-MK2, Vero, BHK-21, and SW-13 cells with maximal viral yields after 4–7 days of incubation. In some cases however, depending on the cell line and strain, the virus may induce little or no cytopathic effect (CPE). In these cases, the presence of virus can be identified by performing an immunofluorescence assay (IFA) with specific antibodies to CCHFV or by RT-PCR.

The neutralizing antibody response to CCHFV, as well as to other nairoviruses, is weak and difficult to demonstrate. Both IgG and IgM antibodies are detectable by IFA by about day 5 of illness and are present in the sera of survivors by day 9. The IgM antibody declines to undetectable levels by the fourth month after infection, and IgG titers may also begin to decline gradually at this time, but remain demonstrable for at least 5 years. An antibody response is rarely detectable in fatal cases and diagnosis is usually confirmed by isolating the virus from the serum or from liver biopsy specimens or by demonstrating the presence of CCHFV antigen by immunohistochemical techniques of paraffin-embedded liver sections or by IFA of liver impression smears.

Molecular-based diagnostic assays, such as RT-PCR, provide a useful complement to serodiagnosis and now often serve as the front-line tool both in the diagnosis of CCHF and in epidemiological studies of the disease.

Prevention and Control

Several groups of individuals are considered to be at risk of contracting CCHF – specifically, people from endemic areas who are liable to be fed upon by ticks, particularly *Hyalomma* spp. ticks. These include individuals who work outdoors, particularly those who work with large domestic animals. Exposures such as crushing infected ticks and butchering infected animals have also been a frequent source of CCHFV infection. Other groups who are at risk include those caring for CCHF patients. In fact, the risk of nosocomial infection in healthcare workers is well documented and can be extremely high, especially during the hemorrhagic period of disease.

Avoiding or minimizing exposure to the virus is the best means of preventing CCHF. Persons in high-risk occupations (i.e., slaughterhouse workers, veterinarians, sheep herders, etc.) should take every precaution to avoid exposure to virus-infected ticks or virus-contaminated animal blood or other tissues. For example, wearing gloves and limiting exposure of naked skin to fresh blood and other tissues of animals are effective practical control measures. Likewise, medical personnel who care for suspected CCHF patients should practice standard barrier-nursing techniques. Tick control may not be practical in many regions of the world where *Hyalomma*

ticks are most prevalent. However, acaricide treatment of livestock in CCHFV-endemic areas is effective in reducing the population of infected ticks. Applying commercially available insect repellents (i.e., meta-*N,N*-diethyl toluamide (DEET)) to exposed skin and using clothes impregnated with permethrin can provide some protection against tick bites. As for other tick-borne viruses, inspecting one's body and clothes for ticks, and their prompt removal can minimize the risk of infection. An inactivated vaccine, prepared from the brains of infected suckling mice, was used in Eastern Europe and the former Soviet Union in the past, but no vaccines are currently available.

Treatment

Treatment options for CCHF are limited and primarily consist of supportive and replacement therapies. Standard treatment consists of monitoring patients with replacement of red blood cells, platelets, and other coagulation factors. Immunotherapy has been attempted by passive transfer of CCHF survivor convalescent plasma, but the efficacy of this treatment is not clear. There is currently no specific antiviral therapy for CCHF approved for use in humans by the US Food and Drug Administration. An antiviral drug, ribavirin, is effective against CCHFV in culture and has shown the most promise in treating CCHF patients over the years. However, for the best patient outcome, treatment should be started early, ideally, before day 5 of illness.

Introduction

X-ray crystallography has yielded atomic models of icosahedral viruses of up to 700 Å diameter (e.g., bluetongue virus, reovirus, and bacteriophage PRD1). However, crystallography has not been successful with larger viruses, is not yet able to yield high-resolution details of nonicosahedral components in intact virus particles, and is of limited use in examining partially purified or low-concentration specimens or samples with mixtures of different conformational states. Many of these limitations can be overcome by using cryoelectron microscopy (cryoEM) and image reconstruction approaches. Furthermore, cryoEM has been useful not only to virologists for understanding virus assembly and virus–antibody and virus–receptor interactions, but also to electron microscopists for driving developments in electron imaging technology.

In the early 1970s, DeRosier, Crowther, and Klug introduced the method for icosahedral particle reconstruction, which marked the beginning of three-dimensional (3-D) electron microscopy for spherical viruses. Initially, these studies used stained and dried specimens. However, in the early 1980s, Dubochet and co-workers developed

vitrification methods that use rapid freezing of solutions to preserve the intact structures of biological macromolecules for electron imaging. They demonstrated the feasibility of reconstructing the 3-D structure of a virus particle in its native conformation without using stain or fixative.

Both the quality of the electron images and the resolving power of the single-particle reconstruction algorithms have been continuously improved in the last 20 years to the extent that it is now possible to routinely obtain virus structures at subnanometer resolutions (6–10 Å). Although not yet equal to X-ray crystallographic resolution, this does allow identification of secondary structure elements such as long α-helices and large β-sheets in protein subunits of virus particles.

All the subnanometer resolution cryoEM structures of viruses solved so far, have made use of the icosahedral properties of the particle. However, the assembly and infection processes in many viruses depend on structures which break the icosahedral symmetry of the particle. Details of the organization of these nonicosahedral components are absent from almost all crystal structures of virions due to the icosahedral averaging used in the data processing. Similarly, cryoEM reconstructions from single-particle images that are dependent on icosahedral averaging do not show the nonicosahedral components.

Recently, image reconstruction techniques have been introduced to compute a density map without imposing icosahedral symmetry. This approach has been successfully used to visualize all the structural components of bacteriophages T7, Epsilon15, and P22 at moderate resolution (17–20 Å).

Another imaging method called electron cryotomography (cryoET) has been used to reconstruct large enveloped viruses such as human immunodeficiency virus (HIV), vaccinia virus, and herpes simplex virus (HSV) at 100–60 Å resolution. Subsequent single-particle averaging of certain computationally extracted components has yielded their 3-D structures to 50–30 Å resolution. This approach is ideal for obtaining low-resolution information from virus particles containing both conformationally constant and variable components.

CryoEM of Single Virus Particles

CryoEM of single particles consists of four basic steps: cryo-specimen preparation, imaging in an electron cryomicrosope, image reconstruction, and structural interpretation. Because there are excellent reviews that describe the detailed procedures involved, in this article the focus is on the fundamental concepts of this methodology, including some practical considerations where appropriate.

Cryo-Specimen Preparation

Specimens in the electron microscope have to be examined in a high vacuum (10^{-6} torr) environment, which would dehydrate and thus destroy the native structure of any normal biological specimen. Fortunately, the rapid freezing methods developed by Dubochet and co-workers can preserve specimens embedded in a thin layer of vitreous ice. Using this procedure, the virus particles are maintained in their original solution state. Vitrification is the process by which water solidifies without undergoing crystallization and it requires extremely rapid cooling. This can be achieved by applying the sample to a microscope grid that has been overlaid with a thin film of holey carbon, blotting away excess sample, and plunging the very thin aqueous film into liquid ethane that has been cooled to liquid nitrogen temperature. An ideal situation is for the ice to be slightly thicker than the virus particles. In practice, there is always variation in ice thickness even across a single microscope grid. For any new specimen, a process of systematic trial and error will eventually identify freezing conditions that yield optimal ice thickness in at least some parts of a grid.

An important practical consideration in cryo-specimen preparation is the concentration of the sample, which ideally should be in the order of 10^{10} particles ml^{-1}. A subnanometer-resolution icosahedral reconstruction generally needs images of several thousands of particles in different orientations. Therefore, a high particle concentration will reduce the number of micrographs that have to be collected, which will, in turn, reduce the number of data sets to be processed. An added benefit is that having a large number of particles per micrograph facilitates the determination of the defocus value of each micrograph, which is necessary for subsequent data processing. However, such concentrations can be difficult to obtain with some virus samples, in which case the necessary data collection and processing can become very time consuming.

Low-Dose Single-Particle Imaging

Following sample preparation, the grids containing the ice-embedded virus particles can be stored in liquid nitrogen until placed into the electron microscope for imaging. Throughout all stages of the process, the frozen-hydrated specimens must be handled extremely carefully to avoid any ice contamination from moisture in the atmosphere. The specimen is kept at or below liquid nitrogen temperature during the electron microscopy session. Frozen-hydrated biological specimens are extremely sensitive to radiation and must be scrutinized using a very low electron dose. They are examined initially at low magnification (100–1000×) to find a suitable area on the grid and

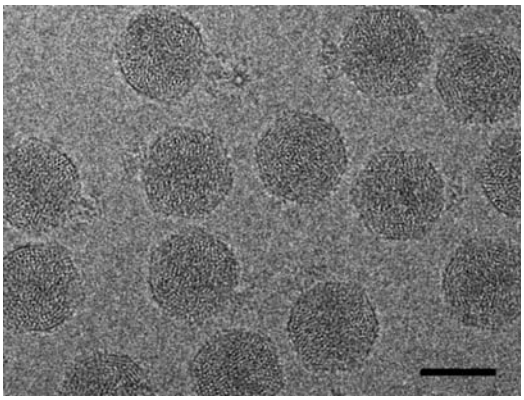

Figure 1 CryoEM imaging. Electron image of frozen-hydrated Epsilon15 phage taken at 300 kV displays the capsids as dark circles. The viral DNA inside is observed as a fingerprint pattern. Scale = 500 Å. Courtesy of Joanita Jakana, Baylor College of Medicine.

then images are recorded at a higher magnification (40 000–80 000×) from the chosen area (**Figure 1**).

The total electron dose that can be tolerated by a specimen depends only slightly on the specimen temperature and the accelerating electron voltage. For most practical purposes, a typical dose is about 15–25 electrons $Å^{-2}$ for single-particle imaging aimed at a resolution of better than 20 Å. A major variable in recording any electron micrograph is the defocus setting for the objective lens, which will vary according to the targeted resolution of the experiment and the type of microscope used. Higher defocus increases image contrast while smaller defocus yields higher-resolution information. Typically, the data for reconstruction are collected with defocus values between 1 and 3 μm in order to produce visible image contrast in the raw micrograph while preserving the higher-resolution features retrievable through image processing.

There are two ways to record an electron micrograph: on photographic film or with a charge-coupled device (CCD) camera. The advances in CCD camera technology now enable most medium-resolution data (down to 6–8 Å) to be recorded directly in digital format ready for subsequent steps of image processing. Given the rapid growth in CCD technology, it is likely that photographic film will eventually be replaced completely.

Icosahedral Reconstruction

Many viruses are composed of spherical protein shells arranged icosahedrally. **Figure 1** shows a representative cryoEM image of this type of particle. It is important that the particles are oriented randomly in the matrix of embedding ice because the task of image reconstruction involves combining particles from different

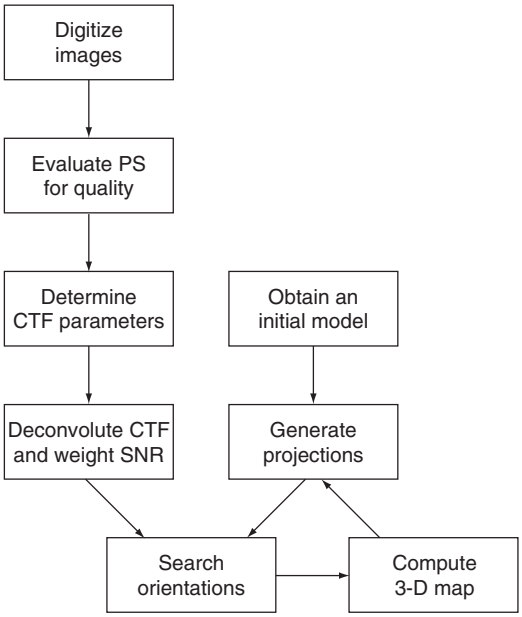

Figure 2 A 3-D image reconstruction scheme for icosahedral particles. The quality of digitized images is evaluated by analyzing their power spectrum (PS). Next, the contrast transfer function (CTF) parameters are determined for each image and used to deconvolute and weigh them according to their signal-to-noise ratio (SNR). The orientations of the deconvoluted images are determined by comparing them against projections from a 3-D map generated from a starting model. The oriented images are used to reconstruct a better 3-D map, which is subsequently used to generate better projections. The new projections are used to improve the accuracy of the search for the image orientations. The 3-D map improves after each iteration until it converges and the processing can stop.

orientations into a 3-D density map. The separate steps in image reconstruction are outlined in **Figure 2** and described briefly below. To simplify the technical aspects of the procedure, numerous image-processing software packages that can be used for icosahedral reconstruction have been developed.

Initially, each micrograph captured from a CCD camera or digitized from photographic film is evaluated for its image quality based on the power spectrum derived from the average of multiple Fourier transforms of computationally isolated particle images. This power spectrum contains information about the structure of the particles, the imaging conditions used, and the image quality. The ring pattern in the power spectrum (**Figure 3**(**a**)) reflects the imaging condition known as the contrast transfer function (CTF). It can vary in appearance according to factors such as defocus, astigmatism, specimen drift, and signal decay as a function of resolution, all of which are attributable to various instrumental factors. The signal-to-noise ratio (SNR) in each micrograph can be computed from the circularly averaged power spectrum. The SNR plot (**Figure 3**(**b**)) indicates the potential signal strength

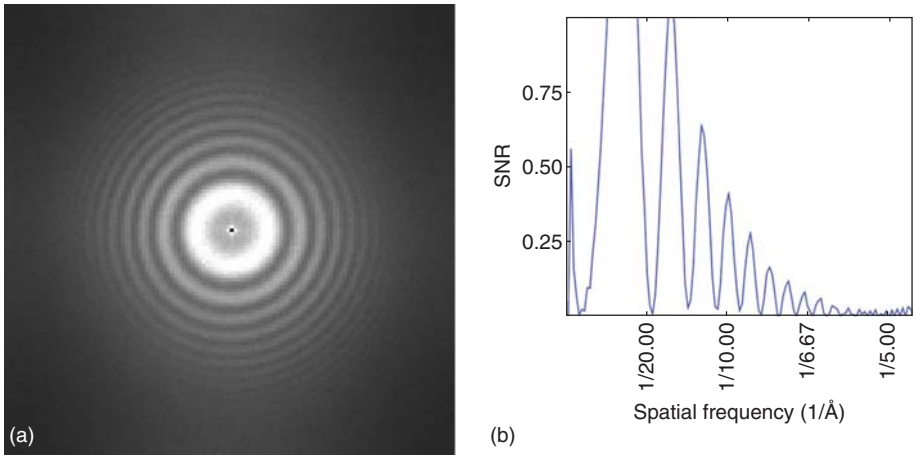

Figure 3 Evaluating image quality. (a) The power spectrum derived from averaging the Fourier transforms of particles boxed out from electron images such as those in **Figure 1**. (b) SNR plot of the boxed particle images as a function of spatial frequency (resolution) computed from the circularly averaged power spectrum. For a conservative measure of 10% SNR, the usable data extends beyond 8 Å resolution. Courtesy of Donghua Chen, Baylor College of Medicine.

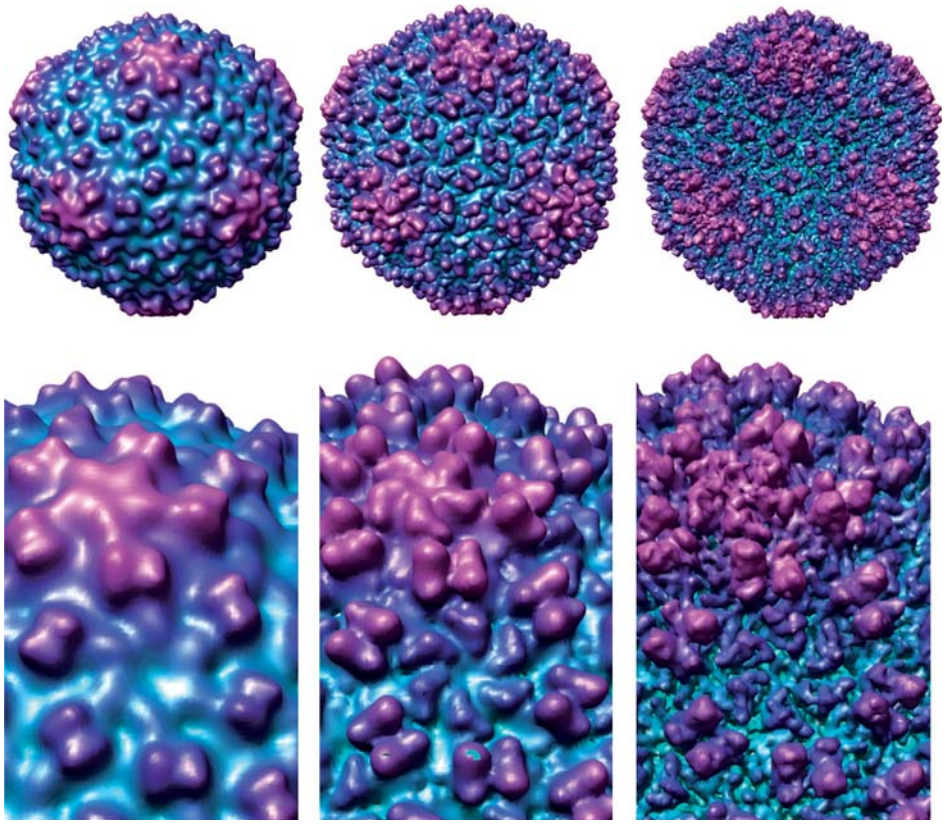
at different resolutions and gives an indication of the ultimately achievable resolution in the reconstruction.

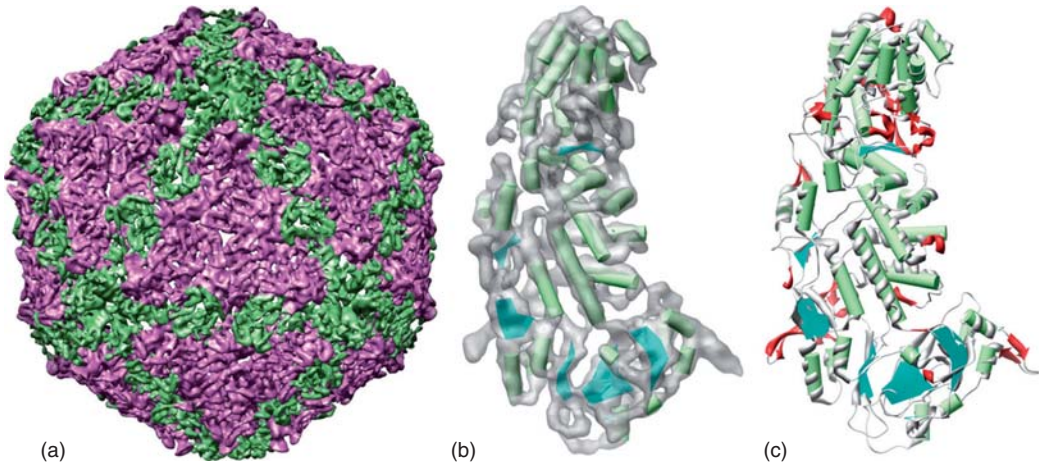
In order to obtain a correct structure, each raw particle image has to be deconvoluted by its CTF and be compensated for the signal decay at high resolution (**Figure 2**). The image deconvolution and signal-to-noise weighing are usually carried out for each raw particle image before the orientation of the particles is determined. Following orientation determination, the corrected particle images are merged to synthesize the 3-D map. Alternatively, the deconvolution can be carried out on the preliminary 3-D maps computed from each micrograph, with the deconvoluted maps being merged subsequently to produce the final map.



The most computationally demanding aspect of image processing is the estimation and refinement of the five spatial parameters (three for rotations around x-, y-, and z-axes, and two for center in x- and y-directions) for each particle image (**Figure 2**). There are a number of different algorithms and software packages that can be used to perform this critical task. Most of these programs require an initial model of the particle, from which they generate multiple projection images showing the particle model in different orientations. These projection images are then compared with each of the raw particle images. The projection image that gives the closest match is assumed to have the same orientation as the virus particle that produced the raw image. Each algorithm uses different criteria for comparing the reference and raw particle images to derive the spatial parameters. Throughout a series of iterative refinement steps, the model is continuously updated and its resolution is gradually increased (**Figure 2**).

During the steps of orientation and center determination, and 3-D reconstruction, the algorithms assume that the particle has icosahedral symmetry. This means that the particle is made up of 60 repeated (asymmetric) units, which are related to each other by five-, three-, and twofold symmetry operations. If the particle does not have the expected symmetry, the algorithm will not yield a consistent map and will not be able to derive its structure. On the other hand, it is possible that in some particles the icosahedral symmetry is preserved only up to a certain resolution, which would limit the ultimate resolution of the reconstruction. This is analogous to a protein crystal only diffracting up to some resolution limit beyond which the crystal structure cannot be resolved.

Interpreting CryoEM Single-Particle Density Maps



The challenge in interpreting a cryoEM density map varies according to its resolution. Maps of different resolutions reveal different structural features of the icosahedral shell proteins (**Figure 4**). A low-resolution map (down to 30 Å) can yield the size, shape, and organization (triangulation number) of the icosahedral particle. In fact, cryoEM is probably the most reliable technique for providing such information. In a moderate resolution map (20–10 Å), the subunit boundaries may begin to be resolved. The segmentation of the map into subunits can be done qualitatively by visual inspection of the structure in front of a graphics terminal or quantitatively by a software program. The accuracy of the segmentation is ultimately dictated by the resolution of the map.

When a cryoEM density map reaches subnanometer resolution, long α-helices and large β-sheets become visually recognizable and can be assessed quantitatively (**Figure 5**). In intermediate resolution (7–9 Å) density maps, it has been shown that it is possible to correctly

(a) (b) (c)

Figure 4 CryoEM maps of Epsilon15 phage at different resolutions. The surface-rendered images of the whole capsid (top row) and a close-up of the asymmetric unit (bottom) show that (a) at 40 Å resolution, the overall morphology and triangulation number can be distinguished; (b) at 20 Å resolution, it is possible to visualize the subunit separation in the hexons and pentons; and (c) at 9.5 Å resolution, α-helices are discernible as rod-like densities (EMD-1176). The display was colored radially.

(a) (b) (c)

Figure 5 CryoEM map of rice dwarf virus matches the crystal structure. (a) The inner capsid map segmented from a 6.8 Å resolution cryoEM reconstruction of the entire virus, with the two different conformations of the capsid protein P3A and P3B colored green and violet, respectively (EMD-1060). (b) Segmented inner capsid shell protein P3A with predicted secondary structure elements annotated as cylinders (α-helices) and surfaces (β-sheets). (c) Overlaying the crystal structure (ribbons, 1UF2) onto the secondary structure prediction shows a good match. (a) Reproduced from Zhou ZH, Baker ML, Jiang W, *et al*. (2001) Electron cryomicroscopy and bioinformatics suggest protein fold models for rice dwarf virus. *Nature Structural Biology* 8: 868–873. (c) Reproduced from Baker ML, Ju T, and Chiu W (2007) Identification of secondary structure elements in intermediate-resolution density maps. *Structure* 15: 7–19, with permission from Elsevier.

identify and annotate nearly all of the helices with $\geq$2.5 turns and sheets with $\geq$2 strands. For example, the match (**Figure 5**(**c**)) between the secondary structural elements determined from the 6.8 Å cryoEM map of the rice dwarf virus and the crystal structure that was obtained later demonstrated the reliability of the cryoEM reconstruction and of the structural feature identification.

Asymmetric Reconstruction of an Icosahedral Particle with a Unique Vertex

Though icosahedral reconstruction methods have been very successful in providing structural information on capsid shell proteins, they reveal nothing about any nonicosahedral components. Recently, however, several image-processing procedures have emerged for reconstructing spherical virus particles with tail structures without imposing symmetry. Roughly speaking, the reconstruction procedure uses an initial icosahedral reconstruction of the particle as a starting model for the asymmetric reconstruction. Because only one vertex of the virus particle has the additional mass of the tail, a crude model can be generated by computationally adding a cylinder of density at one of the fivefold vertices of the icosahedral reconstruction. This tailed model is projected in each of the 60 icosahedrally equivalent views and compared with the raw particle image to identify the view that produces the best match. Once the orientations of all the images have been determined, they are used to reconstruct the map without imposing any symmetry. This process of projection matching is iterated using a constantly updated reconstruction, until the cylindrical symmetry of the tail is broken, revealing its true structure. **Figure 6** shows the asymmetric reconstruction of Epsilon15 phage where, in addition to the capsid shell, multiple nonicosahedrally ordered molecular components and the internal DNA can be visualized.

Modeling Virus Particles with CryoEM Density Map Constraints

It is not uncommon for components of a virus particle to be crystallized and structurally determined while only a low- or medium-resolution cryoEM map of the entire virus particle is available. In these cases, a pseudo-atomic model of the virus particle can often be built by docking the crystal structures of the solved components into the cryoEM map. The docking can be done visually or quantitatively using a fitting program. Examples of this are provided by adenovirus and herpesvirus. In neither case has the intact capsid been crystallized, but inserting the crystal structures of the adenovirus hexon and penton base proteins, or a domain of HSV-1 major capsid protein

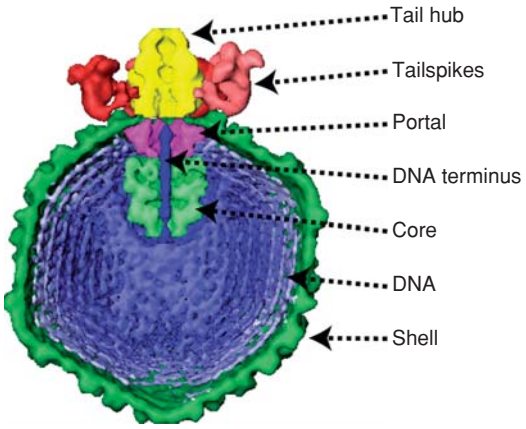


Figure 6 Asymmetric reconstruction of Epsilon15 phage. The map reveals all the structural components of the capsid shell, DNA, core, portal, tailspikes, and tail hub (EMD-1175). Reproduced from Jiang W, Chang J, Jakana J, Weigele P, King J, and Chiu W (2006) Structure of Epsilon15 phage reveals organization of genome and DNA packaging/injection apparatus. *Nature* 439(7076): 612–616.

into the respective cryoEM structures, has provided us with pseudo-atomic models that reveal important features of the capsids. An outstanding example of how cryoEM and crystallographic data can be merged to establish a pseudo-atomic model is provided by the T4 bacteriophage baseplate (**Figure 7**). Here, the crystal structures of six separate molecular components have been fitted into the reconstruction of the baseplate, leading to a proposal for the mechanism of DNA injection into the host cell.

Where there is no crystal structure available, it may still be possible to construct a set of structural models using either comparative modeling or *ab initio* modeling based on the amino acid sequence alone. In these cases, a cryoEM density map can be used as a template to select the most native-like model. A domain of the VP26 capsid protein of HSV, which has a molecular mass of ~10 kDa, has been modeled *ab initio* using the cryoEM structure of the HSV capsid as a selection constraint. Although the validity of this approach has not yet been confirmed by crystal data, it is encouraging that the model fitting the cryoEM data was consistent with published genetic and biochemical data for VP26.

Low-Dose Cryoelectron Tomographic Imaging of Virus Particles

Particles of some viruses have components that assume different conformations in different particles, making it impossible to generate a 3-D density map by averaging these particles. For this type of particle, the only option available is tomography. While the reconstruction

techniques described above work by combining views of multiple particles in different orientations, tomographic reconstruction combines multiple views of the same particle as its orientation is changed by rotating it between consecutive exposures using a tilting microscope holder. Therefore, this technique allows a low-resolution map to be generated by collecting a tilt series from any cryoEM specimen, and it has been used successfully with a range of viruses including HSV virions and capsids, vaccinia virus, and HIV. Because of the constraints on the number of images that can be acquired due to the effects of radiation damage, cryotomography yields only low-resolution data. Therefore, the strategy is to record multiple images of the specimens at low magnification and under low-dose condition. Typically, a magnification of 10 000–25 000× and a dose of 1–2 electrons $Å^{-2}$ per micrograph are used (**Figure 8**).

Once captured, the tilt series images are aligned and merged to generate a 3-D tomogram. Because the grid supporting the specimen obscures the electron beam, the range of tilts that can be used is limited to about ±70°. As a result, there is a missing wedge of data, which means that each tomogram is subject to distortion and must be interpreted cautiously.

Although tomographic reconstructions are generally of low resolution (100–60 Å), post-tomographic averaging of components with constant conformations can yield higher resolutions. For example, post-tomographic data sorting, mutual alignment, and averaging have been used to generate a model of the herpesvirus capsid with an averaged view of the single portal vertex (**Figure 9**(**a**)). Similarly, the spike of the simian immunodeficiency virus (SIV) particle has been aligned and averaged to produce a map that permitted docking of the crystal structures of the spike proteins (**Figure 9**(**b**)). In this type of approach, the final resolution is limited by a number of factors, including the accuracy of the alignment, the number of independent views of the components included in the

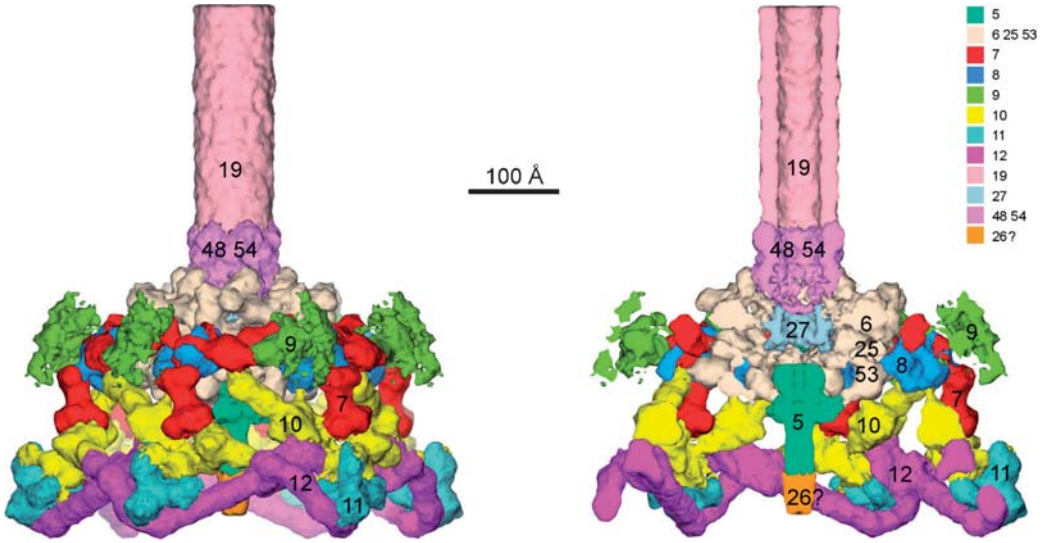

Figure 7 Pseudo-atomic models. Side and cut-away view of the T4 phage tube–baseplate complex. averaging, the symmetry of the components, the proper image deconvolution, the correct compensation for the missing wedge data, and the conformational uniformity of the components.

Biological Insights from CryoEM Maps

The extent of biological information that can be obtained from cryoEM reconstruction varies according to the resolution of the map as well as the design of the experiment. As shown in **Figures 4** and **5**, different structural features can be derived from the cryoEM maps at varying resolutions, ranging from shape, size, triangulation number, capsomere morphology and number, quaternary, tertiary, and secondary structural features of individual protein subunits. Here, a small and not exhaustive set of examples is provided to demonstrate the usefulness of cryoEM maps in the context of virology.

Conservation of Structural Motifs among Viruses

Questions regarding the origin of viruses and their distant evolutionary relationships are handicapped by the low sequence conservation generally found in these small and rapidly evolving entities. Therefore, structural comparison has been used as an alternative indicator of their relatedness. The best-known example of structural analysis revealing a link between supposedly unrelated viruses is that of bacteriophage PRD1 and human adenovirus. Although early cryoEM analysis had shown that the PRD1 capsid structure was very similar to that of adenovirus, it was not until the crystal structures of their respective major capsid proteins were compared that the evolutionary relationship between these viruses was firmly established.

However, in cases where crystal structures are not available, cryoEM maps determined at subnanometer

resolution can provide sufficient information on the pattern of secondary structure elements and thus of the protein folds. **Figure 10** shows a structural comparison of the capsid proteins of the eukaryote-infecting herpesvirus (*Herpesviridae*) and the prokaryote-infecting tailed DNA bacteriophages (*Caudovirales*). Although these proteins have no detectable sequence homology, it is clear from the similar spatial distributions of secondary structural elements that they share a characteristic fold. CryoEM-derived structural data have also revealed conserved features in the unique portal vertices of the two virus types, including a characteristic subunit arrangement and a similar location within the capsid shell (**Figure 9**(**a**)). These observations have led to the conclusion that these very distinct, extant viruses must have arisen from the same primordial progenitors.

Structural Polymorphism during Virus Maturation

Many virus particles undergo structural changes during their morphogenesis. For example, tailed bacteriophages typically form their capsid shell around an internal scaffold of proteins. This initial assembly product (the procapsid) then undergoes a maturation process during which the DNA is packaged, the internal scaffold is lost, and the capsid shell undergoes extensive structural reconfiguration. **Figure 11** demonstrates the structural changes in P22 bacteriophage as revealed from reconstructions of the procapsid and of the mature virion. Not only can changes in the overall size and shape of the capsid be observed but also correlative changes in the quaternary and tertiary structures of individual subunits can be

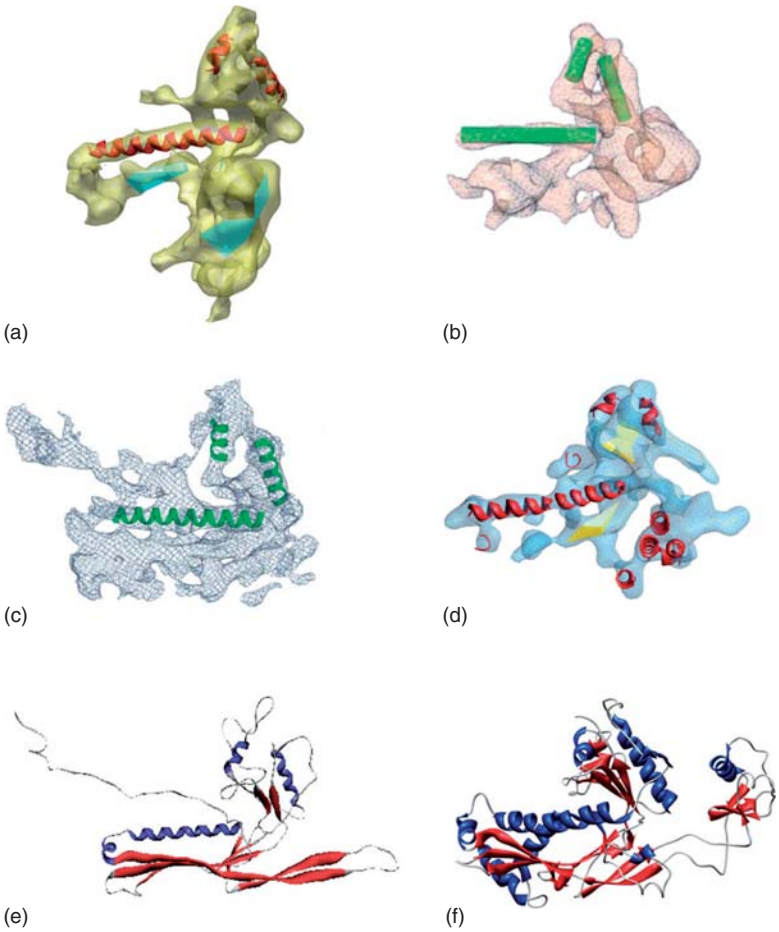

Figure 10 Evolutionary conservation of a structural motif in dsDNA virus particles. CryoEM structure of (a) Epsilon15 phage shell protein, with annotated helices and sheets (EMD-1176), (b) P22 phage coat protein gp5 (EMD-1101), (c) Phi29 phage head protein gp8 (EMD-1120), (d) HSV-1 major capsid protein VP5 floor domain, and crystal structures of (e) HK97 phage head protein gp5 (1OGH) and (f) T4 phage head protein gp24 (1YUE) all have similar structural signatures, which suggest a common ancestry even though they have little sequence similarity. Reproduced from Jiang W, Chang J, Jakana J, Weigele P, King J, and Chiu W (2006) Structure of Epsilon15 phage reveals organization of genome and DNA packaging/injection apparatus. *Nature* 439(7076): 612–616.

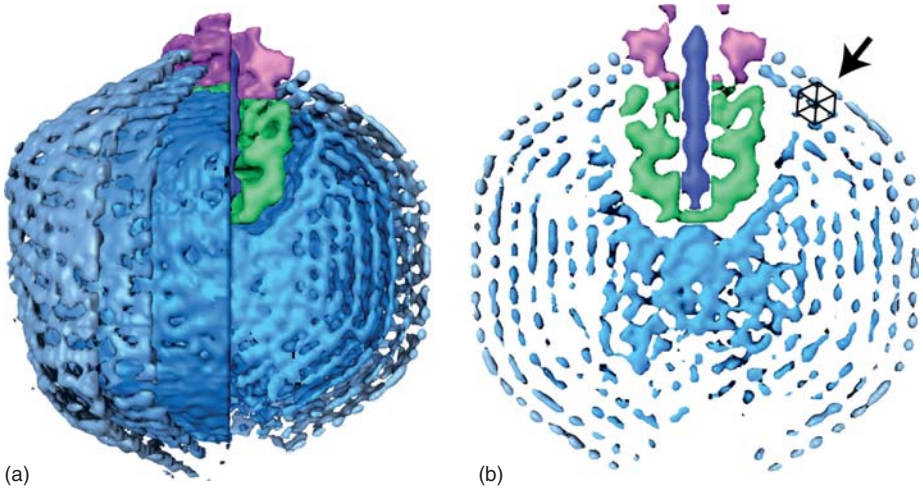
(b) The angular mature capsid is ~700 Å in diameter, and its hexon subunits are arranged hexagonally with more lateral interactions, resulting in a smaller hole (EMD-1101). (c) A close-up view of the procapsid (top) and mature (bottom) hexon. (d) The P22 capsid protein gp5 rearranges when maturing from the procapsid (top, annotated secondary structures in yellow) to the capsid (middle, annotated secondary structures in green), resulting in changes to secondary, tertiary, and quaternary structure, as shown by overlapping the annotated secondary structures (bottom). (d) Reproduced from Jiang W, Li Z, Zhang Z, Baker ML, Prevelige PE, and Chiu W (2003) Coat protein fold and maturation transition of bacteriophage p22 seen at subnanometer resolutions. *Nature Structural Biology* 10:131–135.

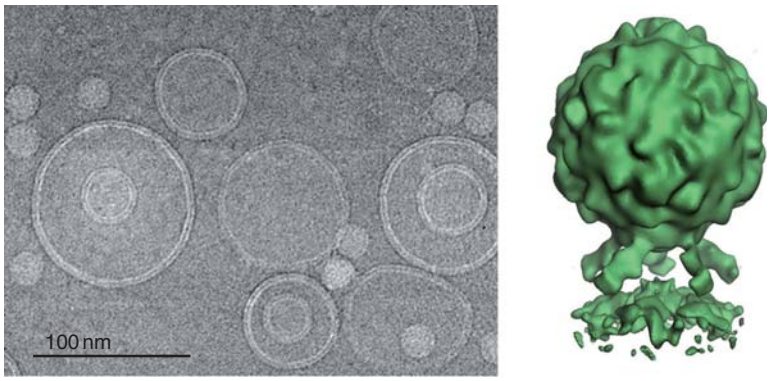
noted. For instance, the organization of subunits in the hexon capsomere changes from a skewed shape to a six-fold symmetrical arrangement. In addition to the overall domain movements in the hexon subunit that bring about this change, the cryoEM structures also reveal more detailed changes such as the refolding of an N-terminal α-helix. Large-scale structural changes have also been visualized during maturation of the HSV capsid. In addition to comparing relatively stable forms of a particle, cryoEM can be used to follow rapid structural changes (e.g., by changing the pH of the buffer immediately before freezing) as observed in Semliki forest virus, Sindbis virus, and La Crosse virus.



Viral Genome Organization

To date, most information on how viral nucleic acids are arranged within particles has come from cryoEM reconstructions. Low-resolution cryoEM reconstruction has revealed that small sections of the RNA genomes in some RNA viruses are bound icosahedrally to the capsid shell proteins, although the bulk of the genome was not resolved even in these cases. However, in general, viral genomes are not packaged icosahedrally within particles and so cannot be visualized by icosahedral reconstruction techniques.

Those double-stranded DNA viruses that package their genomes into preformed capsids pose a particularly interesting dilemma because this must be accomplished without organizing proteins (such as histones) to counter the electrostatic charge of the DNA and the organization must allow for efficient entry and ejection without forming knots or tangles. The arrangement of the nucleic acids in such capsids has been extensively studied and debated. Proposed models include the co-axial spool, spiral fold, liquid crystal, and folded toroid. CryoEM has led the way in shedding light on this question. Analysis of a bacteriophage T7 mutant that was found to orient preferentially in vitreous ice showed the capsids having either concentric rings (axial view) of DNA spaced about 25 Å apart or punctate arrays (side view) suggesting that the DNA was organized in concentric layers. Subsequently, it became possible to examine the DNA in more detail using asymmetric reconstruction algorithms. In Epsilon15 phage, for example, DNA strands are packed as concentric layers in the capsid cavity suggesting a co-axial spool arrangement (**Figure 12**(**a**)), and a slice normal to the DNA strands and parallel to the tail axis shows hexagonal features (**Figure 12**(**b**)). A DNA strand connecting each layer has not yet been observed, but this could be the result of errors in the alignment of the particle images during reconstruction, or due to heterogeneity in where the DNA winding commences. The goal of such studies is to trace the path of the entire nucleic acid molecule within the virion. Asymmetric reconstruction methods at higher resolution are well poised for these determinations.



Virus–Antibody and Cell Receptor Complexes

There is increasing interest in using cryoEM to analyze aspects of virus biology involving interactions with other molecules such as receptors or antibodies. A good

(a) (b)

(b) A slice parallel to the tail axis and normal to the dsDNA strands shows hexagonal features (arrow over polygon).

(a) (b)

Figure 13 Virus–receptor interactions. (a) CryoEM image of poliovirus attached to liposomes with embedded receptors. (b) The reconstruction shows the icosahedral capsid binding to five receptors on the membrane, which orients the capsid so that a fivefold vertex is directed toward the membrane. Courtesy of J. M. Hogle at Harvard Medical School and reproduced with permission from Bubeck D, Filman DJ, and Hogle JM (2005) Cryo-electron microscopy reconstruction of a poliovirus–receptor-membrane complex. *Nature Structural and Molecular Biology* 12: 615–618.

example of the value of this approach is provided by work on virus–receptor interactions in the small icosahedral picornaviruses, notably poliovirus and the common cold virus (rhinovirus). In order to recognize and enter their target cells, viruses must usually bind to specific receptor molecules on the cell surface. When the crystal structure of the rhinovirus particle was first determined, it revealed the existence of a depression or 'canyon' around each fivefold axis of the particle, which was proposed as the binding site for the receptor. However, direct confirmation of this proposal was not obtained until icosahedral reconstruction was carried out on cryoEM images of virus particles bound to their receptors. Although virus receptors are components of the cell membrane, these initial binding studies were carried out using soluble fragments of receptor molecules.

Typical eukaryote cells are too large to freeze rapidly by normal methods making it difficult to study virus binding *in situ*. However, by embedding receptor molecules in artificial liposomes that were small enough to vitrify (**Figure 13**(**a**)), the interaction between the poliovirus particle and its receptor could be visualized in the context of a membrane. Comparison of the micrographs with projection images of an existing icosahedral reconstruction allowed the orientation of the virus particles bound to the liposome to be determined. Then, in a process roughly analogous to that used in the asymmetric reconstruction of tailed bacteriophage particles (described earlier), an

artificial density was introduced at the point on the membrane closest to the virus particle and the reconstruction was repeated without imposing icosahedral symmetry. The structure that resulted from this procedure showed the virus particle, receptor molecules, and adjacent parts of the liposome membrane (**Figure 13**(**b**)), thereby demonstrating that the particle adopts a consistent alignment with respect to the lipid membrane. This not only provided information on how the receptor molecules interact with the virus particle in the context of a membrane, but also revealed the presence of a perturbation to the membrane induced by virus binding. This perturbation might represent an early stage in the formation of the pore, which is necessary for release of the viral genome into the cell.

Concluding Remarks

CryoEM is an important technique that has been used to determine the structures of many viruses. In many cases, achieving subnanometer resolutions has revealed new insights into the structural organization and biological properties of viruses. CryoEM results have been complemented by docking crystal structures or by molecular modeling to provide additional information. Furthermore, conformational changes, structural transformations, and virus–receptor interactions have been observed. Even in cases where the sample is pleomorphic, electron cryotomography has revealed important information. Overall, the study of viruses has been enormously enriched by the use of cryoEM.

Glossary

Chlorotic Yellowing or light green symptoms induced by virus infection affecting chlorophyll accumulation.

Cross-protection Inhibition of systemic virus accumulation and disease by prior inoculation of plants with a mild or symptomless strain of the same virus.

Filiformism Narrowing of the leaf blade, often leading to symptoms referred to as shoestring.
Pseudorecombination Reassortment of the genomic RNAs of two or more strains of a multipartite RNA virus to generate novel combinations of the full complement of genomic RNAs.
Satellite RNA A subviral RNA genome dependent on a helper virus for both replication and encapsidation.
Tonoplast The membrane surrounding the central vacuole of plant cells.

History

Cucumber mosaic virus (CMV) was first described as a disease of cucurbits in 1916 by Doolittle in Michigan and Jagger in New York. The virus can infect a large number of indicator plant species and has been isolated from over 500 naturally infected species. Cross-protection was used in the 1930s to discriminate isolates of CMV with differences in phenotypes or host range (strains). CMV was not purified reliably until the middle 1960s. Later serology and hybridization technology were used to detect and differentiate two major subgroups of CMV. The nucleotide sequence and the genome organization of one strain of each CMV subgroup were determined between 1984 and 1990, while biologically active cDNA clones of several CMV strains were developed in the early 1990s. The major functions of each of the five encoded proteins have been assigned, although each protein is also involved in other host–virus relationships.

Taxonomy and Classification

Isolates of CMV are heterogeneous in symptoms, host range, transmission, serology, physicochemical properties, and nucleotide sequence of the genomic RNAs. On the basis of different criteria (e.g., serological typing, peptide mapping of the coat protein, sequence similarity of their genomic RNA) CMV isolates can be classified into two major subgroups, now named subgroup I and subgroup II. The percentage identity in the nucleotide sequence between pairs of isolates belonging to each of these subgroups ranges from 69% to 77%, depending on the pair of isolates and the RNA segment compared, dissimilarity being highest for RNA2. Nucleotide sequence identity among isolates within a subgroup is above 88% for subgroup I and above 96% for subgroup II, indicating a higher heterogeneity of subgroup I. Analysis of the open reading frames (ORFs) and 5′ noncoding regions of RNA3 of subgroup I isolates shows a group of closely related isolates forming a monophyletic cluster, named subgroup IA; the rest of subgroup I isolates are included in the nonmonophyletic group IB. Analyses of RNA2 show that subgroups IA and IB constitute monophyletic groups, while analyses of RNA1 show no clear division into groups IA and IB. Hence, the different genomic segments have followed different evolutionary histories. Cross-protection occurs between strains from all subgroups. Isolates of subgroup I and II can be distinguished using monoclonal antibodies, and isolates from subgroup IA, IB, and II can be distinguished by reverse transcriptase polymerase chain reaction (RT-PCR). CMV isolates differ from isolates of the other two cucumovirus species, *Tomato aspermy virus* (TAV) and *Peanut stunt virus*, having only 50–67% nucleotide sequence identity, depending on the RNA and isolates being compared.

Geographic Distribution

CMV isolates have a worldwide distribution, having been reported from both temperate and tropical regions. Most reported isolates belong to subgroup I. Subgroup II isolates are found more frequently in cooler areas or seasons of temperate regions. This has been associated with lower temperature optima for *in planta* virus accumulation shown for the few isolates characterized for this property. Most isolates in subgroup IB have been reported from East Asia, which is presumed to be the origin of this subgroup. Subgroup IB isolates also have been reported from other areas, for example, the Mediterranean region, California, Brazil, and Australia. Those in the Mediterranean could have been introduced recently from East Asia.

Host Range and Propagation

The host range of the collective isolates of CMV is over 1300 species in more than 500 genera of over 100 families, with new hosts reported each year. Some recently described strains from new hosts have lost the ability to infect many of the typical hosts of CMV. This may be a general feature for adaptation to unusual hosts. CMV infects most of the major horticultural crops as well as many weed species; the latter act as reservoirs for the virus. Infection of various indicator plants was used to differentiate CMV from other viruses, since unlike most other viruses of cucurbitaceous or solanaceous hosts, CMV could infect representative species of both families. These include cucumber (*Cucumis sativus*), tomato (*Solanum lycopersicum*), and tobacco (*Nicotiana tabacum*), all systemic hosts of CMV, as well as cowpea (*Vigna unguiculata*) and *Chenopodium quinoa*, which limit CMV infection to the inoculated leaves, although there are legume strains that will

infect cowpea systemically. Most isolates of CMV are best propagated in squash (marrow) (*Cucurbita pepo*), tobacco, *N. clevelandii*, or *N. glutinosa.*

Virus Structure and Properties

CMV has icosahedral particles 29 nm in diameter, which sediment as a single component with an $S_{20,w}$ of 98.6– 104*c* (*c* being virus concentration in mg ml^{-1}). Particles are built of 180 capsid protein subunits arranged with $T = 3$ quasisymmetry, contain about 18% RNA, and have an extinction coefficient at 260 nm (1 mg ml^{-1}, 1 cm light path) of 5.0. RNA1 and RNA2 are encapsidated in different particles, whereas RNA3 and RNA4 are probably packaged together in the same particle, some particles may contain three molecules of RNA4. Thus, virus preparations contain at least three different types of particles, but with similar morphology and sedimentation properties. Virus particles also contain low levels of the RNA species designated RNA4A, RNA5, and RNA6. There is a limit to the size of encapsidated RNAs, those larger than RNA1 are not encapsidated *in vivo.* CMV particles are stabilized by RNA–protein interactions, and no empty particles are formed. Particles disrupt at high neutral chloride salt concentrations or at low sodium dodecyl sulfate concentrations; biologically active particles can be reassembled by lowering the salt concentration or removing the sodium dodecyl sulfate. Particles are stable at pH 9.0 and do not swell at pH 7.0, an important difference with bromoviral particles.

The structure of CMV particles has been resolved at 3.2 Å by X-ray crystallography. The $T = 3$ lattice of capsids is composed of 60 copies of three conformationally distinct subunits designated A, B, and C that form trimers with quasi-threefold symmetry. There are 20 hexameric capsomers of B and C subunits with quasi-sixfold symmetry and 12 pentameric capsomers formed by A subunits with fivefold symmetry. The exterior radius along the quasi-sixfold axes is 144 Å, the RNA is tightly packaged against the protein shell and leaves a hollow core of about 110 Å along the threefold axes. The protein subunit has a β-barrel structure, with the long axis of the β-barrel domain oriented roughly in a radial direction. The N-terminal 22 amino acids of the capsid protein are needed for particle assembly. This region is positively charged and, in the B and C subunits, forms amphipatic helices that run parallel to the quasi-sixfold axes. There is an external region of negative electrostatic potential that surrounds the fivefold and quasi-sixfold axes and locates above regions of positive potential which extend to cover nearly homogeneously the inner surface of capsids, where interaction with encapsidated RNA occurs. Electrostatic distributions in CMV particles explain the physicochemical conditions required for particle stability.

Genome Organization

The genome of CMV consists of five genes distributed over three, single-stranded, positive-sense, capped, genomic RNAs: RNA1 (3.3–3.4 kb) encodes the *c.* 111 kDa 1a protein. RNA2 (3.0 kb) encodes the 98 kDa 2a protein, as well as the 13–15 kDa 2b protein, which is translated from a 630–702 nt subgenomic RNA designated RNA 4A that is co-terminal with the 3′ end of RNA2. The ORF expressing the 2b protein overlaps with the ORF encoding the 2a protein, but in a +1 reading frame. RNA3 encodes the 30 kDa 3a protein, as well as the 25 kDa 3b protein, which is expressed from a 1010–1250 nt subgenomic RNA designated RNA4 that is co-terminal with the 3′ end of RNA3. The 224–338 nt 3′ nontranslated regions of all three genomic and both subgenomic RNAs are highly conserved, forming a tRNA-like structure as well as several pseudoknots. The 5′ nontranslated regions of RNA1 (95–98 nt) and RNA2 (78–97 nt) are more conserved in sequence with each other than with those of RNA3 (96–97 nt or 120–123 nt). CMV also produces an RNA5 of unknown function, which is co-terminal with the 3′ nontranslated regions of RNA1 and RNA2. RNA4A and RNA5 are only encapsidated by subgroup II strains. CMV particles also encapsidated a low level of tRNAs, which have been reported in the literature as CMV RNA6. Although rarely reported, some strains of CMV can also encapsidate defective RNAs derived from CMV RNA3.

Satellite RNAs

CMV can also support satellite RNAs varying in size from 333 to 405 nt. These satellite RNAs are dependent upon CMV as the helper virus for both their replication and encapsidation, but have sequence similarity to the CMV RNAs limited to no more than 6–8 contiguous nt. More than 100 satellite variants have been found associated with over 65 isolates of CMV from both of the CMV subgroups. These satellite RNAs usually reduce the accumulation of the helper viruses and on most hosts also reduce the virulence of CMV. However, this attenuation of disease is not due to competition between the helper virus and the satellite RNA for a limited amount of replicase or capsid protein. Some CMV satellite RNAs can also be replicated and packaged by strains of the cucumovirus TAV, although these satellite RNAs do not attenuate the symptoms induced by TAV. Certain satellite RNAs in some selected hosts can enhance the disease induced by CMV. In the case of tomato plants infected by CMV and certain satellites, this has led to systemic necrosis observed in the fields of several Mediterranean countries. This necrosis is actually caused by sequences of the complementary-sense satellite RNA produced in large quantities during satellite RNA replication.

Genetics

The CMV 1a and 2a proteins encode proteins that replicate the virus, but which also function in promoting virus movement in several host species. The 2b protein is an RNA-silencing suppressor protein that antagonizes the salicylic acid defense pathway and also influences virus movement in some hosts. The 3a protein is the major movement protein of the virus and is essential for both cell-to-cell as well as long-distance (systemic) movement. The 3b protein is the sole viral capsid protein and is also required for cell-to-cell and long-distance movement, although the ability to form virions is not a requirement for movement. All of the CMV-encoded proteins are RNA-binding proteins. Viral RNAs from different strains and subgroups can be exchanged to form novel viruses, allowing mapping of some phenotypes to specific RNAs. Higher-resolution mapping requires the use of biologically active cDNA clones for generating chimeras and site-directed mutants. By these approaches, the following functions have been delimited to specific RNAs, with some mapped to specific nucleotide changes: hypersensitive response in tobacco, rapid local and systemic movement in squash, seed transmission in legumes, temperature-sensitive replication in melon; and replication of satellite (all in RNA1); hypersensitive response versus systemic infection in cowpea, suppression of gene silencing, and host range and pathology responses (all in RNA2); limited movement between epidermal cells, systemic movement in cucurbits, virion assembly, hypersensitive response on *Nicotiana* sp., local and systemic infection in cucurbits or in maize, symptom responses, and aphid transmission (all in RNA3).

Replication

CMV replication takes place on the vacuole membrane (the tonoplast). Replication involves the 1a and 2a proteins of the virus and presumably several host proteins. The purified CMV replicase contains the 1a and 2a proteins, as well as a host protein of *c.* 50 kDa of unknown function. The 1a protein of CMV contains a putative N-terminal proximal methyltransferase domain believed to be involved in capping of the RNAs, as well as a putative C-terminal proximal helicase domain, presumed to be required for the unwinding of the viral RNAs during replication. The 1a protein has been found to be able to bind to several tonoplast intrinsic proteins, although what roles these have in virus replication has not been established. The N-terminal region of the 2a protein interacts with the C-terminal region of the 1a protein *in vivo* and *in vitro*. Phosphorylation of the 2a protein prevents interaction with the 1a protein. The C-terminal half of the 2a protein contains conserved domains found in RNA polymerases and therefore together with the 1a protein forms the core of the CMV replicase.

CMV replication is initiated by the binding of the tonoplast-associated replicase to the tRNA-like structure and various pseudoknots present in the 3′ nontranslated region of the positive-sense CMV RNAs. Minus-sense RNA is then synthesized from each of the genomic RNAs and the synthesized minus-sense RNA acts as a template for synthesis of new plus-stranded genomic RNAs. The minus-sense RNA2 and RNA3 also serve as the templates for the synthesis of the two plus-sense subgenomic RNAs (4 and 4A), through recognition of the subgenomic promoters present on the minus-sense RNAs. The subgenomic RNAs are not themselves replicated, but defective RNAs and satellite RNAs are replicated by the CMV replicase. Differences in the relative levels of accumulation of the various CMV genomic RNAs and satellite RNAs have been observed in different host species, which probably is due to host-specific differences in template copying.

Movement

CMV moves cell to cell via plasmodesmata between cells until it reaches the vasculature, when the virus moves systemically via the phloem. The viral RNAs move as a nucleoprotein complex between cells involving the 3a movement protein and some involvement by the capsid protein. This movement does not involve interactions with microtubules. No specific plant proteins have yet been identified as being involved in cell-to-cell movement. CMV appears to move between epidermal cells as well as from epidermal cells down to mesophyll cells toward vascular cells. The 2b protein also influences the path of virus movement, since without the 2b protein, the virus moves preferentially to and between mesophyll cells. The virus replicates in all of these cell types, but not in the sieve elements of the vasculature. Virion assembly may take place inside sieve elements from RNAs and capsid protein moving from neighboring vascular cells. Virion assembly is necessary in some, but not all, species for systemic infection. A 48 kDa phloem protein (PP1) from cucumber phloem exudates interacts with CMV particles *in vitro* and increases virus particle stability. How the virus moves from the vasculature back to mesophyll and epidermal cells is unknown. The virus moves from plant to plant either by transmission by the aphid vectors of CMV, or in some cases via seed transmission, at a low but variable frequency.

Pathology

The symptoms induced by CMV are not generally specific to CMV, but rather reflect sets of host responses to viral pathogens. Therefore, symptoms such as light

green–dark green mosaics, generalized chlorosis, stunting, leaf filiformism, and local chlorotic or necrotic lesions associated with various strains of CMV are not specific to CMV, but can also be elicited by other viruses in the same plant species. Some strains of CMV can induce a bright yellow chlorosis in some *Nicotiana* species. This can be due to either specific amino acid changes in the viral capsid protein, or the presence of a chlorosis-inducing satellite RNA. A white-leaf disease of tomato also was due to the effects of a particular satellite RNA, as well as systemic necrosis and lethal necrosis disorders seen in the field of several Mediterranean countries. Some pathogenic responses, such as local lesions versus systemic infection in cowpea have been mapped to two amino acid changes in RNA 2, while other pathogenic responses have been mapped to sequences present in more than one viral RNA molecule, and to different viral sequences for different strains, indicating that several interactions are involved in the elicitation of some symptom responses.

Cytopathology associated with infection by CMV includes viral inclusions within the cytoplasm and vacuoles, and as membrane-bound clusters in sieve elements. In some cases, angular inclusions corresponding to virus crystals can be seen in vacuoles by staining and light microscopy. CMV infection usually also leads to proliferation of cytoplasmic membranes, which originate from the plasma membrane, the endoplasmic reticulum, or the tonoplast. Effects on the nucleus or nucleolus (e.g., vacuolation), usually due to virion accumulation, have been observed with some strains of CMV. Similarly, some strains have caused effects on mitochondria or chloroplasts. Yellowing strains, in particular, show effects on chloroplasts development leading to smaller and rounded chloroplasts that have fewer grana and starch granules. These various effects appear to be host specific. How virus–plant interactions lead to cytopathic effects remains unknown; however, as the virus expands from the initial site of infection, rings or zones of responses occur, in which the expression patterns of numerous plant genes are altered in a spatial- and temporal-specific manner.

Transmission

Seed transmission of CMV has been reported in many plant species, with efficiencies varying from less than 1% up to 50%. Virus may be present in the embryo, endosperm, and seminal integuments, as well as in pollen. RNA1, and possibly protein 1a, affects the efficiency of seed transmission.

Horizontal transmission of CMV is vectored by aphids in a nonpersistent manner. Over 80 species of aphids have been reported to transmit CMV, *Aphis gossypii* and *Myzus persicae* being two efficient and most studied vectors. Transmission efficiency depends on several factors, particularly the specific combination of virus isolate and aphid species, and the accumulation of particles in the source leaf. Differences in transmissibility of various isolates by different aphid species are determined solely by the virus coat protein and amino acid determinants for transmission have been mapped. The amino acid positions that determine transmission are either exposed on the outer surface of capsids (e.g., amino acid position 129, on the β strand H-I loop) or lay in the inner surface (e.g., position 162). Hence, the effect could be through direct interaction with the aphid mouth parts or by affecting particle stability. Loss of transmissibility upon repeated mechanical passage seems to be rare, perhaps because of tradeoffs with particle stability, but particle stability is not always correlated with transmissibility. Transmission efficiency also depends on the host plant, as shown by the resistance to transmission on melon genotypes containing the *Vat* gene, which does not confer resistance to the aphid or the virus, but impairs aphid transmission.

Ecology and Epidemiology

CMV infects a wide range of food crops, ornamentals, and wild plant species. Economic losses in crops are highest in field-grown vegetables and ornamentals, pasture legumes, and banana. In recent times, CMV has caused severe epidemics in many crops, including necrosis of tomato in Italy, Spain, and Japan; mosaic and heart rot of banana worldwide; mosaic of melons in California and Spain; mosaic of pepper in Australia and California; and mosaic of lupins and other legumes in Australia and the USA. In crops in which seed transmission is effective (e.g., pasture or fodder legumes), the primary inoculum for epidemics may be the seedlings from infected seeds. In most vegetable and ornamental crops, seed transmission does not occur or is negligible, and the primary inoculum must come from outer sources as other crops or weeds, which should be near the crop as aphid transmission is nonpersistent. In the absence of crops during unfavorable seasons, infected perennial weeds or crops, and infected seeds from weeds act as reservoir inoculum. Seed transmission has been shown to be important in several weed species from different regions. In spite of its general broad host range, there is evidence of host adaptation or preference for some CMV strains, which might have important consequences for inoculum flows among host species. Also, the dynamics of virus infection may differ largely in weeds and crops within a region, indicating that the relevant reservoirs and inoculum sources for crops need not be the most frequently infected weeds. In banana, secondary spread of infection within the

crop is ineffective for most strains, and alternative hosts are both primary and secondary inoculum sources for epidemics.

Variation and Evolution

In agreement with the high mutation rates of RNA genomes, populations of CMV derived from biologically active cDNA clones were found to be genetically diverse. When the cDNA-derived population was passaged in different hosts, the amount of genetic diversity depended on the host species. Genetic diversity has been shown to be countered by genetic drift associated to population bottlenecks during systemic colonization of the host and, probably also, during host-to-host transmission. Sequence analyses have shown different evolutionary constraints for the different viral proteins, which show different evolutionary dynamics. A second source of genetic variation is the exchange of RNA sequences by recombination or by reassortment of genomic segments. Experimentally, recombination has been shown to occur between the 3′ nontranslated region of the genomic RNAs, with recombinants being up to 11% of the population. Recombinants in the 3′ nontranslated region may have an increased fitness in some hosts, as shown for isolates infecting alstroemeria. Recombination in the RNA3 also was frequent in mixed infection between CMV and TAV. Recombination between CMV strains or CMV and TAV strains seems to be facilitated by stem–loop structures in the RNA. In spite of abundant evidence for frequent recombination, analyses of the genetic structure of field populations of CMV show that recombinant RNAs are not frequent, and that selection operates against most recombinants. A second mechanism of genetic exchange is reassortment of genomic segments also called pseudorecombination. Reassortants exchanging any genomic segment have been obtained between different CMV strains, which multiply efficiently under experimental conditions. Natural reassortants also have been described, and reassortment may have played an important role in the evolution of CMV, as suggested by the different phylogenies obtained for each genomic RNA. In field population, reassortant isolates are rare and seem to be selected against, as is the case for recombinants. Evidence for selection against genotypes originating by genetic exchange suggests co-adaptation of the different viral genes that, when disrupted, results in a decreased fitness. Analyses of the population structure of CMV in Spain and California indicate a metapopulation structure, with local extinctions and recolonizations, which suggests that population bottlenecks occur, probably associated with unfavorable seasons for the host plants and/or the aphid vectors. Interestingly, this is not the case for the population structure of the satellite RNA. Analyses in Italy and Spain during epidemics of CMV plus satellite RNAs have shown that the satellite RNAs have an undifferentiated population. The different population structure for CMV and its satellite RNAs indicates that the satellite RNAs expanded as a molecular parasite on the CMV population, rather than satellite expansion was linked to a particular CMV isolate.

Control

Control of CMV can be achieved by planting of resistant crops, but resistance in many crop species is often not available to a broad range of CMV strains. The use of insecticides to control the aphid vectors of the virus has met with only limited success, since the virus is transmitted in a nonpersistant manner and thus before the aphids would have been killed by the insecticide, it would have transmitted the virus. Rather, insecticides are used to reduce aphid numbers and thus reduce the progressive spread of infections. Since many species of weeds act as reservoirs for the virus and many of these are asymptomatic hosts, it is important to remove these from the borders of fields to eliminate the source of infectious material that could then be spread by aphids. This also applies to removal of infected crop plants during the growing season. Others sources of resistance include the use of transgenic plants expressing either protein-mediated or RNA silencing-mediated resistance. Although most of these approaches have led to resistance to only members of one of the two major subgroups, the use of pyramiding of viral segments from different subgroups offers the promise of obtaining a broad spectrum resistance to CMV together with other viruses infecting the same crop species. Transgenic expression of satellite RNAs has also been used to confer resistance to CMV. This has met with success, but has raised concerns about using a virulent pathogen, as did the use of mild strains of CMV for cross-protection against severe strains.

Cytokines and Chemokines

D E Griffin, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Chemokine Chemotactic cytokine that regulates trafficking of cells during immune responses.
Cytokine Soluble protein produced by a variety of cells that mediates cell-to-cell communication important for innate and adaptive immune responses.
Inflammasome A multiprotein complex of more than 700 kDa that is responsible for the activation of caspases 1 and 5, leading to the processing and secretion of the pro-inflammatory cytokines IL-1β and IL-18.
Lymphotoxin A cytokin secreted by activated T_H1 cells, fibroblasts, endothelial and epithelial cells.

Introduction

Cytokines are small soluble proteins produced by a wide variety of cells and are important mediators of cell-to-cell communication. Production of these biologically potent proteins is particularly associated with generation of the innate and acquired immune responses. Cytokines regulate both the initiation and maintenance of immune responses and some also induce production of cellular antiviral molecules. Chemokines (chemotactic cytokines) regulate trafficking of leukocytes during immune responses and infiltration of leukocytes into infected tissues. Both cytokines and chemokines share the properties of pleiotropy and redundancy. Each cytokine and chemokine has more than one function and most functions can be performed by more than one of these soluble factors.

Cytokines can act at a distance, but their effects are usually most potent in the areas in which they are produced. They mediate their effects by binding to small numbers of high-affinity receptors on responding cells. Cytokine receptors have a modular design consisting of two or more chains, each with a single transmembrane-spanning domain. Individual chains may participate in formation of the receptor for more than one cytokine. Chemokine receptors are single G-protein-coupled molecules with seven-transmembrane domains. The biologic function of many cytokines and chemokines is regulated by a short half-life for both the protein and the mRNA and by the production of circulating cytokine inhibitors such as soluble forms of the cytokine receptor or biologically inactive forms of the cytokine itself. A number of viruses, particularly in the herpesvirus and poxvirus families, encode inhibitory homologs of cytokines, chemokines, or their receptors, attesting to their importance for antiviral immunity.

Overview of Cytokine Networks

Cytokines associated with the innate immune response are those induced early after infection by virus replication *per se*. One of the most important of these early immunologically nonspecific responses are type 1 (α and β) interferons (IFNs) that are generally synthesized and released by infected cells. Some cells, for example, plasmacytoid dendritic cells, produce IFN rapidly after infection. IFN-α/β can induce an antiviral state in surrounding cells and can also influence the characteristics of the subsequent adaptive immune response. In addition, phagocytic cells, responsible for processing and presentation of viral antigens to initiate the antigen-specific immune response, produce a variety of cytokines, including IFN-α/β. These antigen-presenting cells, generally dendritic cells and monocyte/macrophages, may or may not be infected or produce infectious virus. Important cytokines and chemokines produced by antigen-presenting cells in the initial phases of the response to many viral infections are tumor necrosis factor (TNF), monocyte chemotatic proteins (MCP), and interleukin (IL)-1, IL-6, IL-12, and IL-18. These soluble factors promote the activation of T cells and recruitment of inflammatory cells into areas of virus replication. IL-12 stimulates natural killer (NK) cells to produce IFN-γ, promotes differentiation of $CD8^+$ cytotoxic T lymphocytes, and influences the early development and differentiation of CD4 T cells toward a delayed type hypersensitivity cellular immune response (type 1).

$CD4^+$ and $CD8^+$ T lymphocytes are the effectors of the specific cellular immune response and function primarily through synthesis of cytokines. T cells do not produce cytokines constitutively, but upregulate expression in response to stimulation through the T-cell receptor. $CD8^+$ T cells are stimulated by viral antigens presented in association with class I major histocompatibility (MHC) antigens. This type of stimulation is most likely to occur if the virus replicates in the antigen-presenting cell because antigens presented in association with MHC class I must be processed by proteasomes in the cytosol. $CD8^+$ T cells often have cytotoxic activity through production of granzymes and perforin or Fas ligand, but also produce substantial amounts of IFN-γ and lymphotoxin (LT). Viral antigens are presented to $CD4^+$ T cells as

peptides in association with class II MHC antigens. Processing of antigens for presentation in association with MHC class II occurs through an endosomal pathway; therefore, virus replication is not required. Activated $CD4^+$ T cells produce IL-2, a T-cell growth factor that supports proliferation of both $CD4^+$ and $CD8^+$ T cells.

With further development of the virus-specific immune response, $CD4^+$ T cells tend to differentiate into different types of T-helper (Th) cells. Type 1 $CD4^+$ T (Th1) cells develop under the influence of IFN-γ and produce primarily IFN-γ and TNF-β (LT-α) and are associated with classic delayed type hypersensitivity or cellular immune responses. Type 2 $CD4^+$ T cells develop under the influence of IL-4 and produce primarily IL-4, IL-5, and IL-13 and are associated with strong antibody responses to viral antigens. A third type of $CD4^+$ effector cells (Th17) develop under the influence of transforming growth factor (TGF)-β and produce IL-17 and IL-6 and are associated with inflammation and autoimmune disease. Cytokines produced by $CD4^+$ T cells are necessary for B-cell development and for the switch from B cells producing IgM to B cells producing more mature forms of immunoglobulin such as IgG, IgA, and IgE and for B cell maturation into long-lived antibody-secreting cells. Both $CD4^+$ and $CD8^+$ T-cell responses are associated with mononuclear infiltrates into areas of virus replication. Regulatory T cells control and dampen ongoing immune responses, in part, through production of IL-10 or TGF-β.

Brief Description of Cytokine Families

TNF

The TNF family has three members: TNF-α, TNF-β/LT-α, and LT-β. These cytokines have approximately 30% homology and interact with cellular receptors in the TNF receptor (TNFR) superfamily. Activated macrophages are the major source of TNF-α and T cells are the major source of LT. TNF-α is synthesized as a proprotein (26 kDa) which is membrane bound and cleaved by a specific multidomain cell-surface metalloprotease to yield a 17 kDa protein. The active form of the soluble protein is a cone-shaped trimer that can bind to either of two TNFRs (TNFR1, p55 or TNFR2, p75). Binding of TNF to TNFR1 induces nuclear factor kappa B (NF-κB) and can trigger apoptosis. Homotrimers of LT-α also bind to TNFR1 and TNFR2, but LT-β reacts with a separate member of the TNFR family, the LT-β receptor. TNF interacts with a wide variety of cells systemically and locally and induces pro-inflammatory cellular responses such as expression of adhesion molecules, release of cytokines, chemokines and procoagulatory substances, synthesis of acute phase proteins, and production of fever. TNF also has some antiviral activity and is an important early participant in the immune response to infection. In bacterial infections, TNF is one of the mediators of endotoxin-induced (septic) shock. TNF and LT also play an important role in development of lymphoid tissues because lymphoid architecture in mice with deletions of these genes is abnormal.

IFN-γ

IFN-γ is a glycosylated protein of 25 kDa that is produced by NK cells and by type 1 CD4 and CD8 T cells (immune IFN). Although IFN-γ induces antiviral activity, it is structurally unrelated to IFN-α/β and uses a distinct receptor. However, IFN-γ shares some components of the intracellular signaling pathways for type 1 IFN. The biologically active form of IFN-γ is a dimer. A primary role for IFN-γ is the activation of macrophages to increase phagocytosis, tumoricidal properties, and intracellular killing of pathogens, particularly bacteria and fungi. IFN-γ induces macrophage production of a variety of inflammatory mediators and reactive oxygen and nitrogen intermediates. IFN-γ increases expression of high-affinity immunoglobulin F_c receptors on phagocytes, which increases recognition of opsonized microorganisms by these cells. IFN-γ also increases expression of MHC antigens by macrophages and this facilitates antigen presentation to T cells. The IFN-γ cell-surface receptor is composed of two chains, IFN-γR1 (α) and IFN-γR2 (β). The α (R1) chain is sufficient for binding, but the β (R2) chain is required for signaling and receptor complex formation. T-cell responsiveness is regulated by receptor expression. Both Th1 and Th2 cells express IFN-γR1, but only Th2 cells express IFN-γR2. Therefore, Th1 cells produce, but do not respond to, IFN-γ while Th2 cells respond to, but not produce this cytokine. Macrophages express both receptor chains and are a primary target of IFN-γ activity.

IL-1

The IL-1 family has three members: IL-1α, IL-1β, and IL-1 receptor antagonist (IL-1RA). IL-1α and IL-1β have only distantly related amino acid sequences, but similar structure, and recognize the same receptors. IL-1RA binds the IL-1 receptor without transducing a signal and blocks the activities of IL-1α and IL-1β. Activated monocytes and macrophages are the major source of IL-1, although many other cells can produce this cytokine. IL-1β is synthesized as a precursor protein of 31 kDa that is processed by the caspase interleukin-1 β-converting enzyme (caspase-1) within the 'inflammasome' to the active secreted 17 kDa form. IL-1 acts systemically, as well as locally, and can produce fever, sleep, and anorexia, frequent symptoms of viral infection. Hepatocytes are among the cells that produce IL-1RA as a part of the acute-phase response to inflammation and infection, presumably to control the effects of IL-1. There are two IL-1 receptors but only IL-1R1 transduces an activation

signal to responding cells. IL-1R2 appears to function as a decoy receptor that regulates IL-1 activity by binding the cytokine without transducing a signal.

IL-18, also known as IFN-γ-inducing factor, is an 18 kDa cytokine produced by macrophages that shares structural features with the IL-1 family of proteins. It is synthesized as a proprotein that is cleaved by caspase 1 to its biologically active form. IL-18 stimulates IFN-γ production by T cells, NK cytotoxicity, and T-cell proliferation.

IL-2

IL-2 is a unique 15 kDa cytokine produced primarily by activated type 1 $CD4^+$ T cells. IL-2 plays an important role in supporting proliferation of activated helper T cells, cytotoxic T cells, B cells, macrophages, and NK cells. For stimulated $CD4^+$ T cells, IL-2 acts in an autocrine fashion because Th1 cells can produce IL-2 and upregulate high-affinity IL-2 receptors as well. The high-affinity IL-2R consists of three chains – IL-2Rα, β, and γ – which are expressed on the surface of activated T cells. IL-2Rα is a unique protein, whereas IL-2Rβ and IL-2Rγ are members of the hematopoietic growth factor receptor superfamily. Members of this superfamily share a 210-amino-acid domain in the extracellular region of the molecule that contains a distinct cysteine and tryptophan motif at the N-terminus and a Trp-Ser-X-Trp-Ser motif at the C-terminus. The whole domain is folded into two barrel-like structures with the ligand-binding region between. In addition to the IL-2 receptor, this receptor superfamily includes components of receptors for cytokines IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, granulocyte macrophage-colony stimulating factor (GM-CSF), and granulocyte-colony stimulating factor (G-CSF). Signal transduction is through the IL-2Rβ chain. Intermediate-affinity IL-2R βγ receptors are expressed on monocytes and NK cells. IL-2Rγ (γ constant) also participates in the formation of the multichain IL-4, IL-7, IL-9, and IL-15 receptors. Defects in expression of this molecule lead to severe combined immunodeficiency in humans. Binding of IL-2 to the high-affinity receptor leads to T-cell proliferation.

IL-4

There are five members of the IL-4 family of cytokines: IL-3, IL-4, IL-5, IL-13, and GM-CSF. These cytokines have approximately 30% protein sequence homology, have similar α-helical structures, are linked in the same chromosomal region, and are produced by type 2 $CD4^+$ T cells. IL-3 and GM-CSF are two of the four major human myeloid growth factors that also include G-CSF and M-CSF. IL-3 is produced by activated T cells and binds to a heterodimeric receptor. The β subunit of the IL-3R is shared with the receptors for IL-5 and GM-CSF.

IL-4 and IL-13 have similar effects on B cells and monocytes. Both can serve as a costimulating factor for B-cell proliferation, drive activated B cells into immunoglobulin secretion, and, in human B cells, induce class switching to IgG4 and IgE. IL-4 is regarded as an anti-inflammatory cytokine because it antagonizes the effects of IFN-γ on macrophages and downregulates type 1 $CD4^+$ T-cell responses. IL-13 induces monocyte proliferation and monocytosis *in vivo*. IL-4 is important for promoting the differentiation of $CD4^+$ T cells to type 2 cytokine production. IL-4 and IL-13 are produced by type 2 $CD4^+$ T cells. IL-4 is also produced by a subset of $CD4^+$ T cells that are $NK1.1^+$ (NK T cells), by type 2 $CD8^+$ T cells and by mast cells, basophils, and eosinophils.

IL-5

IL-5, along with IL-3 and GM-CSF, acts as an eosinophil stimulating factor and its receptor shares a common β chain with these cytokines. The high-affinity IL-5R has a unique α chain. IL-5 induces proliferation and differentiation of eosinophil progenitors, whereas IL-3 and GM-CSF probably act at earlier stages of development. IL-5 is produced by type 2 $CD4^+$ and $CD8^+$ T cells and by NK cells. IL-5 also induces antigen-stimulated B cells to differentiate into immunoglobulin-secreting plasma cells and enhances secretion of IgA.

IL-6

IL-6 is a member of a family of cytokines and neuronal differentiation factors that includes leukemia inhibitory factor, oncostatin M, IL-11, and ciliary neurotrophic factor. The receptors for these cytokines share the transmembrane protein gp130 that transduces the cytokine signal. IL-6 is a functionally diverse cytokine produced by macrophages and monocytes early in the response to infection. It induces hepatic synthesis of acute phase proteins, supports proliferation of B cells, and has an important role in production of IgA.

IL-7

IL-7 is a 15 kDa protein that is produced primarily by epithelial cells and supports the growth and development of immature B and T cells. IL-7 is produced by bone marrow stromal cells, thymic epithelial cells, keratinocytes, and intestinal epithelial cells and supports lymphocyte development in these locations. In the thymus, IL-7 induces rearrangement of germline T-cell receptor genes by upregulating expression of the RAG-1 and RAG-2 recombinases. The α chain of the IL-7 receptor is a member of the hematopoietic growth factor family and associates with the IL-2Rγ chain to form a functional high-affinity IL-7R.

IL-10

IL-10 is an 18 kDa polypeptide that forms homodimers. It is predicted to be a member of the 4 α–helix bundle family of cytokines. It is produced by a wide variety of cells, including type 2 $CD4^+$ and $CD8^+$ cells, B cells, mast

cells, macrophages, and keratinocytes. Epstein–Barr virus encodes a viral homolog of IL-10 that is functionally active. The activities of IL-10 are diverse, but its principal function appears to be limitation of inflammatory responses. IL-10 inhibits cytokine production by Th1 cells, NK cells, and macrophages and has been associated with viral persistence. It suppresses the synthesis of TNF-α, IL-1α, IL-6, IL-8, GM-CSF, and G-CSF by macrophages while increasing the production of IL-1RA. IL-10 stimulates proliferation and differentiation of activated B cells and T cells and of mast cells and is important for differentiation of regulatory T cells. The functional IL-10R consists of two subunits, IL-10R1 and IL-10R2, both of which belong to the class II cytokine receptor family. Expression of both subunits is required for signal transduction.

IL-12

IL-12 is a structurally unique heterodimeric cytokine composed of two disulfide-linked 35 and 40 kDa polypeptides. The 40 kDa protein conveys receptor-binding activity, is shared with IL-23 and is constitutively produced by many cells. Only the heterodimer is biologically active, so regulation of synthesis of the 35 kDa chain controls IL-12 activity, while synthesis of the IL-23 19 kDa chain controls IL-23 activity. IL-12 is produced by macrophages and dendritic cells and stimulates the production of IFN-γ by NK and T cells. IL-12 is important for differentiation of $CD4^+$ T cells into Thl cells and IL-23 promotes differentiation into Th17 cells. At least two classes of the IL-12 receptor exist. The IL-12R β1 chain is expressed in both Th1 and Th2 cells while the β2 chain is expressed only in Th1 cells. The IL-23 receptor is composed of IL-12β1 and a unique IL-23R subunit. For IL-12 responsiveness and for T-cell differentiation, both β1 and β2 subunits are necessary so only potential Th1 cells respond to this cytokine. Both IL-12R β1 and β2 subunits are related to the gp130 group of cytokine receptors. Homodimers of p40 bind with high affinity to the IL-12R, transduce no signal and block the effect of the heterodimer.

IL-15

IL-15 is a novel cytokine functionally related to IL-2, but without significant IL-2 sequence homology. It binds to a receptor with the β and γ chains of the IL-2R, but has its own unique α chain. IL-15 induces T-cell proliferation, enhances NK cell function, is a potent T-lymphocyte chemoattractant, and stimulates production of IL-5. Unlike IL-2, it is produced primarily by monocyte/macrophages and endothelial cells.

IL-17

IL-17 (IL-17A) is the founding member of a family of six cytokines (IL-17A-F). IL-17 is a 155-amino acid glycoprotein that functions as a disulfide-linked 35 kDa homodimer. IL-17 is produced by a separate lineage of activated $CD4^+$ (Th17) and $CD8^+$ T cells that have been implicated in autoimmune disease.

Chemokines and Chemokine Families

The chemokine superfamily includes a large number of structurally related, basic, heparin-binding, small molecular weight (8–10 kDa) proteins that have potent chemotactic and immunoregulatory functions. Chemokines attract specific, but overlapping, populations of inflammatory cells, induce integrin activation, and can be divided into four families with different biologic activities based on the spacing of the first two of four conserved disulfide-forming cysteine residues in the amino-terminal part of the molecule. The largest groups are the CXC or α-chemokines and the CC or β-chemokines. In general, CXC chemokines are the primary attractants for neutrophils, whereas CC chemokines modulate responses of monocytes, macrophages, lymphocytes, basophils, and eosinophils. C chemokines have only one set of cysteines and are chemotactic for lymphocytes. The CX3C chemokine fractalkine is unusual in that it is a type 1 transmembrane protein with the chemokine domain on top of an extended mucin-like stalk. Herpesviruses and poxviruses encode viral chemokine binding proteins (vCKBPs) that are important regulators of the host immune response.

α-Chemokines

The first CXC chemokine to be identified was platelet factor 4 (PF4, CXCL4) that is stored in the granules of platelets that also contain neutrophil-activating protein (NAP-2, CXCL7) ready to be released at sites of tissue injury. The best-characterized α-chemokine is IL-8 (CXCL8) that can be rapidly induced in most cells and is also chemotactic for neutrophils. Other α-chemokines with chemotactic activity for neutrophils include GRO-α (CXCL1), GRO-β (CXCL2), GRO-γ (CXCL3)γ, epithelial cell-derived neutrophil activating protein (CXCL5), and granulocyte chemotactic protein-2 (CXCL6). Sequence identities between these various family members range from 24% to 46%. IP-10 (CXCL10) is a structurally similar, but functionally distinct, CXC chemokine that is an attractant for monocytes and T cells rather than granulocytes.

β-Chemokines

The CC chemokines have two large subgroups: the MCPs and the macrophage inflammatory proteins (MIPs). MCP-1 (CCL2), produced by endothelial cells in response to IL-1β and TNF-α, functions as a dimer, attracts and activates monocytes, NK cells, $CD4^+$, and $CD8^+$ T cells, promotes

Th2 responses and is a potent histamine-releasing factor for basophils. MCP-2 (CCL8) and MCP-3 (CCL7) are structurally and functionally related chemokines important in Th2 responses, whereas MIP1α (CCL3) and MIP1β (CCL4) are important in Th1 responses. Other CC chemokines commonly increased during viral infection are RANTES (CCL5) and I-309 (CCL1). Sequence identities between family members are 29–71%. These chemokines activate integrins, thereby inducing or increasing adhesion to endothelial cells or extracellular matrix proteins to promote development of an inflammatory response. Two novel, related β chemokines, MCP-4 (CCL13) and eotaxin (CCL11), are preferential chemoattractants for eosinophils. CCL11 is produced by epithelial and endothelial cells, often in concert with IL-5.

Chemokine Receptors

Chemokine receptors are seven-transmembrane, G-protein-coupled molecules that signal through the pertussis toxin-sensitive Gαi subfamily of hetereotrimeric G proteins. In general, the α chemokine receptors (CXCRs) are distinct from the β receptors (CCRs). Each receptor can bind multiple chemokines within its class and each chemokine can bind multiple receptors. Therefore, the specificity of cellular attraction to a site and subsequent activation is probably achieved by selective mixtures of chemokines and cellular receptors. These molecules serve as secondary receptors for entry of human immunodeficiency virus into T cells and monocytes.

CXCR5 and CCR7 and their ligands (CXCL13, CCL19, and CCL21) are major regulators of dendritic cell and lymphocyte trafficking to secondary lympoid tissue. Th1 cells more frequently express CXCR3, CXCR6, CCR2, CCR5, and CX3CR1 than Th2 cells which more frequently express CCR3, CCR4, and CCR8. Tissue-specific homing is chemokine dependent. For instance, T cells that home to skin preferentially express CCR4 and CCR10, whereas their ligands CCL2 and CCL27 are produced by dermal macrophages, dendritic cells, and keratinocytes. B cells producing IgG upregulate CXCR4 which promotes homing.

Glossary

Cytomegalia From Greek *kytos*, cell, and *megas*, large. Refers to the cellular enlargement or swelling (cytomegalia) seen in cytomegalovirus-infected cells. This swelling is typically accompanied by the presence of intranuclear inclusion bodies, which are sometimes called 'owl eye' inclusion bodies because the dense staining inclusion body is surrounded by a cleared halo.

Classification of Cytomegaloviruses

Cytomegaloviruses (CMVs) are large, enveloped, double-stranded DNA viruses with an icosahedral capsid that belong to subfamily *Betaherpesvirinae* of the family *Herpesviridae*. There are three genera. Genus *Cytomegalovirus* contains human cytomegalovirus (HCMV; species *Human herpesvirus 5*) and a number of other primate CMVs. Genus *Muromegalovirus* contains murine cytomegalovirus (MCMV; *Murid herpesvirus 1*) and rat cytomegalovirus (RCMV; *Murid herpesvirus 2*). Genus *Roseolovirus* contains human herpesviruses 6 and 7 (HHV-6 and HHV-7; *Human herpesvirus 6* and *Human herpesvirus 7*). Other CMVs that have not yet been fully classified within the *Betaherpesvirinae* are guinea pig cytomegalovirus (GPCMV; *Caviid herpesvirus 2*), tree shrew herpesvirus (THV; *Tupaiid herpesvirus 1*), swine cytomegalovirus (SuHV-2; suid herpesvirus 2), European ground squirrel cytomegalovirus (ScHV-1; sciurid herpesvirus 1), and American ground squirrel cytomegalovirus (ScHV-2; sciurid herpesvirus 2).

The recognized nonprimate CMVs are described in **Table 1**. With the exception of MCMV, RCMV, and GPCMV, little is known about the life cycle and pathogenesis of nonprimate CMVs. Nevertheless, general characteristics include strict species specificity, an ability to induce cytomegalia in infected cells, cell-associated replication in cell culture, a slow replication cycle and the establishment of persistent and latent, lifelong infection in the natural host. Tropism for secretory glands, particularly the salivary gland, is also a common feature. Infection is generally asymptomatic unless the host is immunosuppressed or has an immature immune system. In such hosts, infection may result in morbidity or even mortality.

Table 1 Classification of known and putative nonprimate CMVs by the International Committee on Taxonomy of Viruses

Family	00.031	*Herpesviridae*
Subfamily	00.031.2	*Betaherpesvirinae*
Genus	00.031.2.02	*Muromegalovirus*
Examples	00.031.2.02.001	*Murid herpesvirus 1* (murine cytomegalovirus)
	00.031.2.02.002	*Murid herpesvirus 2* (rat cytomegalovirus)
Unassigned in the subfamily	00.031.2.00.004	*Caviid herpesvirus 2* (guinea pig cytomegalovirus)
	00.031.2.00.049	*Tupaiid herpesvirus 1* (tree shrew herpesvirus)
Unassigned in the family	00.031.0.00.062	Suid herpesvirus 2 (swine cytomegalovirus)
	00.031.0.00.063	Sciurid herpesvirus 1 (European ground squirrel cytomegalovirus)
	00.031.0.00.046	Sciurid herpesvirus 2 (American ground squirrel cytomegalovirus)

Murine Cytomegalovirus

Murid herpesvirus 1 is the type species of the genus *Muromegalovirus*. The term murine cytomegalovirus (MCMV) is more commonly used for the virus than murid herpesvirus 1. The natural host for MCMV is the house mouse, *Mus musculus domesticus*. Because of the strict species specificity of CMVs, MCMV is widely used as an animal model of HCMV infection. Consequently, more is known about MCMV than any other nonprimate CMV.

Virion Structure and Morphology

CMV virions are spherical, *c.* 230 nm in diameter, and comprise four morphologically distinct elements: the core, capsid, tegument, and envelope. The core encompasses the double-stranded DNA viral genome, which is packaged as a single linear molecule into the protein capsid.

The viral capsid is composed of 162 capsomers comprising hexons and pentons in a $T = 16$ icosohedral lattice structure. The capsids of CMVs are larger and incorporate a larger genome than other herpesviruses. Unlike other CMVs, MCMV preparations may contain a high proportion of multicapsid virions, which contain a number of capsids enclosed within a common membrane. The capsid of MCMV is composed of five proteins: the major capsid protein (MCP), the minor capsid protein, the minor capsid binding protein, the smallest capsid protein, and an assembly/protease. These are encoded by genes *M86*, *M85*, *M46*, *M48.2*, and *M80*, respectively.

The tegument of MCMV is a proteinaceous layer of material between the capsid and envelope, and resembles the matrix of other viruses. By electron microscopy the tegument is seen to have an ordered structure, particularly proximal to the capsid. The tegument proteins of MCMV have been defined by their homology to known HCMV tegument proteins. In HCMV there are at least 25 proteins associated with the tegument. Typically, tegument proteins are phosphorylated (and have the prefix pp). At least nine MCMV tegument proteins with homologs in HCMV have been detected in MCMV virions. These are the upper and lower matrix phosphoproteins (encoded by *M82* and *M83*), large tegument protein (*M48*), pp150 (*M32*), and the gene products from *M25*, *M47*, *M51*, *M94*, and *M99*. The role of most tegument proteins is unknown, but the function of some can be inferred from the function of HCMV homologs. For example, the upper matrix protein of HCMV, also known as pp71, is a transcriptional transactivator that regulates immediate early gene expression, possibly by

inhibiting the effects of the host cell transcriptional inhibitor hDaxx. Other tegument phosphoproteins are likely to play similar roles in the transcriptional regulation of viral genes.

The envelope of MCMV is composed predominantly of lipids obtained from the intracellular membranes of the host cell and contains a considerable number of virus-encoded glycoproteins. The envelope of CMVs is more pleiomorphic, and contains more glycoproteins, than envelopes of other herpesviruses. The major envelope glycoprotein, a product of the *M55* gene, is the highly conserved glycoprotein B (gB) and is a dominant B-cell antigen in CMV-infected animals and humans. It has been found in every mammalian herpesvirus and is one of the most highly conserved herpesvirus proteins. The glycoproteins of CMVs form three distinct complexes that mediate viral attachment and entry into host cells (**Table 2**).

Genome Architecture and Coding Potential

The MCMV genome comprises a single unique sequence with short terminal direct repeats and several short internal repeats. Unlike that of HCMV, the linear genome of MCMV does not have an isomeric structure because it lacks internal repeat sequences related to the terminal repeats. The nomenclature devised for MCMV genes numbers them left to right along the genome. MCMV genes with homologs in HCMV are assigned the uppercase prefix '*M*', while genes with no sequence identity with HCMV genes are identified by the lowercase prefix '*m*'.

The genome of the Smith strain of MCMV is 230 278 bp in size, and has a coding potential estimated to be between 170 and 204 open reading frames (ORFs), including newly defined splice variants of previously described ORFs. MCMV shares with other members of the herpesvirus family a number of evolutionarily conserved proteins, which are involved in processes such as DNA replication and virion maturation and structure, and are located within the central region of the genome. The two terminal regions of the genome contain genes that are unique to MCMV and include the *m02* and *m145* gene families, respectively (**Figure 1**). Many of the genes in these unique regions encode proteins that are involved in modulation of the host's immune response.

Replication

Viral replication is initiated when infectious virions enter a susceptible host cell (**Figure 2**). A series of receptors have been implicated in the binding, fusion, and entry of CMVs. Most information has come from studies of HCMV, in which infection is initiated by loose tethering of the virus via viral gCI and gCII complexes and heparan sulfate proteoglycans (HSPGs) on the cell surface. Tethering promotes a stronger binding reaction between the viral gCI complex and host cellular receptors. These receptors have not been fully defined, although for HCMV the epidermal growth factor receptor (EGFR) is thought to be one of the host receptors important in viral binding. This receptor binding promotes receptor co-localization with other host proteins, in particular integrins, into lipid rafts. The β1 and β3 chains of integrins have been implicated in the entry of MCMV into host cells. Integrin-binding domains have been localized to the N-terminus of gB in all betaherpesviruses and most gammaherpesviruses. Finally, receptor binding and/or co-localization triggers intracellular signaling and fusion between the host cell and viral membranes. Cellular signaling appears important for translocation of the capsids to the nucleus.

Table 2 Structural glycoproteins of MCMV

Glycoprotein (gene)	*Complex*	*Essential*	*Function*
gB (*M55*)	gCI	Yes	Binds to cellular receptors (e.g., EGFR) and triggers intracellular signaling. *May activate host TLR2. Major B-cell epitope*
gN (*M73*)	gCII	Yes	With gM binds HSPG
gM (*M100*)	gCII	Yes	With gN binds HSPG
gH (*M75*)	gCIII	Yes	As a component of the gCIII complex is involved in binding and membrane fusion. *May activate host TLR2*
gL (*M115*)	gCIII	Yes	Required for transport of gH to the gCIII complex. As a component of the gCIII complex is involved in binding and membrane fusion
gO (*m74*)	gCIII	No; deletion virus has small plaque size	Enhances cell-to-cell spread of MCMV. As a component of the gCIII complex is involved in binding and membrane fusion
gp24 (*m73.5*)		Unknown	Unknown

The data are a compilation of information from HCMV and MCMV. Text in italics denotes the host response to glycoproteins. In HCMV, gB forms the disulfide-linked homodimeric gCI complex. The gCII complex is a disulfide-linked heterodimer between gM (*UL100*) and gN (*UL73*). The HCMV glycoproteins gL, gH, and gO (encoded by the genes *UL115*, *UL75,* and *UL74,* respectively) form the noncovalently associated heterotrimeric complex gCIII. All three complexes are essential for viral replication. MCMV homologs are believed to serve a similar function, although gN has only been demonstrated in the virions of HCMV. Note that gp24 has only been demonstrated in MCMV. In HCMV, gB and gH appear to bind TLR2, but this has not been demonstrated for MCMV.

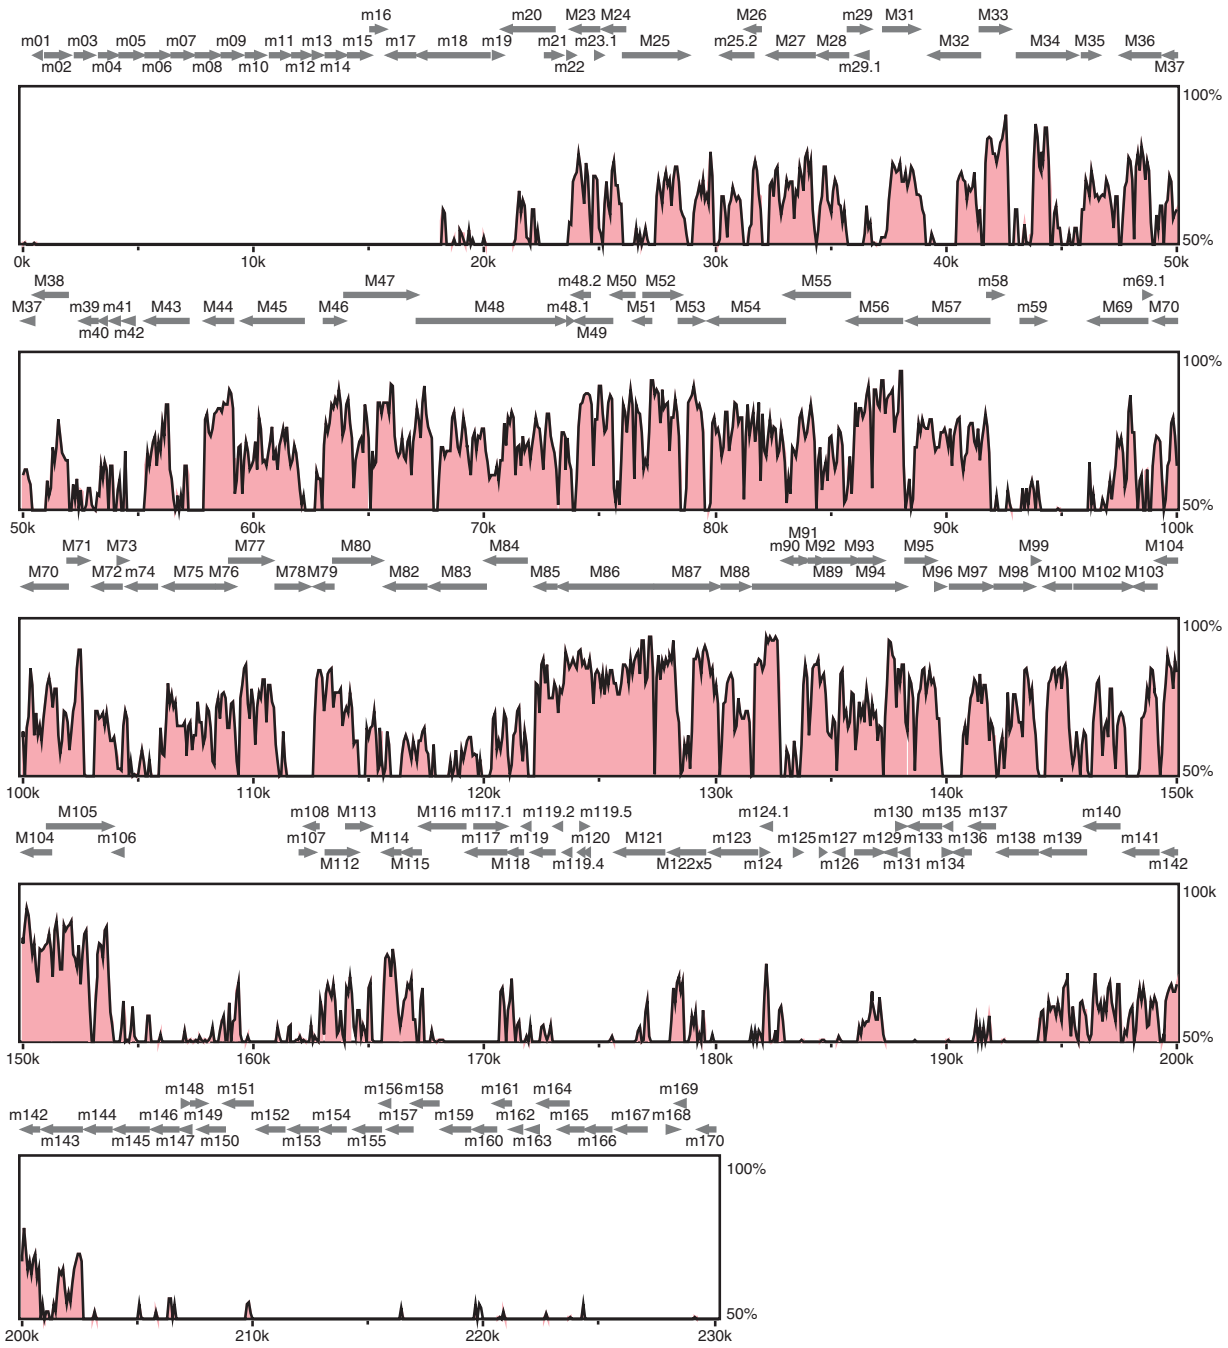

Figure 1 Moving window comparison of the sequence similarity (shown from 50% to 100%) of the MCMV and RCMV genomes. Selected MCMV genes are marked with an arrow above the plot. The central regions of the genome are highly conserved and represent the herpesvirus-conserved genes. The left and right terminal sequences contain species-specific genes and therefore show little or no sequence similarity. Image created using LAGAN and VISTA (http://genome.lbl.gov/vista/index.shtml).

The exact mechanism by which viral DNA enters the nucleus is unknown. However, it is believed that viral DNA migrates to nuclear domain 10 (ND10) complexes within the nucleus where viral gene transcription occurs. All betaherpesviruses have three gene sets, α, β, and γ, that are temporally regulated. These genes are expressed in the immediate early (IE), early (E), and late (L) phases of viral replication, respectively. The IE phase occurs immediately after viral DNA enters the nucleus and is controlled by the major IE promoter (MIEP) in MCMV. The MIEP controls expression of the transcriptional activator genes *ie1* (*m123*) and *ie3* (*M122*). While both the *ie1* and *ie3* genes are essential for replication, the former is required specifically at low multiplicities of

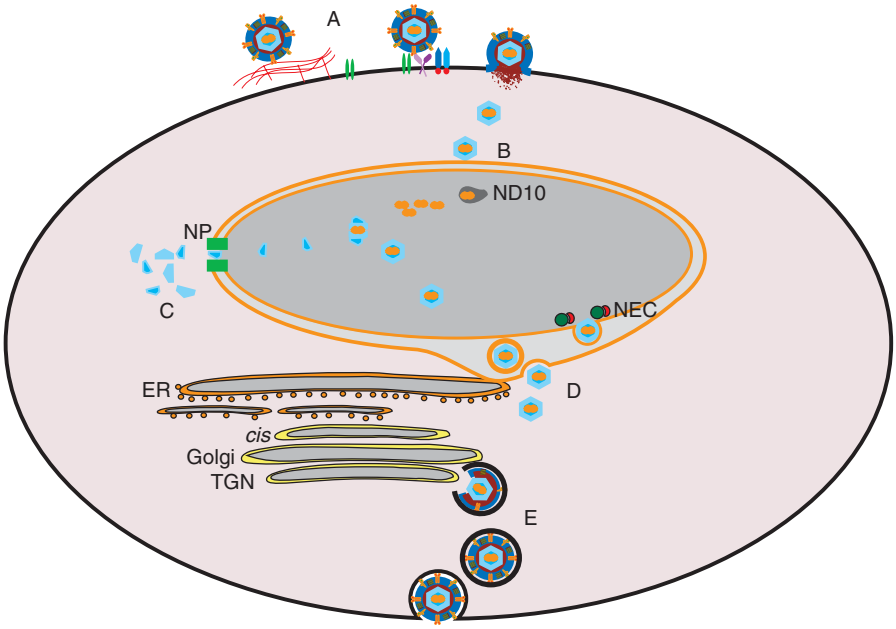

Figure 2 CMV life cycle. (A) Virus is loosely tethered to the host cell by binding to HSPG via either gB (gCI complex) or gM/gN (gCII complex). Virus is bound more tightly by association with cell receptors such as EGFR (HCMV). Binding causes receptor clustering and the interaction of other receptors such as host cell integrins. The interaction between host receptors and viral glycoproteins induces membrane fusion and the delivery of viral capsid and tegument proteins into the host cell cytoplasm. (B) Viral capsid is transported to the nucleus and, by a process that is not understood, the viral DNA enters the nucleus. Viral DNA is localized at ND10 complexes where viral gene expression is initiated. (C) Viral proteins, including capsid proteins, are produced in the cytoplasm. DNA encapsidation and capsid assembly occur in the nucleus. Capsid proteins either diffuse into the nucleus via nuclear pores or are transported due to the presence of nuclear localization motifs. Large capsid proteins, such as MCP, which lack these motifs, are transported to the nucleus in association with capsid proteins that possess them. (D) Viral capsids acquire a primary envelope as they migrate through the inner nuclear membrane (INM). Viral proteins p35 and p38 (*M50* and *M53*) form the nuclear egress complex (NEC) and serve to disassociate the INM. Transport of the capsid through the outer nuclear membrane results in de-envelopment. (E) The final viral envelope is derived from cytoplasmic organelles, possibly in the *trans*-Golgi network (TGN). Fully formed virions enter the secretory pathway and exit the cell by exocytosis.

infection. A third IE gene, *ie2*, not present in HCMV, is transcribed from a different promoter and in the opposite direction. The *ie2* gene is not essential for MCMV replication either *in vitro* or *in vivo*.

There is an absolute requirement for IE gene expression prior to E gene expression. Genes transcribed during the E phase of viral replication include those required for entry into the L phase of viral replication, and other genes, such as the immune evasion genes. L phase genes mostly encode structural proteins and are expressed after the start of viral DNA replication, which occurs in the nucleus approximately 16 h after infection. During DNA replication, the sequences at the genomic termini fuse via a 3′ nucleotide extension to form the intermediates for MCMV replication, which occurs by a rolling-circle mechanism. Maturation of the MCMV genome involves the processing and cleavage of newly synthesized concatemeric viral DNA into genome-length monomers prior to packaging into preformed nucleocapsids in the cell nucleus. Herpesvirus-conserved *pac1* and *pac2* DNA sequence motifs are required for cleavage and packaging of the MCMV genome.

The origin of DNA replication of MCMV is the *ori* Lyt region between *M57* and *M69* (**Figure 1**), which extends over 1.7 kbp and is extremely rich in repeat sequences that act as binding elements for various transcription factors. MCMV-encoded proteins required for origin-dependent replication include the DNA polymerase (*M54*), a polymerase accessory protein (*M44*), the single-stranded DNA-binding protein (*M57*), and a helicase-primase complex encoded by *M70*, *M102*, and *M105*. All of these proteins have been detected within purified MCMV virions.

The formation of capsids and the packaging of viral DNA occur in the nucleus of infected cells. Capsid proteins are produced in the cytoplasm and are transported back to the nucleus across the nuclear membrane. The transport of capsid proteins is a result of either their small size, which allows diffusion across the nuclear pore complex, or the presence of nuclear localization signals. Large capsid proteins such as the MCP, which do not contain nuclear localization signals, are transported in association with those that do. Viral DNA is packaged into complete capsids and transported to the cytoplasm via the nuclear membrane where the capsids acquire their primary

envelope as they bud through the inner nuclear membrane (INM) as shown in **Figure 2**. In MCMV infection, the virus penetrates the INM with the aid of *M50*/p35 and a partner gene, *M53*/p38. The proteins p35 and p38 form the nuclear egress complex (NEC) and recruit cellular kinases to the INM, specifically to the nuclear lamina. Recruitment of cellular kinases results in phosphorylation and degradation of the lamina, and facilitates egress of the virus from the nucleus.

The mechanism of egress of CMVs from infected cells is incompletely understood. Studies from other herpesviruses suggest that there are two phases of envelopment. A primary envelopment involving the host's INM precedes a final secondary envelopment from another host compartment, possibly the *trans*-Golgi network (TGN), where the virions also gain their tegument. The mature enveloped virions, now present in secretory vesicles, are transported to the plasma membrane, where they are released into the extracellular space by exocytosis (**Figure 2**).

Pathogenesis

During acute experimental intraperitoneal infection, MCMV replicates predominantly in the spleen and liver and to a lesser extent in the lungs. However, the virus persists in the lungs for longer than in the spleen or liver. Other organs infected during the acute phase include the adrenal glands, kidneys, heart, and ovaries. During the chronic or persistent phase, the virus replicates predominantly in the salivary gland. Intranasal inoculation, which may mimic natural infection, results in viral replication predominantly in the lungs and salivary gland. Histologically, MCMV-infected cells exhibit typical swelling or cytomegalia (from which the virus derives its name) with intranuclear inclusion bodies. In MCMV-infected mice, mononuclear cell infiltration may be observed in inflammatory responses in the heart, lung, adrenals, and other organs.

The seroprevalence of MCMV in free-living mice can be up to 100%, particularly when mouse population densities are high. Transmission of the virus is presumed to be via saliva, possibly as a result of biting and grooming. However, MCMV is found in urine and breast milk, as well as the reproductive tract of male and female mice. This suggests additional modes of transmission, such as from mother to pup during feeding and by sexual activity. Interestingly, infection with multiple strains of MCMV is common, suggesting that mice are either infected simultaneously with multiple MCMV strains or that the lack of sterilizing immunity allows sequential reinfection of mice.

A number of diseases induced by HCMV in humans have been modeled with MCMV in mice. These include myocarditis, hepatitis, adrenalitis, and interstitial pneumonitis. However, natural congenital infection has not been modeled in mice, since MCMV, unlike HCMV, does not cross the placenta in immunocompetent hosts. Mice have also been used to investigate host resistance to CMV. A number of factors affect the capacity of MCMV to cause disease in mice. These include the dose and route of inoculation of the virus as well as the age and genetic constitution of the host. Several genetically linked innate resistance mechanisms have been identified in mice, including *Cmv1*, *Cmv3*, and *Cmv4*. These loci control resistance to MCMV via innate immune responses. Other genetic resistance mechanisms have been demonstrated in New Zealand white mice (*Cmv2*) and in a mouse strain carrying an *N*-ethyl-*N*-nitrosourea-induced mutation of the protein Unc93b1 in which signaling via Toll-like-receptors (TLRs) 3, 7, and 9 is deficient. TLRs 3, 7, and 9 recognize single-stranded RNA, double-stranded RNA (dsRNA), and unmethylated DNA, respectively. Previous studies have highlighted the importance of TLRs 2, 3, and 9 in resistance to MCMV.

Latency

Persistent infection is a common feature of the betaherpesviruses. The infection may be either chronic, in which infectious virus is produced at very low levels for long periods in particular organs or tissues such as the salivary gland, or latent, in which infectious virus is no longer detected, although the viral genome is present in certain cells in the body. Reactivation from latency usually occurs during immunosuppression to yield infectious virus, which may induce disease and be transmitted to susceptible hosts.

Regulation of transcription is tightly controlled during latency. In MCMV, regulation of IE gene expression is an early checkpoint on the way from latency to recurrence. The IE1/3 transcriptional unit gives rise to IE1 and IE3 mRNAs by differential splicing, which is driven by the $P^{1/3}$ promoter with a strong upstream enhancer that serves as a molecular switch, connecting IE1/3 transcription to the cellular environment. External stimuli, such as the pro-inflammatory cytokine tumor necrosis factor alpha (TNF-α), act as the first signal in the reactivation pathway, inducing transcription factors which activate the enhancer by binding to defined sequence motifs. IE3 is believed to be the major transactivator of E gene expression. MCMV latency is controlled after the initiation of IE1/3 transcription and this is the second checkpoint in the pathway of molecular reactivation. The full mechanism of reactivation has not been elucidated, but models postulate a multistep system of MCMV reactivation involving many checkpoints before the production of infectious virus.

Host Immune Responses and Viral Evasion Strategies

The host immune response to MCMV and the many countermeasures employed by MCMV reflect a dynamic

host and pathogen interaction and co-evolution. A range of host immune responses involving antibody, $CD4^+$ T cells, $CD8^+$ T cells, and natural killer (NK) cells help control MCMV infection, and are summarized in **Table 3**.

Innate intracellular defense mechanisms, such as interferon production (see below), apoptosis, and the dsRNA-dependent protein kinase R (PKR)-mediated shutdown of protein synthesis, are all targets of MCMV genes. There are three genes encoded by MCMV whose products inhibit apoptosis and facilitate tropism in specific cell types: apoptosis is inhibited in macrophages by the product of *M36*, in endothelial cells and fibroblasts by the product of *M45*, and in endothelial cells by the product of *m41*. An additional gene, *m38.5*, appears to be a homolog of the HCMV viral mitochondria-localized inhibitor of apoptosis (vMIA) encoded by *UL37*. Finally, the products of MCMV genes *m142* and *m143* form a dsRNA-binding complex that inhibits host PKR-mediated shutdown of protein synthesis.

NK cells are the primary host cell involved in the early innate response to MCMV. NK cells limit the severity, extent, and duration of acute infection and also affect the subsequent acquired immune response. MCMV infection can be lethal in their absence. NK cell control of MCMV infection is mediated by direct lysis of infected cells and by the production of cytokines. Direct NK cell killing is mediated predominantly by perforin, particularly in the spleen. Cytokine contol of infection is most evident in the liver and is predominantly mediated by interferon gamma (IFN-γ). MCMV encodes at least six genes that

Table 3 Immune evasion strategies of MCMV

		MCMV immune subversion		
Host control	*Effect*	*Gene*	*Function*	*Mechanism*
Innate immunity				
NK cells	Control of MCMV replication in acute infection	*m145*	Inhibits NK cell killing	Downregulates MULT-1, a ligand for the NK cell activating receptor, NKG2D, on infected cells
	Cytokine production enhances later immune responses such as T-cell activation and may affect DC/NK cell cross talk	*m152*	Inhibits NK cell killing	Downregulates RAE-1, a ligand for the NK cell activating receptor, NKG2D, on infected cells
		m155	Inhibits NK cell killing	Downregulates H60, a ligand for the NK cell activating receptor, NKG2D, on infected cells
		m144	Inhibits NK cell killing	MHC homolog, ligand unknown
		m138	Inhibits NK cell killing	Downregulates MULT-1 and H60 ligands for the NK cell activating receptor, NKG2D, on infected cells
		m157	Activates NK cells	Binds the NK cell activating receptor Ly49H (Cmv1)
Monocyte/ macrophages	Phagocytosis of infected cells and cytokine production	Nil	MCMV infects monocytes and macrophages, increasing IL-10 expression and reducing MHC class II expression	Infected monocytes disseminate virus to other organs such as the salivary gland. Differentiation in the tissues to macrophages allows for productive infection
Cytokines	Various effects on both innate and acquired immune responses	*M27*	Inhibits innate intracellular resistance to MCMV	Downregulates STAT-2, induces type I and type II IFN resistance
		M33	Migration of cells, including smooth muscle cells	Agonist independent GPCR, functional homolog of HCMV US28
		m129/131	Promotes inflammation	Chemokine homolog, macrophage chemoattractant. May aid dissemination of MCMV to the salivary gland within macrophages

Table 3 Continued

		MCMV immune subversion		
Host control	*Effect*	*Gene*	*Function*	*Mechanism*
Acquired immunity				
DCs	Priming of T cells Cytokine production Activation of NK cells	*m147.5* and other unidentified genes	Inhibition of T-cell priming Inhibits NK cell function Reduction in IL-2 and IL-12 production	Failure of DC maturation, possibly due to multiple MCMV genes affecting MHC expression, co-stimulatory molecule expression, and cytokine production. *m147.5* specifically downregulates CD86
CD8 T cells	Direct killing of infected cells	*m04*	Blocks CTL function	Binds MHC class I and remains associated on cell surface
	Control of reactivation from latency	*m06*	Blocks CTL function	Targets MHC class I to lysosome for degradation
		m152	Blocks CTL function	Retains MHC class I in ERGIC
CD4 T cells	Control of viral replication in the salivary gland	Nil		
Antibody	Reduces viral dissemination Reduces MCMV titer after reactivation Passive transfer protects mice from MCMV	*m138*	Fc receptor homolog (fcr-1). No known role in evasion of antibody responses	

MCMV has multiple mechanisms for evading host control. NK cells and $CD8^+$ CTLs are the primary effector cells in host control and this is reflected in the number of immune evasion strategies MCMV employs to evade these mechanisms. Dendritic cells (DCs) also play a major role in the acquired immune systems control of MCMV infection by priming MHC class I and II restricted responses and, in the innate response, by cytokine release and by activation of NK cells. MCMV causes functional paralysis of DC and inhibits the expression of MHC and co-stimulatory molecules on the surface of DCs. These effects presumably serve to reduce T-cell priming as well as the activation of NK cells and may alter the type of immune response generated by perturbing cytokine responses. Macrophages are a major host control mechanism, but MCMV subverts this role by infecting monocytes and using the cells as a means of dissemination to other organs such as the salivary gland. Once in the tissues, monocytes differentiate into macrophages and become permissive for MCMV production. MCMV-encoded chemokine (MCK-2) and chemokine receptor (*M33*) may serve to recruit inflammatory cells to the site of infection to aid viral dissemination.

affect NK cell responses (**Table 3**). The complexity of this interaction is demonstrated in **Figure 3**.

$CD8^+$ cytotoxic T lymphocytes (CTLs) are crucial for the resolution of acute MCMV infection in BALB/c mice. CTLs lyse MCMV-infected fibroblasts *in vitro* and are found in the spleen of infected mice within 3 days. Sensitized CTLs recognize both structural and nonstructural viral antigens. This has been best studied in BALB/c mice where almost 50% of CTLs are directed against the nonstructural pp89 (*IE1*) protein of the Smith strain of MCMV. Epitope mapping has identified the immunodominant H-$2L^d$-restricted pp89 peptide as the nonomer YPHFMPTNL. Other peptides recognized in BALB/c mice are encoded by genes *m04*, *M45*, *m164*, *M83*, and *M84*. Recent studies in C57BL/6 mice have also identified a broad range of CD8 T-cell epitopes.

MCMV encodes a number of genes that are believed to affect CTL-mediated control of infection. Some, such as *m04*/gp34, *m06*/gp48, and *m152*/gp40, affect major histocompatibility complex (MHC) class I molecule expression on the surface of infected cells and/or inhibit CTL recognition and killing (**Table 3** and **Figure 3**). Their role *in vivo* is yet to be fully explained, but MCMV mutants in which all three genes are deleted exhibit reduced growth in the salivary glands of mice. MCMV also inhibits T-cell priming by causing functional paralysis of dendritic cells (DCs). The MCMV genes responsible for this effect are largely unknown, although *m147.5* is known to downregulate the co-stimulatory molecule B7.2 on the surface of infected DCs.

Antibody and $CD4^+$ T cells play lesser roles in the resistance of mice to MCMV infection. Antibody reduces dissemination of the virus within the host and reduces viral loads after reactivation from latency. As yet, there are no known MCMV genes that target antibody function directly. The MCMV-encoded (*m138*) Fc receptor inhibits NK cell function but does not appear to play a role in inhibiting host-antibody-mediated protection. Similarly, no MCMV-encoded gene has been identified that directly targets host $CD4^+$ T-cell responses. This perhaps reflects the moderate role of host $CD4^+$ T cells in resistance to MCMV, although $CD4^+$ T cells are important in the control of MCMV replication in the salivary gland.

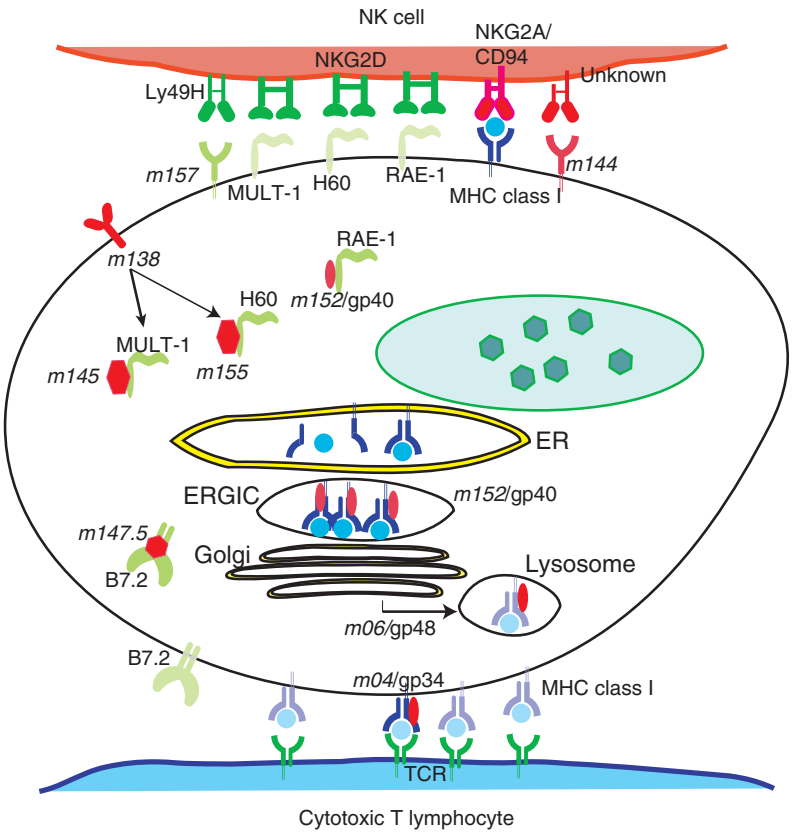

Figure 3 MCMV NK cell and CD8$^+$ CTL immune evasion strategies. MCMV has multiple methods of moderating host immune responses. Receptors or genes that inhibit immune responses are shown in red; those that activate immune responses are shown in green. The MHC class I molecules activate immune responses when ligated by host TCR (T-cell receptor) but inhibit responses when ligated by host NK cell NKG2A/CD94 heterodimer and are therefore shown in blue. When downregulated by an MCMV gene, host proteins are shown on the surface of the cell with reduced shading. MCMV targets NK cells by multiple mechanisms. MCMV downregulates host stress ligands that activate NK cells via the NK cell activating receptor NKG2D. MCMV genes *m138*, *m145*, *m152*, and *m155* affect the host proteins MULT-I and H60, MULT-1, H60, and RAE-1, respectively. These interactions have been depicted to occur in the cytoplasm because their actual locations are unknown. MCMV *m144* is an MHC homolog and inhibits NK cells by interaction with an unknown ligand, presumably an NK cell inhibitory receptor. Host CTL responses are avoided by interference with MHC class I expression. The gp48 (*m06*) protein targets MHC class I for degradation in the lysosome, gp40 (*m152*) retains MHC class I in the endoplasmic reticulum-Golgi intermediate compartment (ERGIC), and gp34 (*m04*) binds to MHC class I and inhibits CTL function (and possibly NK cell function). The gene product from *m147.5* downregulates the co-stimulatory molecule B7.2 and functions with other unidentified genes to inhibit DC function and reduce T-cell priming and NK cell function. Note, NKG2D is also found on T cells as a co-stimulatory receptor, but the role of *m138*, *m145*, *m152*, and *m155*, if any, on T-cell response to MCMV has not been explored.

Cytokine responses are also crucial to the resolution of MCMV infection in mice. This is exemplified by the increased sensitivity of interferon-αβ receptor 1 chain (IFNAR1) and IFN-γR1 knockout mice to MCMV. IFNAR1/IFN-γR1 double-knockout mice are exquisitely sensitive to MCMV infection. This increased sensitivity is probably due to the combined effects of defective cellular innate and acquired immune responses due to loss of IFN-γ (type II IFN) signaling as well as the loss of innate intracellular responses resulting from a loss of type I IFN signaling. As a countermeasure to host type I and II IFNs, MCMV induces a state of type I and II IFN resistance by *M27*-mediated downregulation of STAT2. In addition, infection is enhanced by an MCMV-encoded chemokine and chemokine receptor. *M33* encodes a G protein-coupled receptor (GPCR) homolog that is constitutively active in an agonist-independent manner and promotes dissemination of the virus to the salivary gland, possibly by recruitment of macrophages. The MCMV-encoded (*m129/131*) chemokine MCK-2 serves a similar function in that it increases inflammation, and deletion of *m129/131* reduces viral titers in the salivary gland (**Table 3**).

Rat Cytomegalovirus

CMVs have been identified in, and isolated from, several species of rat. The Maastricht strain of RCMV is the most

widely studied and was isolated from the brown rat, *Rattus norvegicus*. Another strain of RCMV, the English strain, was isolated from *R. norvegicus*; however, its classification as a CMV has been questioned. Recently, more putative strains of RCMV have been isolated from *R. norvegicus*, *Rattus rattus* (black rat), and *Rattus argentiventer* (rice field rat). This article focuses on the Maastricht strain of RCMV.

The Maastricht strain of RCMV was isolated from a wild brown rat in 1982, and has been maintained *in vitro* and *in vivo* in inbred laboratory strains of *R. norvegicus*. The genome has been fully sequenced and consists of a unique region bounded by terminal repeats. Its genome is 230 138 bp in length and is collinear with that of MCMV, encoding at least 170 ORFs, approximately two-thirds of which share significant sequence homology with genes found in MCMV (**Figure 1**). One RCMV gene, *r127*, appears to be unique among CMVs, encoding a homolog of the parvovirus *rep* gene. As with MCMV, RCMV encodes several genes (e.g., the GPCRs *R33* and *R78*, the MHC class I homolog *r144*, and the CC chemokine homologs *r129* and *r131*) which are homologs of cellular genes and which have therefore presumably been appropriated by the virus during evolution.

As is the case with other CMVs, RCMV is able to modulate and subvert host immune responses. RCMV downregulates the level of MHC class I molecules on the surface of infected cells. However, unlike MCMV, this effect is short-lived and does not result in proteolytic degradation of MHC class I molecules, rather in their delayed exit from the endoplasmic reticulum (ER). The RCMV gene *r131* is a pro-inflammatory CC-chemokine homolog, and appears to act similarly to the MCMV gene *m129/131* in that deletion of these genes results in decreased inflammation at the site of inoculation. This *r131*-mediated inflammation may recruit susceptible target cells to the site of infection, allowing virus dissemination throughout the body. *R33* has been shown to promote smooth muscle cell migration; however, it may play other roles in viral disease.

Pathogenesis

Following intraperitoneal inoculation of RCMV into rats, low levels of virus can be found in the visceral organs and bone marrow at 4 days post infection (p.i.). Virus can be detected in the salivary gland, in the striated duct cells, from 10 days p.i., with virus titers peaking at 28 days p.i., before gradually decreasing over several months. Interestingly, although at 6 months p.i. viral DNA can occasionally be detected in the visceral organs, infectious virus can only ever be isolated from the salivary gland at this time point. RCMV is capable of entering latency within the infected rat, although the major sites of latent infection are unknown. Virus can be reactivated from latency following immunological stress, such as immunosuppression or stimulation with allogeneic cells, resulting in virus replication.

As is the case with other CMVs, RCMV infection does not result in overt disease in immunocompetent hosts. However, in the immunocompromised animal, it may cause considerable morbidity and mortality. In immunocompetent rats, RCMV is capable of causing vascular injury, such as endothelial cell damage and leukocyte adherence to the aortic endothelium. RCMV infection may also lead to an influx of macrophages and lymphocytes and loosening of endothelial cells from the basement membrane. Inoculation of virus into immunocompromised animals, however, produces a different scale of pathology. Extensive cell necrosis results in organ damage, with multiple hemorrhages in lung, liver, spleen, and kidney. Virus also induces damage to the microvascular epithelium, vasculitis, and thrombotic occlusions.

The tendency of RCMV to induce vascular disease has made it a good model for studying the role of HCMV in these diseases in humans. Atherosclerosis is a chronic inflammatory disorder of large- and medium-sized arteries, and seroepidemiological and histopathological studies have implicated HCMV in the pathogenesis of this disease. RCMV induces vascular lesions with endothelial cell damage and leukocyte presence in the subendothelium, the presence of subendothelial foam cells, and morphological changes to the large blood vessels of infected rats. It has been suggested that RCMV induces smooth muscle cell migration, promotes leukocyte influx, and increases cellular expression of adhesion molecules, inflammatory cytokines, and chemokines, all components of the atherosclerotic process. Infection of rats with RCMV has also been shown to be a suitable model for arterial restenosis and transplant vascular sclerosis (chronic rejection). Both conditions have been linked to infection with HCMV in humans.

Guinea Pig Cytomegalovirus

Classic viral inclusions were first seen in the salivary gland of guinea pigs in the 1920s. However, GPCMV was not isolated until 1957. Since this time, almost all research conducted on GPCMV has used the Hartley strain of the virus.

The genome of GPCMV, while not fully sequenced, is approximately 230 kbp in length and is collinear with those of other CMVs, sharing genes with HCMV, MCMV, and RCMV within the central two-thirds of its genome but having GPCMV-specific genes near the termini. Several genes have been fully sequenced, particularly those with significant homology to potential HCMV vaccine targets. Again, as with other CMVs, gene expression is temporally regulated with IE, E, and L kinetics, although expression in the latter categories has been less well studied.

Following inoculation with GPCMV, viremia occurs for approximately 10 days, with infectious virus being detectable, and disease evident, in lungs, spleen, liver, kidney, thymus, pancreas, and brain for about another 3 weeks. Virus may be detected in the salivary gland for up to 10 weeks p.i.

GPCMV is unique among rodent CMVs in its ability to cross the placenta and infect the fetus. Hence, it is widely used as a model of congenital infection with HCMV. The guinea pig placenta consists of a single trophoblast layer separating maternal and fetal circulation, and is histologically similar to the human placenta. Infection during early pregnancy leads to pup resorption, while infection late in pregnancy generally leads to pup mortality. Following infection mid-gestation, GPCMV can be detected in placental tissue, even in the face of maternal anti-GPCMV antibodies. However, even in this case, only a proportion of pups attached to infected placentas are infected with GPCMV. These infected pups exhibit CMV disease in the brain, visceral organs, and inner ear, analogous to congenital infection with HCMV. GPCMV has been extensively used in studies of vaccination against congenital CMV infection. Vaccines against both gB and GP83 have been shown to protect against congenital GPCMV infection, although protection against pup mortality was dependent on maternal antibody titer.

Other Nonprimate Cytomegaloviruses

Swine cytomegalovirus is endemic in swine herds worldwide, and has also been shown to reactivate from pig-to-baboon xenotransplants. It causes rhinitis in young swine and is able to cross the placenta, resulting in generalized disease, runting, and fetal death. Initial sequence analysis of the DNA polymerase complex genes suggests that this virus is more closely related to HHV-6 than to CMVs. Tree shrew herpesvirus has been sequenced and has been found to resemble MCMV and other betaherpesviruses. A CMV has been isolated from deer mice (*Peromyscus maniculatas*) in North America, and has been characterized as a CMV based on physical and biological properties and genetic homology with several genes of other CMVs. CMVs have also been isolated from European and American ground squirrels, and designated as sciurid herpesvirus 1 and sciurid herpesvirus 2, respectively.

Agents resembling CMVs have also been described in hamsters, moles, voles, field mice, the Australian native rodent antechinus, cats, and dogs. These agents have not been characterized further and may not actually be CMVs.

Glossary

Paralogs Genes that share homology through gene duplication and often have diverged functions or expression patterns.

Stealth virus An unproven chimeric virus that lacks or suppresses genes that trigger immune responses and is thereby able to go undetected by the immune system.

Introduction

In addition to the well-studied cytomegaloviruses (CMVs) of human (HCMV; salivary gland virus) and mouse (MCMV), related agents with typical CMV-like characteristics have been described in rats (RCMV), guinea pigs (GpCMV), pigs (PCMV), elephants (EEHV, elephant endotheliotropic herpesvirus), Old and New World primates (collectively known as simian CMVs and represented

by viruses such as RhCMV), and tree shrews (HVTupaia) (**Table 1**). GpCMV was originally recognized in 1920 and served as a model system for the biology and pathogenicity of HCMV disease for many years.

Most natural nonhuman primate populations studied harbor persistent or latent infections with host-specific simian CMVs. Isolates have been reported from almost all major primate groups, including gorilla, chimpanzee, bonobo, drill, baboon, rhesus and other macaques, African green monkey, spider monkey, owl monkey, capuchin, and marmoset. Infection is also common in captive breeding populations and, even when infection is usually inapparent in the absence of immunsuppression, virus is shed intermittently in urine and saliva. Indeed, simian CMVs are potential contaminants in primary cell cultures obtained from primate sources. Also, all simian CMVs can be adapted to grow in human fibroblasts. For research purposes, the main value of simian CMVs is for genome evolutionary comparisons and as animal models for HCMV disease, in which they are potentially superior to rodent CMVs. The genomes of primate CMVs differ among themselves and from HCMV to a surprisingly large degree, but nonetheless are more closely related to HCMV than are their equivalents in nonprimates.

Classification and Evolution

CMVs are members of the family *Herpesviridae* and belong to subfamily *Betaherpesvirinae* (**Table 1**). Formally, this subfamily is divided into three genera, namely *Cytomegalovirus* (HCMV-like viruses from primates), *Muromegalovirus* (MCMV-like viruses from rodents), and *Roseolovirus* (HHV-6-like viruses, so far only from great apes). There is

Table 1 Primate and other viruses classified in or potentially belonging to the subfamily *Betaherpesvirinae*

Genus	*Host group*	*Host species*	*Common abbreviation*	*Formal name*	*RefSeq accession*
Cytomegalovirus	Old World primate	Human	HCMV	*Human herpesvirus 5*	NC_001347; NC_006273
		African green monkey	AgmCMV	*Cercopithecine herpesvirus 5*	
		Rhesus macaque	RhCMV	*Cercopithecine herpesvirus 8*	NC_006150
		Chimpanzee	CzCMV	*Pongine herpesvirus 4*	NC_003521
Possible members		Bonobo	BoCMV		
		Baboon	BaCMV		
		Vervet	SA6	Cercopithecine herpesvirus 3	
		Vervet	SA15	Cercopithecine herpesvirus 4	
	New World primate	Marmoset	MaCMV	Callitrichine herpesvirus 2	
		Owl monkey	HVAotus type 1	Aotine herpesvirus 1	
		Owl monkey	HVAotus type 3	Aotine herpesvirus 3	
		Cebus	CeCMV		
		Capuchin	AL-5	Cebine herpesvirus 1	
		Capuchin	AP-18	Cebine herpesvirus 2	
Muromegalovirus	Rodent	Mouse	MCMV	*Murid herpesvirus 1*	NC_004065
		Rat	RCMV1	*Murid herpesvirus 2*	NC_002512
Possible member		Rat	RCMV2		
Roseolovirus	Old World Primate	Human	HHV-6A	*Human herpesvirus 6*	NC_001664
		Human	HHV-6B	*Human herpesvirus 6*	NC_000898
		Human	HHV-7	*Human herpesvirus 7*	NC_001716
Possible member		Chimpanzee	PaHV-6		
Proboscivirus (proposed)	Elephant	African elephant	EEHV	Elephantid herpesvirus 1	
Unassigned	Various	Guinea pig	GpCMV	*Caviid herpesvirus 2*	
		European ground squirrel	SqCMV1	Sciurid herpesvirus 1	
		American ground squirrel	SqCMV2	Sciurid herpesvirus 2	
		Pig	PCMV	Suid herpesvirus 2	
		Tree shrew	HVTupaia	*Tupaiid herpesvirus 2*	NC_002794

one genus pending, *Proboscivirus* (EEHV). Based on the relatively high G + C content of their genomes and their adaptability to grow in fibroblasts in cell culture, most traditionally recognized 'CMVs' are likely to be evolutionarily more similar to genera *Cytomegalovirus* or *Muromegalovirus* than to the (A + T)-rich genus *Roseolovirus*. The taxonomy of the *Betaherpesvirinae* will be shaped further with the continuing addition of members that are currently not fully classified , such as GpCMV, PCMV, and HVTupaia.

The genomes of nine betaherpesviruses are currently available, namely those of HCMV (strain AD169 in 1990, 229 354 bp; strain Merlin in 2004, 235 645 bp), CzCMV (in 2003, 241 087 bp), RhCMV (strain 68-1 in 2003, 221 459 bp; strain CMV 180.92 in 2006, 215 678 bp), MCMV (strain Smith, in 1996, 230 278 bp), RCMV (strain Maastricht in 2000, 229 896 bp), HHV6A (strain U1102 in 1995, 159 321 bp), HHV-6B (strain Z29 in 1999, 162 114 bp), HHV-7 (strain JI in, 1996, 144 861 bp; strain RK in, 1998, 153 080 bp), and HVTupaia (in 2001, 195 857 bp). The first complete betaherpesvirus genome sequenced was that of the AD169 isolate of HCMV. However, AD169 is a highly passaged laboratory strain that had suffered deletions and duplications during passaging in culture. Five more HCMV genomes have now been sequenced in the form of bacterial artificial chromosomes, and AD169 has been replaced by strains Merlin and FIX as the prototype HCMV genomes. Two strains of AgmCMV have now also been sequenced (GR2715 and Colburn), and work is in progress on EEHV as well as several other nonhuman primate CMV species.

All formally recognized and probable betaherpesviruses are listed in **Table 1**, with their common and official names and the RefSeq accession numbers of their complete sequences. Two very different muromegaloviruses (with somewhat different gene contents) are both known as RCMV, and are represented by the Maastricht (M) and English (E) strains as RCMV1 and RCMV2, respectively. CMV-like viruses have been associated with fatal hemorrhagic disease in young African and Asian elephants. Ongoing genetic analysis indicates that they are very distinct from members of the three recognized genera, and this has resulted in proposal of a new genus, *Proboscivirus*. An unusual herpesvirus isolate, referred to as 'stealth virus', was reported to have been recovered from a human patient with central nervous system (CNS) neuropathy, but genetic analysis has revealed that this virus is virtually identical to several characterized simian CMV isolates from African green and vervet monkeys (AgmCMV). Another AgmCMV isolate, 'Colburn', was also originally thought to have been of human origin, but it is unclear whether it is truly a human isolate rather than a contaminant from primary monkey cell cultures. Based on genome analyses, the bovine herpesvirus BHV-4 and two equine herpesviruses EHV-2 and EHV-5 were originally thought to be CMVs, but were reclassified into the genus *Rhadinovirus* in subfamily *Gammaherpesvirinae*.

Typically, betaherpesviruses have no more than 40 of their 110–165 genes in common with alpha- and gammaherpesviruses. Another 35 genes appear to be betaherpesvirus specific and are likely to be shared by all CMV and HHV-6-like viruses, whereas most of the remaining genes are unique to different virus genera or individual species. As judged by the presence of several large families of related genes in HCMV, AgmCMV, and RhCMV, it appears that the CMVs, which possess the largest of all mammalian herpesvirus genomes, underwent a rapid genomic expansion in the early stages of mammalian evolutionary radiation. In contrast, the roseoloviruses (HHV-6 and HHV-7) and HVTupaia can be considered to be mini-CMVs lacking most of the repeated gene families and the entire S segment of the genome. Unlike other herpesviruses, betaherpesviruses in general do not encode either thymidine kinase or the small subunit of ribonucleotide reductase, although EEHV has both of these. However, probably all betaherpesviruses encode a phosphotransferase (UL97) activity that is the target for the effective anti-CMV agent ganciclovir and its derivatives. Like all other known herpesviruses, primate CMVs encode the typical set of six core DNA replication proteins including DNA polymerase (POL), DNA primase (PRI), helicase (HEL), single-stranded DNA-binding protein (SSB), polymerase processivity factor (PPF), and primase accessory factor (PAF). In contrast to the CMVs and muromegaloviruses, the roseoloviruses and EEHV encode a homolog of the HSV UL9 origin-binding protein (OBP).

Virion Structure

Primate CMV virions are structurally similar to those of other members of the *Herpesviridae*, and are essentially indistinguishable from those of HCMV in the electron microscope. However, many of the virion proteins of each species display characteristic size variations by polyacrylamide gel electrophoresis (PAGE) analysis. Large nuclear and cytoplasmic inclusion bodies detectable in lytically infected cells by light microscopy are a hallmark of all betaherpesviruses.

Genome Structure

The genomes of all known CMV DNA molecules are *c.* 210–240 kbp in size, and most have a G + C content of around 58%, in contrast to the 145–166 kbp and 46% G + C content of HHV-6 and HHV-7. Structurally, two distinct CMV genome types can be discerned. The

genomes of New World primate CMVs (HVAotus types 1 and 3), HCMV, and CzCMV represent one type, having internal inverted repeats flanking two unique regions (the L segment consisting of unique region U_L flanked by inverted repeats TR_L/IR_L, and the S segment consisting of unique region U_S flanked by inverted repeats TR_S/IR_S), which generate four isomeric arrangements of the segments, similar to the pattern observed in herpes simplex virus. On the other hand, AgmCMV, RhCMV, HVTupaia, and several rodent CMVs (MCMV, RCMV, and GpCMV) have noninverting DNA molecules. HHV-6 and HHV-7 lack the entire 40 kbp S segment of HCMV and the L segment is bounded by large direct terminal repeats of 5–10 kbp. MCMV has a similarly sized gene block in place of the S segment, but the region has very little organizational resemblance or similarity to the S segment of HCMV. Large blocks of genes at the left and right ends of the L segment of each genome are also unique to each of the three genera for which complete sequence data are available, including the segments mapping to the right of and adjacent to the major immediate-early (MIE) genes in nonhuman primate simian CMV genomes, which differ dramatically from each other as well as from the equivalent regions in HCMV.

DNA and amino acid sequence analysis indicates that species from different mammalian hosts are diverged in accordance with their host phylogeny, with different genes having diverged at different rates. For example, in a region that is highly conserved between HCMV and AgmCMV, the major single-stranded DNA-binding proteins (UL57) have 72% overall amino acid sequence identity, whereas a group of three adjacent betaherpesvirus-specific glycoproteins mapping to the left of the MIE region (UL118, UL120, and UL121) vary from as much as 35% identity overall to as little as 15% in one region. Similarly, the betaherpesvirus-specific IE2 (UL122) immediate-early (IE) regulatory proteins of HCMV and AgmCMV have 58% amino acid sequence identity, but only over the C-terminal half of the protein, and both are equally diverged from RhCMV in this region. Amino acid sequence differences between homologous CMV genes from even the most closely related host species, such as HCMV and CzCMV, are frequently at least 20–30%.

Even the DNA molecules of individual isolates of a single primate CMV species are often distinguishable on the basis of multiple restriction fragment length polymorphisms stemming from overall intraspecies nucleotide variations of up to 3–4%. In fact, different isolates or strains of HCMV and simian CMVs display a number of significant genomic differences. First, so-called laboratory strains of HCMV (such as AD169 and Towne), AgmCMV (Colburn), and RhCMV (68-1) have all undergone deletions and rearrangements. They have also accumulated frameshift or truncation mutations in a number of genes that appear to be critical for preserving natural tropism for endothelial and macrophage cell types, but are evidently selected against during adaptation to fibroblast cells. These changes particularly affect a set of three small genes (UL128, UL130, and UL131A). Even the less passaged HCMV (strain Toledo) has undergone a large inversion that affects UL128.

A second type of strain sequence difference has been documented in HCMV for many years within a subset of 'variable' genes, which include gB (UL55), gN (UL73), gO (UL74), exon 3 of UL37 (UL37ex3), UL9, RL12, RL13, UL144, UL146, and UL147. In each case, even when analyzed directly by polymerase chain reaction (PCR) sequencing of clinical samples, the proteins from different genomes can display up to 30–60% divergence at the amino acid level, with collections of isolates examined falling into clusters of 3, 5, 8, or even 15 subtypes, depending on the locus. The subtype patterns in different 'variable' gene loci are unlinked, and this is indicative of high levels of mixed infections, recombination, and chimerism in HCMV samples. The origin and biological significance of subtype patterns are not well understood, but are most likely related to founder and bottleneck effects during the recent evolutionary spread and migration of humans. Isolates of CMV from nonhuman primate host species also display similar patterns of variability.

The sequenced prototype betaherpesviruses contain several interesting, and in some cases genus-specific, genes that are related to cellular genes and appear to be used primarily for evasion of immune responses. For example, HCMV encodes four viral G protein-coupled receptors (vGPCRs; UL33, UL78, US27, and US28), at least one of which (US28) functions as a broad-spectrum chemokine receptor that promotes migration of smooth muscle cells, and three glycoproteins (US3, US10, and US11) that together function to destabilize or inhibit cellular HLA-mediated responses. HHV-6 and MCMV each encode two GPCR proteins. HCMV and MCMV also each encode diverged homologs of HLA-I (at different locations in their genomes), and HCMV also possesses two separate anti-apoptotic proteins known as vMIA (UL37) and vICA (UL36). Spliced genes in MCMV and RCMV encode two functional β-chemokines, whereas HCMV encodes two α-chemokines (UL146 and UL147). HHV-6 (but not HHV-7) encodes an REP protein apparently captured from adeno-associated virus, and both HHV-6 and HHV-7, as well as RCMV but not MCMV, encode different OX-2-related proteins. RhCMV and AgmCMV, but not HCMV or CzCMV, encode a highly spliced COX2 gene, and HCMV, RhCMV, and AgmCMV encode a spliced vIL-10 gene, whereas CzCMV does not.

The total genome contents of the two 'great ape' CMVs (HCMV and CzCMV) differ by at most a half dozen out of 165 clearly defined genes. However, differences between HCMV and the 'Old World primate' CMVs (RhCMV and AgmCMV) are numerous. One

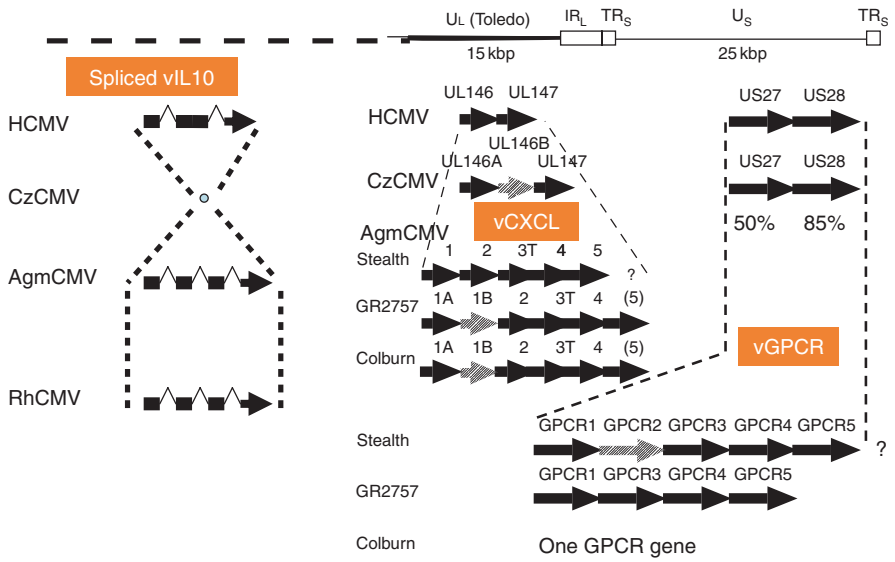

Figure 1 Comparison of the organization of the spliced vIL10 genes, the UL146 vCXCL α-chemokine ligand gene cluster, and the US28 vGPCR chemokine gene cluster in CMV genomes. Amino acid sequence identity between HCMV and CzCMV is indicated for the US27 and US28 proteins. Stealth, GR2757, and Colburn are distinct isolates of AgmCMV. The position of the additional (but inverted) 15 kbp segment in HCMV strain Toledo U_L compared to strain AD169 is indicated by the solid line. The spliced vIL10 gene is present in HCMV, AgmCMV, and RhCMV but absent from CzCMV. Another spliced gene (the COX2 gene) is present (at another location) in AgmCMV and RhCMV, but not in HCMV or CzCMV.

manifestation is the presence of either five or six tandemly repeated but highly diverged paralogs of the paired US27/US28 vGPCR genes of HCMV in multiple strains of RhCMV and AgmCMV, and the presence of either seven or eight tandemly repeated but highly diverged paralogs of the paired UL146/UL147 α-chemokine genes of HCMV in different strains of AgmCMV (**Figure 1**). Also, there are three, rather than two, of the α-chemokine genes in this cluster in CzCMV and at least three in RhCMV. Both the vGPCR and α-chemokine gene clusters appear to be undergoing highly dynamic evolution in Old World primate CMVs.

Epidemiology and Physical Properties

Features of host range, virus propagation, virus transmission, tissue tropism, pathogenicity, histopathology, and immune responses of primate CMVs, together with the physical properties and assembly pathways of the virions, and a number of biochemical properties of their structural proteins, closely resemble those of HCMV and MCMV. In general, long-term persistent asymptomatic infection is nearly universal among natural primate populations in the wild, with primary infections occurring in infants and juveniles. Even captive colony-borne animals are rarely free of these viruses, which can be shed intermittently in saliva and urine throughout the host's lifespan. Like all other herpesviruses, primate CMVs have enveloped icosahedral capsids and replicate in the nucleus. Infection of humans with simian CMVs via prolonged contact with seropositive monkeys or apes, or from vaccines grown in unscreened primary cell cultures from primate sources, is plausible, but has not been documented unambiguously. Laboratory-adapted strains such as AgmCMV Colburn grow vigorously in human fibroblast cell culture (**Figure 2**) and have been known to outgrow HCMV in cell culture. However, primary isolates grow slowly in both human and simian fibroblasts.

Replication Strategies

The lytic cycle pathway of gene expression for primate CMVs follows the typical herpesvirus cascade of IE mRNAs and proteins followed by activation of delayed-early (DE) then late (L) class genes, with synthesis of viral DNA. In cell culture, fully permissive host cell types for HCMV are restricted almost exclusively to diploid cells, including human fibroblasts, vascular endothelial cells (and the U373 astrocytoma cell line), smooth muscle cells, and differentiated macrophages. Fresh clinical HCMV isolates usually need to be adapted for efficient growth in fibroblasts by multiple rounds of passaging, which is accompanied by selection of inactivating point mutations (or deletions) in certain 'cell tropism' genes and a loss of ability to grow in endothelial cells or macrophages.

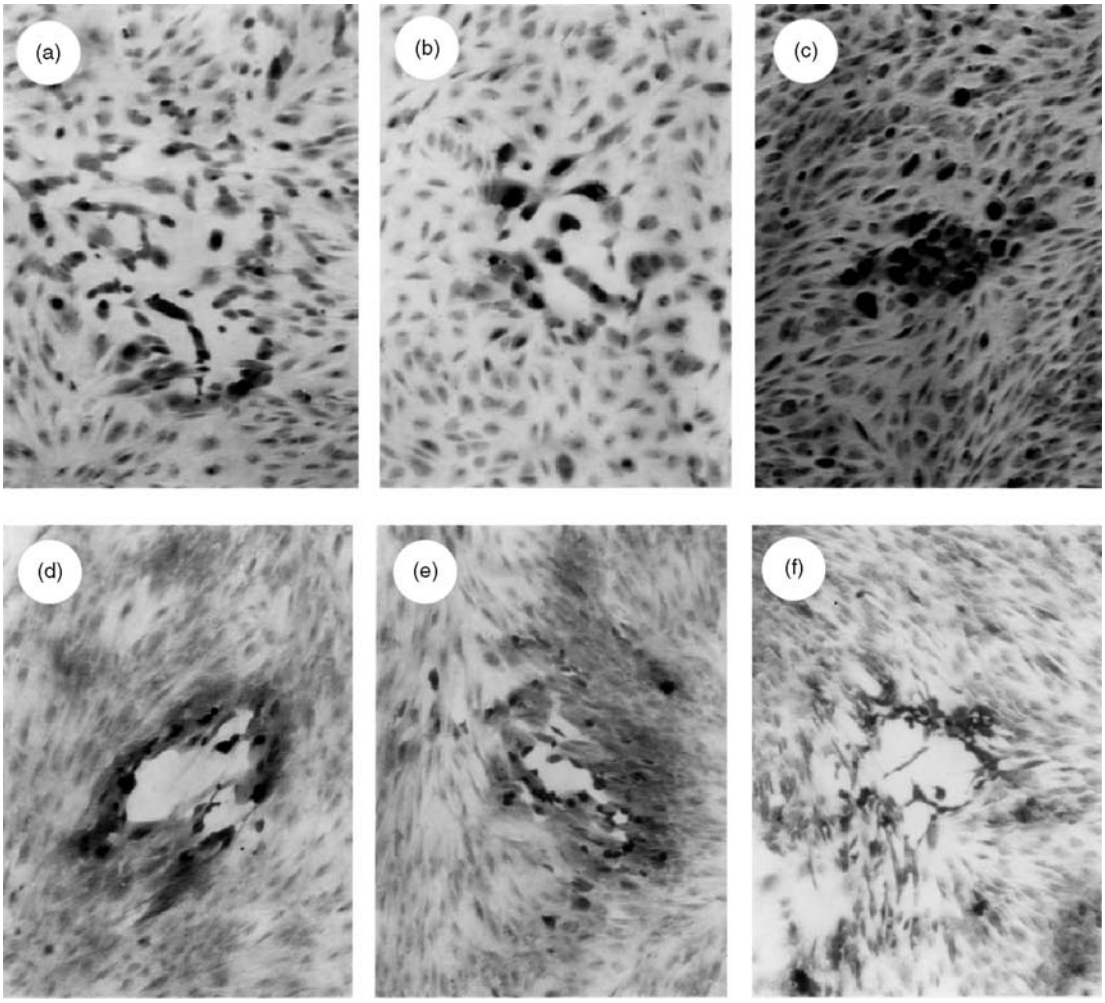

Figure 2 Infection of human diploid fibroblasts (HF cells) with human and other primate CMVs. HF cells at passage level 15 were infected and examined daily for cytopathic effects. All infections produced characteristic cytomegalic cells in culture. (a) HCMV (Towne strain) plaque at 7 days after infection; (b) AgmCMV plaque at 8 days after infection; (c) BaCMV plaque at 11 days after infection; (d) CzCMV plaque at 14 days after infection; (e) RhCMV plaque at 14 days after infection; (f) CeCMV plaque at 8 days after infection.

Laboratory strains of HCMV replicate their DNA efficiently by 72 h in human fibroblasts, but express only the MIE proteins and fail to synthesize any viral DNA in rodent or monkey fibroblasts. AgmCMV, RhCMV, BaCMV, and CzCMV replicate their DNA and form plaques in both human and simian fibroblasts (**Figure 2**). In contrast, MCMV carries out viral DNA synthesis in human, monkey, and rodent fibroblasts. Most transformed human cell types are nonpermissive for HCMV replication, with the block occurring between DNA entry and synthesis of MIE mRNA. However, some differences between HCMV and AgmCMV have been observed at this stage. For example, HCMV fails to synthesize MIE proteins in infected human (NTera) or mouse (F9) teratocarcinoma stem cells, in human 293 or NBE cells, or in mouse L-cells. In contrast, AgmCMV produces MIE proteins in infected NTera, 293, and NBE cells, but not in F9 or L-cells. After differentiation with retinoic acid (RA), NTera stem cells can become permissive for HCMV MIE expression and infectious virus production. Similarly, F9 cells treated with RA induce AgmCMV, but not HCMV, MIE expression. These biological differences among the different species of Old World primate CMVs appear to coincide with structural differences in the organization of *cis*-acting transcriptional control elements and adjacent accessory domains located both upstream of and within the large first intron of the MIE genes. Although a major site *in vivo* for quiescent inactive infection for HCMV and MCMV is believed to involve monocytes, many other sites of inapparent noncytopathic infection occur, but whether any of these can be defined as the true site of reactivatable latent state infection has not yet been resolved.

Control of Gene Expression

Similarly organized MIE transcription units, which encode regulatory proteins that trigger the lytic cycle, have been described for HCMV, CzCMV, AgmCMV, RhCMV, BaCMV, GpCMV, RCMV, MCMV, HHV-6, and HHV-7. In each case, these transcription units produce several multiply spliced mRNAs whose expression is controlled by powerful upstream *cis*-acting enhancer regions. The predominant viral mRNAs synthesized after infection of permissive cells in the presence of cycloheximide (an inhibitor of protein synthesis) are the MIE mRNAs, and these are also the only HCMV or AgmCMV mRNAs and proteins produced after infection of nonpermissive rodent fibroblasts. At least two types of phosphorylated nuclear regulatory proteins are encoded by the MIE transcription unit. These include the highly abundant, acidic IE1 (UL122) nuclear protein and the less abundant IE2 (UL123) DNA-binding transactivator/repressor protein. The IE2 DNA-binding transcription factor proteins are not only essential for stimulating transcription of downstream DE and L HCMV promoters, but they also specifically downregulate their own MIE promoters (negative autoregulation) and are probably also engaged in control of viral DNA replication, altering cell cycle function and blocking interferon and apoptotic responses. In particular, both the IE1 and IE2 proteins target to subnuclear domains known as PODs (protein oncogenic domains), which contain the PML proto-oncoprotein, and appear to modify these sites (also known as ND10 (nuclear domain 10)) for utilization by the viral genomes to initiate viral IE transcription and viral DNA synthesis.

In contrast to the rest of the viral genome, the IE1 and the IE2 coding regions of the MIE transcription units in HCMV, CzCMV, AgmCMV, MCMV, RCMV, HHV-6, and HHV-7 (and probably all other betaherpesviruses) are highly CpG-suppressed, which suggests that they are accessible to cellular methylation events at some stage of the viral life cycle during which all other viral genes are transcriptionally silent. The 490-amino-acid residue HCMV IE1 protein has only 15% amino acid sequence identity with AgmCMV or RhCMV IE1, and much less still is conserved between the primate and MCMV and RCMV versions, although all of the betaherpesvirus IE1 proteins (except for those of HHV-6 and HHV-7) have a highly acidic, Glu-rich C-terminus. In contrast, the 579-amino-acid residue IE2 proteins of HCMV, AgmCMV, RhCMV, MCMV, RCMV, and their much larger counterparts in HHV-6 and HHV-7, exhibit between 25% and 58% sequence identity over the C-terminal 270-residue conserved DNA-binding domain. As expected, the CzCMV IE1 and IE2 proteins are much more similar to the HCMV versions.

The upstream MIE promoter/enhancer regions, which serve to sense the intranuclear environment and control entry into or out of the lytic cycle, are large, complex, noncoding DNA sequence domains that consist of often multicopy, high-affinity binding sites for numerous constitutive or inducible cellular transcription factors. In HCMV, CzCMV, AgmCMV, RhCMV, BaCMV, GpCMV, and MCMV, these sites include response elements for cyclic AMP (CRE, PKA), phorbol esters (TPA, PKC), and RA, together with recognition motifs for SRF/ETS, CREB, SP-1, AP-1, and nuclear factor kappa B (NFκB). Even among the five Old World primate CMVs that have been examined in detail, the organization of these sites within the MIE enhancer regions differs significantly, and the number and pattern of the adjacent tandemly repeated 15 and 30 bp high-affinity NFI/YY1 motifs also differ greatly (**Figure 3**). Overall, the MIE control region in AgmCMV encompassing the BENT, NFI, ENH, and INTRON segments totals 2.3 kbp in size, much more than the approximately 1.1 kbp MIE control region in HCMV.

Other specific regulatory proteins common to HCMV and HHV-6, such as the UL36 and UL37 proteins, members of the US22 family, the UL82 and UL83 matrix phosphoproteins, and the UL84 replication-associated protein, are all conserved in primate CMVs. However, the second immediate early promoter (IES) and its novel, complex NFκB-containing enhancer is found in HCMV and CzCMV upstream from gene US3, and is not conserved in RhCMV or AgmCMV.

The CMV lytic cycle origin of DNA replication (Ori-Lyt) is located to the right of and adjacent to the single-stranded DNA-binding protein gene (UL57), near the center of the HCMV, CzCMV, AgmCMV, RhCMV, and MCMV genomes. It differs significantly from virus to virus in structural organization and apparently cannot be complemented by the protein replication machinery from another virus within this group. Although Ori-Lyt is located at the equivalent site in the genomes of HHV-6 and HHV-7 (and presumably also EEHV), it differs in structure and in its UL9-dependent mode of DNA replication from that in CMVs. It is still not known whether any betaherpesviruses utilize a latent cycle origin of DNA replication, such as that found among gammaherpesviruses.

Future Perspectives

Persistent, inapparent infection with CMVs is probably virtually ubiquitous in most individuals of all mammalian species. However, the biological and pathological properties of primate CMVs have attracted the interest of herpesvirologists and clinicians interested in HCMV disease in acquired immune deficiency syndrome (AIDS) and organ transplant patients, not so much because of the serious morbidity or economic consequences of these infections in their own hosts, but more often as models for latency and pathogenesis or immunological responses in HCMV. MCMV, RCMV, GpCMV, RhCMV, and

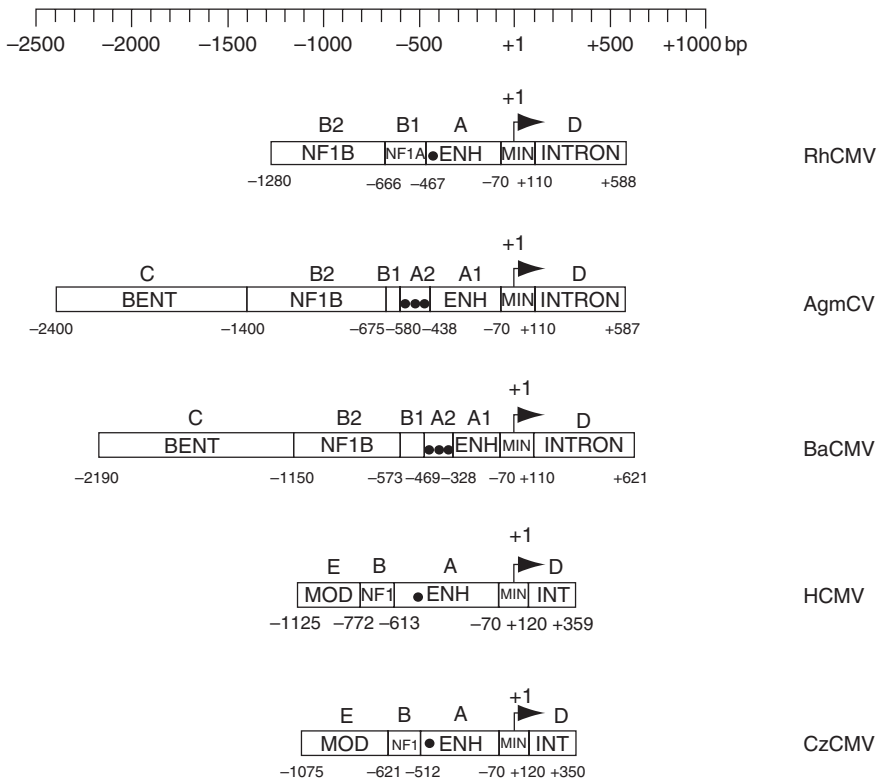

Figure 3 Upstream control regions in the MIE genes of HCMV and other primate CMVs. The diagram illustrates the respective size and organization of domains containing specific transcription factor-binding motif patterns. These include clusters of nuclear factor 1 (NF1) and YY1 sites, the distal enhancer containing multiple CRE, SRE, and NFκB sites (ENH), the proximal promoter and TATATAA box region (MIN) that includes the start site of transcription at +1 (arrowed), and the 5′ half of the large first intron (INTRON). Where appropriate, additional upstream AT-rich (BENT) and modulatory (MOD) regions are also included. Domain boundaries are designated as + or – nucleotide positions with reference to the start site of transcription and given in bp. The domains have also been designated A–E with subcategories 1 or 2 in the case of the NF1 and ENH block. Adapted from Chan YJ, Chiou CJ, Huang Q, and Hayward GS (1996) Synergistic interactions between overlapping binding sites for the serum response factor and ELK-1 proteins mediate both basel enhancement and phorbal ester responsiveness of primate cytomegalovirus major immediate-early promoters in monocyte and T-lymphocyte cell types. *Journal of Virology* 70: 8590–8605, with permission from American Society for Microbiology.

BaCMV have all been investigated as models for virus reactivation, and for control of acute and chronic disease by anti-CMV agents (such as ganciclovir, a nucleotide analog that specifically inhibits CMV DNA replication) in association with allografted organ transplants or immunosuppression. There is also interest in questions related to whether different CMVs can cross host species barriers with possible pathological consequences, which is of concern with BaCMV and PCMV for xenografted organ transplants. Primate CMVs also have comparative value in molecular genetics and biochemical analysis because of their similarities to and differences from HCMV or HHV-6 and HHV-7. Current basic scientific interest in genomic evolution (made possible by large-scale DNA sequencing), as well as the role of transcriptional gene regulation mechanisms in determining cell tropism and the switching between latent and lytic cycle virus–cell interaction pathways, and the many novel mechanisms used by betaherpesviruses for immune evasion, should lead to an expansion of these types of studies with nonhuman primate CMVs over the next several years.

D

Defective-Interfering Viruses

L Roux, University of Geneva Medical School, Geneva, Switzerland

© 2008 Elsevier Ltd. All rights reserved.

This article is reproduced from the previous edition, volume 1, pp 371–375, © 1999, Elsevier Ltd.

History

In 1943, Henle and Henle reported the decreased infectivity for mice of influenza virus stocks obtained after a series of undiluted passages in embryonated chicken eggs. In the early 1950s, von Magnus showed that such undiluted passages generate incomplete virus particles capable of limiting the growth of infectious virus (hence exhibiting interference). This first characterization was soon followed by similar reports by Mims, on the one hand, and Cooper and Bellet, on the other, dealing respectively with Rift Valley fever virus and vesicular stomatitis virus (VSV). In the late 1950s, Cooper and Bellet went so far as to assign interference to sedimentable particles, but failed to identify them as antigenically related to VSV. From the mid-1960s on, the characterization of other positive- and negative-stranded RNA virus defective particles continued. In 1970, a review by A. Huang and D. Baltimore set the basic definition of defective interfering (DI) particles and emphasized their widespread occurrence. Since then, DI particles have been described for almost all the known DNA and RNA viruses, including plant and even fungal viruses.

Structure

DI particles have the same protein composition as their homologous nondefective 'parents', often called St. However, they differ from the St particles in the primary structure of their genome. As emphasized later, DI genomes lack part of the genetic information. They may or may not serve as coding sequences. However, they always conserve the *cis*-sequences needed for replication initiation (origins of replication), sometimes present in more than one copy, and sequences involved in encapsidation. Foreign sequences can also be inserted. DI particles can sometimes be separated from St particles on the basis of size, when the size of the particle closely corresponds to the size of the genome (for instance rhabdovirus), or on the basis of particle density differences (changes in nucleic acid to protein ratios). Often, however, only viral stocks enriched in DI particles are available owing to the size heterogeneity of the virus particles.

Generation of DI Genomes

DI DNAs very likely arise from various recombinational events not necessarily linked to genome replication, and which result in deletion, tandem duplication, insertion of host DNA, and polymerization of small monomer sequences. DI RNAs have been proposed to arise almost exclusively during genome replication by a mechanism of 'leaping polymerase' consisting of polymerase stop/fall-off or slippage/reinitiation events (**Figure 1**). In this model the replicase complex moves with the nascent RNA still attached to it. Depending on where reinitiation takes place, and on the number and the direction of the leaps, the resulting molecules can be of the copy-back type, with more or less intramolecular inverted complementary sequences (a), of the internal deletion type (b), and of the duplication type (c). Multisteps (b) or (c) and combinations of steps (b) and (c) can, moreover, lead to various mosaic types. Insertion of host RNA is also observed, especially in plant DI RNA. The frequency at which the polymerase leaps and resumes its synthesis is unknown. The probability for this exercise to be successful in producing a viable DI genome has been estimated for VSV to range in the order of 10^{-7}–10^{-8} per genome replication.

Defectiveness

The DI genomes contain interrupted or rearranged open reading frames. They partly or completely lack the full

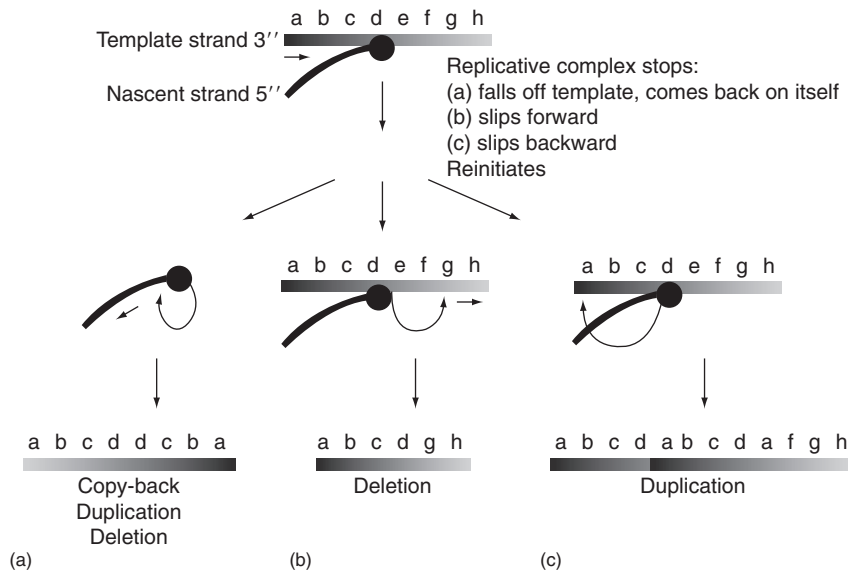

Figure 1 Defective RNA genome generation.

coding capacity of the viral genome. They are therefore defective, and depend for their replication and for their propagation (formation of virus particles) on the functions provided by the homologous standard virus (helper). Co-infection of cells with DI and standard particles is therefore essential for DI particle multiplication. Consequently, low-multiplicity infections, and particularly plaque purification, represent conditions which decrease, and potentially eliminate, DI particles from a viral preparation.

Interference

As stated earlier, the generation of a defective genome is likely to represent a rare event. This event would never be seen unless it was successfully amplified. During this amplification step the defective genome is preferentially replicated over the nondefective genome. This ability to replicate efficiently at the expense of the nondefective genome is called interference. The mechanisms of interference are not completely understood. They obviously change depending on the specificity of the viruses, and appear to be also affected by the host cell types. In general, interference involves an early step in genome replication, and can be pictured as a competition for limiting replication 'factors' (viral replicase, encapsidation proteins, host cell factors). Reiterated origins of replication or encapsidation sites on DI DNAs, presence of higher affinity sites for the replicase or for the encapsidation on both positive and negative polarity DI RNAs, and shorter length of the replicating units, higher availability for replication of molecules not involved in transcription, have been shown or postulated as taking part in the interference mechanism.

Defective Interfering versus Defective Viruses

Based on the outcome of experimental co-infections of defective with nondefective viruses, a distinction has been made between defective interfering or defective noninterfering particles, according to the ability of the defective viruses to selectively restrict nondefective virus replication. This distinction may not apply during the first events following the generation of a defective genome. As this is bound to be a rare event, an interference mechanism has to be invoked any time this defective genome is amplified to the point it can be detected, or become predominant.

Cyclic Variations of Defective Interference

The dependence of DI genome replication on functions provided by the nondefective genome on the one hand, and the interference exhibited by DI genome on the other hand, result in out-of-phase cyclic variations of both DI and St genome replication. As illustrated in **Figure 2**, efficient St genome replication must precede extensive DI genome replication. This in turn establishes conditions of high interference which results in inhibition of St genome replication. Decrease of helper function availability leads to DI genome replication dampening, and therefore to release from interference, allowing efficient St genome replication to resume. These cyclic variations have been observed in serial passages of St and DI viruses in cell culture, as well as in persistent infections. The periodicity of a complete cycle is generally a matter of days or of a few serial passages.

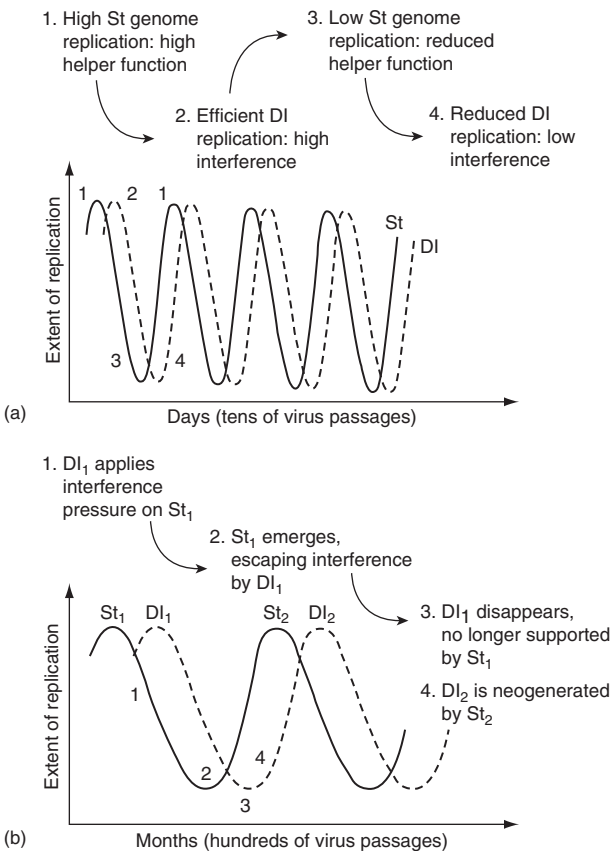

Figure 2 Cyclic variation of DI replication in (a) days, and (b) months.

Assay for DI Particles

DI particles can be detected by physical separation on velocity or density gradients when applicable (see the section titled 'Structure'). The presence of subgenomic nucleic acids in viral stocks or in infected cells (distinct from viral messengers) can also be diagnostic. The ability to decrease the infectivity of a viral stock or to protect infected cells from the lytic infectious virus (see the section titled, 'Biological effects') are used in various biological assays to estimate quantitatively and qualitatively the DI particle composition of a viral stock. These assays, although appropriate to characterize DI particle preparations, are generally not sensitive enough to exclude, when negative, the presence of DI particles in a viral preparation. The test that still remains the most dependable to assess presence or absence of DI particles consists of multiple independent serial undiluted passages. It is based on the observation that a viral stock contaminated with an undetectable amount of DI particles will, on subsequent independent serial passages, promote in each series amplification of the same contaminating DI particles. A DI particle-free stock, on the other hand, will yield in each series different DI particles or different sets of DI particles.

Biological Effects

DI particles have been shown to modulate the course of an infection. In cell culture, attenuation of the cytopathic effects is the most frequently described, and DI particles can promote cell survival and establishment of persistent infections. As far as negative-stranded RNA viruses are concerned, copy-back DI RNAs appear to prevent induction of apoptosis through a mechanism which has still to be unravelled, in which a certain category of small leader RNAs may participate. A possible role of the matrix M protein, the concentration of which is decreased to the point where viral assembly and budding at the cell surface is highly diminished in the presence of DI genomes, has also been considered. DI ability selectively allows emergence of St virus (St_2) which escapes interference (**Figure 2**(**b**)). St_2, resistant to interference, is selectively amplified over St_1, still sensitive to interference, and soon becomes predominant. It loses its ability to support DI_1, which therefore disappears. St_2 will generate its own DI_2, which in turn will favor emergence of a new St variant. Thus, DI viruses serve as mutational drivers favoring virus evolution, through cycles of high and low interference whose periodicity is this time measured in months or in hundreds of viral passages (compare **Figures 2**(**a**) and **2**(**b**)).

DI Particles in Experimental Animals

DI particles are generated and amplified in the whole animal, as well as in cell culture. They can change the symptoms of viral infection from rapid death to slow, progressing paralysis. They can sometimes fully protect the animals from an otherwise lethal infection. Interference is likely to be involved in this modulation of symptoms, but other phenomena like increased interferon induction and immune response modulation are reported.

DI Particles in Natural Infections

Involvement of DI particles in natural infections is still poorly documented. This is partly because the experimental results supporting the strong potential for infection modulation of DI particles have not been fully recognized, as detection of DI particles in natural infections is not straightforward. Unpredictable cyclic variations in DI replication, efficiency of DI replication

changing with the types of infected tissues, and potent interfering ability associated with poor DI particle replication are all factors which undoubtedly make DI particle detection difficult *in vivo*. Last but not least, virus isolation, which is used to characterize the infectious agent associated with a disease, often represents conditions (low multiplicity of infection) known to impair DI particle replication drastically.

Nevertheless, association of a chicken influenza virus strain, efficiently producing DI particles, with an epidemic of low morbidity and low mortality, and conversely, a high-mortality epidemic associated with a strain free of DI particles, have been reported. Murine and feline leukemia virus strains causing immune deficiency syndromes are shown to contain predominantly replication-defective viral genomes before onset and during the development of the disease. The pathogenicity of some bovine and swine pestiviruses has clearly been associated with presence of DI RNAs in the animals. For the bovine viral diarrhea virus (BVDV), a pestivirus of the same family as hepatitis C virus, the presence of a particular DI RNA can turn noncytopathic virus into a fatal infectious agent. In plants, at least three examples of DI RNAs are described to be involved in infection modulation. Interestingly, depending on the types of viruses, DI RNAs can either attenuate or exacerbate the symptoms.

DI RNAs are identified in stool and blood samples of humans suffering from hepatitis A virus, an infection known to be rather moderate and prolonged. DI particles are identified in measles virus-attenuated vaccine preparations which have been, and are being, widely and successfully used (raising the question of DI particle participation in vaccine attenuation). Measles viruses defective in viral assembly are currently found associated with human subacute sclerosing panencephalitis (SSPE). The brain cells of SSPE patients were, moreover, shown to harbor many species of measles virus copy-back DI RNAs. Direct amplification of a portion of the HIV *tat* gene from infected patients demonstrates that about a third of the sequences correspond to defective *tat* function. Moreover, human immunodeficiency virus (HIV)-1 sequences isolated from a cohort of six blood or blood product recipients infected with one donor all contained a similar deletion in the *nef* gene. Remarkably, all the patients harboring this deleted viral genome remained free of HIV-related diseases 12–16 years after infection, suggesting that this defective species of HIV genome is responsible for this decreased pathology. Epstein–Barr virus (EBV) replicative infections developing in human epithelial lesions involve a deleted rearranged form of EBV DNA (het DNA). This het DNA is associated, in experimental infections, with disruption of latency and persistent productive infections. Specific identification of viral hepatitis B (HBV) genomes containing an interrupted precore antigen (HBeAg) coding sequence in patients dying from fulminant hepatitis suggests that such defective genomes may be responsible for the exacerbation of the disease. This contrasts with more recent data reporting experimental evidence for the existence of DI-like viruses in HBV human chronic carriers; fluctuations between these naturally occurring core internal deletion variants and helper HBV in three chronic carriers were reminiscent of the cycling phenomenon in other DI viral systems.

Future Perspectives

Defective interfering particles are ubiquitous in the realm of animal and plant viruses. In experimental conditions they appear as necessary companions of their nondefective homologs. Capable of affecting the extent of viral growth, the course of viral infections, and serving as selective pressure to drive mutational changes, they can be seen as natural regulators of virus evolution. The demonstration of their participation in natural infections, and of their ability to affect the course of diseases, constitutes a challenge for the years to come. As pointed out by the few examples listed earlier, their direct detection in infected tissues will certainly be needed to assert their involvement in natural infections. The availability of sensitive detection techniques (like polymerase chain reactions), allowing direct observation of viral genomes without the possible distortion of virus isolation, bears great hope. More than giving increased insights into the physiopathology of viral infections, in times where the modifications of the viral genomes represent an imperative step in the generation of viral recombinant vaccines or of appropriate vectors for gene targeting, DI viral genomes represent natural versions of defective genomes that can serve as model tools for creation of more adapted vectors.

Dengue Viruses

D J Gubler, John A. Burns School of Medicine, Honolulu, HI, USA

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Arbovirus A virus transmitted to vertebrates by hematophagous (blood-feeding) arthropods.
Endemic A disease constantly present in a human population.
Extrinsic incubation The time between infection and becoming infectious.
Hyperendemicity The co-circulation of multiple dengue virus serotypes in the same population.
Vertical transmission Transmission of a virus from a female arthropod to her progeny.

History

Dengue fever is a very old disease; the earliest record of a dengue-like illness found to date is in a Chinese encyclopedia of disease symptoms and remedies, first published during the Chin Dynasty (AD 265–420) and formally edited in AD 610 (Tang Dynasty) and again in AD 992 during the Northern Sung Dynasty. There are reports of epidemics of dengue-like illnesses in the French West Indies in 1635 and in Panama in 1699. By the late 1700s, the disease had a worldwide distribution in the tropics, with epidemics of a clinically compatible disease occurring in 1779 in Batavia (Jakarta), Indonesia and Cairo, Egypt, and in 1780 in Philadelphia, Pennsylvania, USA. From the late 1700s to World War II, repeated epidemics of dengue-like illness occurred in most tropical and subtropical regions of the world at 10- to 30-year intervals. There is no documentation, however, that dengue viruses were responsible for all these epidemics because diagnosis was based only on clinical reports. Clinical descriptions of some early epidemics were compatible with chikungunya virus infection, which has a transmission cycle similar to that of the dengue viruses. It is likely that epidemic chikungunya did occur, but recent data show that the dengue viruses, not chikungunya virus, were responsible for the majority of epidemics in the past 50 years.

The virus etiology of dengue fever was not documented until 1943–44, when Japanese and American scientists simultaneously isolated the viruses from soldiers in the Pacific and Asian theaters during World War II. Albert Sabin isolated dengue viruses from soldiers who became ill in Calcutta (India), New Guinea, and Hawaii. The viruses from India, Hawaii, and one strain from New Guinea were antigenically similar, whereas three others from New Guinea were different. These viruses were called dengue 1 (DENV-1) and dengue 2 (DENV-2) and designated as prototype viruses (DENV-1, Hawaii, and DENV-2, New Guinea C). The Japanese virus, isolated by Susumu Hotta, was later shown to be DENV-1. Two more serotypes, called dengue 3 (DENV-3) and dengue 4 (DENV-4), were subsequently isolated by William McD. Hammon and his colleagues from children with hemorrhagic disease during an epidemic in Manila, Philippines, in 1956. Although thousands of dengue viruses have been isolated from different parts of the world since that time, all fit antigenically into the four serotype classification.

Many early workers suspected that dengue viruses were transmitted by mosquitoes, but actual transmission was first documented by H. Graham in 1903. In 1906, T. L. Bancroft demonstrated transmission by *Aedes aegypti*, later known to be the principal urban mosquito vector of dengue viruses. Subsequent studies in the Philippines, Indonesia, Japan, and the Pacific showed that *Aedes albopictus* and *Aedes polynesiensis* also were efficient secondary vectors for dengue viruses.

During and following World War II, *Ae. aegypti* greatly expanded its distribution in Asia, becoming the dominant day-biting mosquito in most Asian cities. Multiple dengue virus serotypes were also disseminated widely at that time. A dramatic increase in urbanization in the postwar years created ideal conditions for increased transmission of urban mosquito-borne diseases. These changes, plus an increased movement of people within and among countries of the region via airplane, resulted in increased movement of dengue viruses between population centers, increased frequency of epidemic activity, the development of hyperendemicity (co-circulation of multiple serotypes), and the emergence of epidemic dengue hemorrhagic fever/dengue shock syndrome (DHF/DSS) in many countries of Southeast Asia during the 1960s. By 1975, DHF/DSS was a leading cause of hospitalization and death among children in the region. During the 1980s and 1990s, epidemic DHF/DSS continued to expand geographically in Asia. In the 1970s DHF/DSS moved into the Pacific Islands after an absence of 25 years. In the Americas, where *Ae. aegypti* had been eradicated from many countries as a result of efforts to control yellow fever, increased epidemic dengue fever closely followed the reinfestation of countries by this mosquito in the 1970s, 1980s, and 1990s.

With the development of hyperendemicity, DHF/DSS has emerged as a global public health problem in the past 25 years. In 2007, dengue fever is the most important

arbovirus disease of humans, with more than 2.5 billion people living in areas at risk for dengue in a belt around the tropics of the world (**Figure 1**). An estimated 100 million dengue infections and 500 thousand cases of DHF/DSS occur each year. The average case–fatality rate for DHF/DSS is 5%.

Taxonomy and Classification

Dengue viruses belong to the family *Flaviviridae,* genus *Flavivirus*. There are four serotypes: DENV-1, DENV-2, DENV-3, and DENV-4. They belong to a larger, heterogeneous group of viruses called arboviruses. This is an ecological classification, one which implies that transmission between vertebrate hosts, including humans, is dependent on hematophagous arthropod vectors.

As are other flaviviruses, dengue viruses are comprised of a single-stranded RNA genome surrounded by an icosahedral nucleocapsid. The latter is covered by a lipid envelope, which is derived from the host cell membrane from which the virus buds. The complete virion is about 50 nm in diameter. The mature virion contains three structural proteins as follows: the nucleocapsid core protein (C), a membrane associated protein (M), and the envelope protein (E). Functional domains responsible for virus neutralization, hemagglutination, fusion, and interaction with virus receptors are associated with the E protein. Epitope mapping has demonstrated three to four major antigenic sites.

Antigenically, the four dengue viruses make up a unique complex within the genus *Flavivirus*. Although the four dengue serotypes are antigenically distinct, there is evidence that serologic subcomplexes may exist within the group. For example, a close genetic relationship has been demonstrated between DENV-1 and DENV-3 and between DENV-2 and DENV-4. The sizes of the genomic open reading frames of DENV-1, DENV-2, DENV-3, and DENV-4 are 3392 to 3396, 3391, 3390, and 3387 amino acids, respectively, the shortest among the mosquito-borne flaviviruses. An amino acid sequence positional homology of 63–68% is observed among the DENV serotypes compared to 44–51% between DENVs and other flaviviruses such as yellow fever and West Nile.

There are 53 flaviviruses recognized by the International Committee on Taxonomy of Viruses (this classification considers dengue 1 virus with four serotypes instead of four distinct viruses), including the genus prototype, yellow fever virus, and Japanese encephalitis, Murray Valley encephalitis, St. Louis encephalitis, West Nile, Zika and other viruses, all of which are transmitted by mosquitoes. Another group of flaviviruses are tick-borne and include tick-borne encephalitis, Omsk hemorrhagic fever, and Kyasanur Forest disease viruses. A small number of flaviviruses have no known arthropod vector, and three have been isolated only from insects.

Geographic and Seasonal Distribution

Dengue viruses have a worldwide distribution in the tropics (**Figure 1**). The viruses are endemic in most urban centers of the tropics, with transmission occurring year-round, and epidemics occurring every 3–6 years. It is well documented, however, that dengue viruses are maintained during interepidemic periods in most tropical areas and, although the risk of infection is lower than during epidemic periods, it is still substantial to unsuspecting visitors.

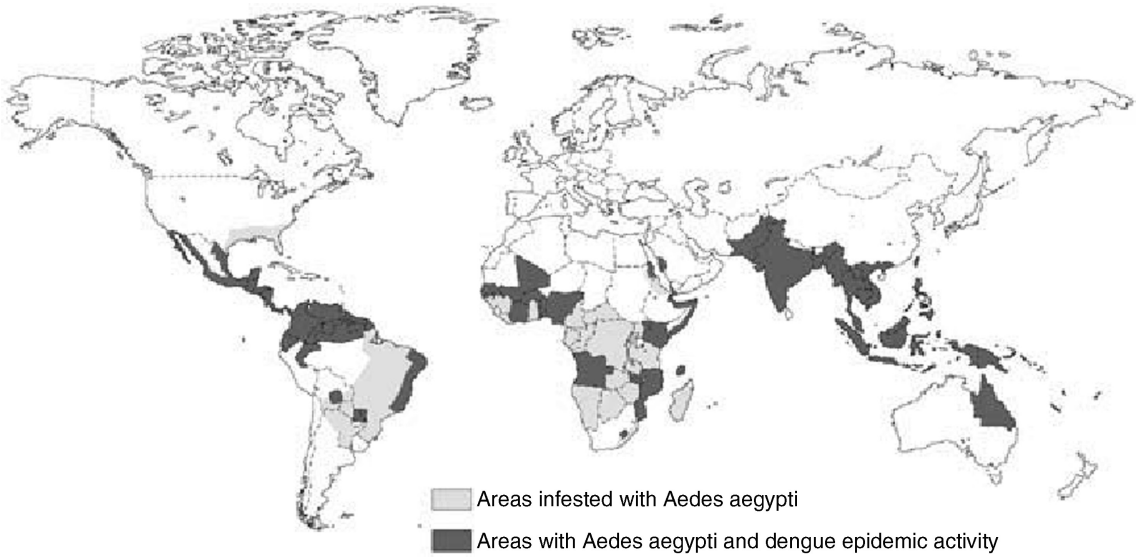

Figure 1 Global distribution of dengue fever and its principal epidemic mosquito vector, *Aedes aegypti, 2007*.

Peak transmission of dengue viruses usually is associated with periods of higher rainfall in most endemic countries. Factors influencing seasonal transmission patterns of dengue viruses are not well understood, but obviously include mosquito density, which may increase during the rainy season, especially in those areas where water level in larval habitats is dependent on rainfall. In areas where water in storage containers is not influenced by rainfall, however, other factors such as higher humidity and moderate ambient temperatures associated with the rainy season increase survival of infected mosquitoes, thus increasing the chances of secondary transmission to other persons. Virus strain and serotype, and herd immunity also influence transmission dynamics.

Host Range and Virus Propagation

There are only three known natural hosts for dengue viruses: *Aedes* mosquitoes, humans, and lower primates. Viremia in humans may last 2–12 days (average, 4–5 days) with titers ranging from undetectable to more than 10^8 mosquito infectious doses 50 (MID_{50}) ml^{-1}. Experimental evidence shows that several species of lower primates (chimpanzees, gibbons, and macaques) become infected and develop viremia titers high enough to infect mosquitoes, but do not develop illness. Viremia levels in lower primates are more transient, often lasting only 1–2 days if detectable, with titers seldom reaching 10^6 MID_{50} ml^{-1}.

Dengue viruses are known to cause clinical illness and disease only in humans. Baby mice, which are used for the isolation and assay of many other arboviruses, may show no signs of illness after intracerebral inoculation with most unpassaged strains of dengue viruses. Experimentally, however, some strains can be adapted to produce illness and death in baby mice. SCID, $Rag^{2-1-8c-1}$ and AG129 mice have been used for pathogenesis studies.

Mosquitoes only of species of the genus *Aedes* appear to be natural hosts for dengue viruses. Species of the subgenus *Stegomyia* are the most important vectors in terms of human transmission, and include *Ae. (S.) aegypti*, the principal urban vector worldwide, *Ae. (S.) albopictus* (Asia, the Pacific, Americas, Africa, and Europe), *Ae. (S.) scutellaris* spp. (Pacific), and *Ae. (S.) africanus,* and *Ae. (S.) luteocephalus* (Africa). It is uncertain what role *Ae. Albopictus* plays in transmission in areas where it has been recently introduced. Species of the subgenera *Finlaya* (Asia) and *Diceromyia* (Africa) appear to be important mosquito hosts involved in forest maintenance cycles of these viruses. Two other species, *Ochlerotatus* (=*Aedes*) *(Gymnometopa) mediovittatus* (Caribbean) and *Oc.* (=*Aedes*) *(Protomacleaya) triseriatus* (North America), have been shown to be excellent experimental hosts of dengue viruses.

Low passage or unpassaged dengue viruses can be propagated with consistent results only in laboratory-reared mosquitoes and in mosquito cell lines. Mosquito species most commonly used for *in vivo* propagation include *Ae. aegypti, Ae. Albopictus,* and *Toxorhynchites* spp., all of which can be reared with ease in the laboratory. Only three mosquito cell lines show high susceptibility to dengue viruses: C6/36 from *Ae.albopictus,* AP-61 from *Ae. Pseudoscutellaris,* and TRA-284 from *Tx. amboinensis*.

Dengue viruses can also be propagated in baby mice (see above) and in several vertebrate cell lines. These all have lower susceptibility to infection than do mosquito cells however, and dengue viruses must be adapted to each system by serial passage before consistent results can be obtained. Mammalian cell lines commonly used include LLC-MK2 and VERO (monkey kidney), BHK-21 (baby hamster kidney), FRhL (fetal rhesus lung), and PDK (primary dog kidney).

Genetics

Laboratory and epidemiologic studies have documented that genetic variants of dengue viruses occur in nature. DENV-3 isolated during epidemics in Puerto Rico in 1963 and 1977, and in Tahiti in 1965 and 1969, are antigenically and biologically very similar to each other, but very different from Asian strains of the same serotype. Similar antigenic differences were observed between Caribbean and Asian strains of DENV-4.

Oligonucleotide fingerprinting, restriction enzymes, primer extension sequencing, and nucleotide sequence comparison all have been used to study genetic variation among dengue viruses. In general, viruses circulating in the same geographic region during the same general time frame show genetic homogeneity, while differing from viruses of the same serotype from other regions. Because there is no good animal model for dengue however, it is not well understood how genetic variation influences phenotypic expression, in terms of clinical presentation or epidemic potential.

With increased transmission worldwide, dengue viruses have increased in diversity in recent years, most likely influencing both virulence and epidemic potential. This is supported by epidemiologic and virologic studies conducted in areas with sequential, but contrasting disease severity and transmission dynamics, such as Sri Lanka prior to and after the first DHF epidemic there in 1989. Other evidence includes the striking difference in replication characteristics between the South Pacific/American and the Southeast Asian subtypes of DENV-3 and DENV-2.

The number of genetic subtypes identified in each serotype varies with the method used, but more viruses have now been studied by partial nucleotide sequencing. Based on sequencing a 600 bp region of the envelope protein, which correlates well with sequencing the entire

envelope protein, there are two distinct genotypes of DENV-1, four of DENV-2, four of DENV-3, and three of DENV-4. Of considerable epidemiologic interest is that there are currently two genotypes of DENV-2 circulating in the American region. One, designated American, has been in the Americas since at least 1952, whereas the second, designated Southeast Asia, was isolated for the first time from dengue patients in Jamaica in 1982 shortly after the 1981 Cuban epidemic of DHF/DSS. Analysis by restriction enzymes and primer extension sequencing has shown that the Jamaican virus is nearly identical to strains of DENV-2 isolated in Vietnam in 1987, suggesting that the DENV-2 virus causing the Cuban epidemic was introduced from Vietnam. This conclusion is supported by the fact that many Cubans were working in Vietnam on various aid projects during the late 1970s and early 1980s. The Southeast Asia genotype has subsequently become the predominant and most wide-spread strain of DENV-2 virus in the American region.

Although there have been increasingly frequent reports of intraserotypic recombination events among the dengue viruses, the data suggest that this has not been important in their evolution. However, with increased occurrence of the cocirculation of multiple serotypes in an area (hyperendemicity), there have been increased reports of concurrent infections with two serotypes. This will increase the probability that interserotypic recombination might occur.

Evolution

The two principal theories of flavivirus evolution are: (1) that the tick-borne and mosquito-borne flaviviruses evolved from viruses with no known vector and (2) that the tick-borne and no known vector viruses evolved from a common ancestor and the mosquito-borne viruses arose separately. The origin of dengue viruses is unknown. Their natural history, however, suggests a long association with mosquitoes, possibly prior to becoming adapted to lower primates and humans. Biologically, dengue viruses are highly adapted to their mosquito hosts, being maintained by vertical transmission (from female mosquito to her offspring) in those species responsible for the forest maintenance cycle, with periodic amplification in lower primates (**Figure 2**). Such forest cycles have been documented in Southeast Asia and Africa. At some point in the past, probably with the clearing of the forests and development of human settlements in Asia, these viruses moved out of the jungle and into a rural environment where they were, and still are, transmitted to humans by peri-domestic mosquitoes such as *Ae. albopictus*. Migration of people ultimately moved the viruses into the cities of the tropics where they became 'urbanized' and transmitted by the highly domesticated, urban *Ae. aegypti* mosquito, which had been spread around the world via sailing ships and increased commerce.

Because of the rather slow rate of change (genetic drift) of the dengue virus genome, viruses isolated over long periods of time in the same geographic region still show striking homogenicity. The greatest genetic difference between dengue virus strains was observed between DENV-2 and DENV-3 isolated from forest mosquitoes in Africa and Asia, respectively, and viruses of the same serotype isolated from humans or mosquitoes in nearby urban areas. This would suggest that there is little gene flow between the forest and urban cycles. On the other hand, both laboratory and field evidence suggest that significant genetic changes that influence epidemic potential do occur in nature (see above).

Serologic Relationships and Variability

Dengue viruses share common morphology, genomic structure, and antigenic determinants with 52 other flaviviruses.

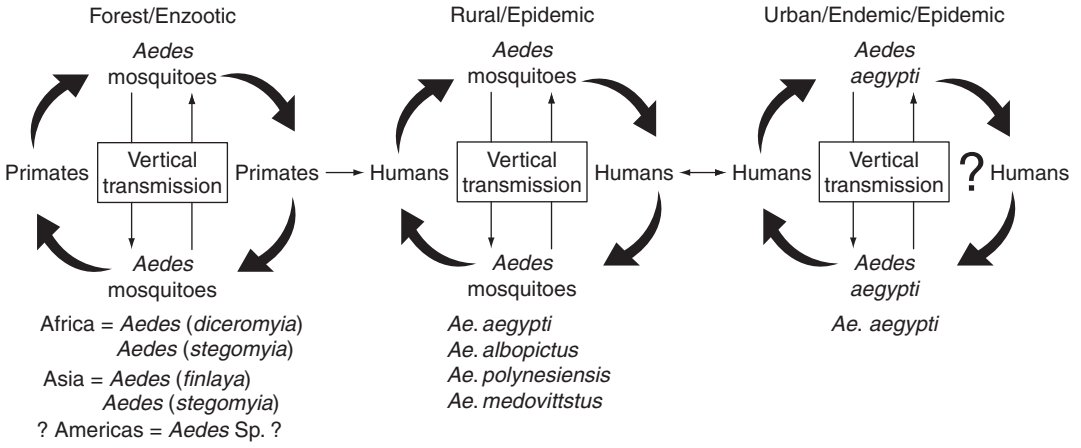

Figure 2 Natural transmission and maintenance cycles of dengue viruses.

Serologic tests most frequently used to determine antigenic relationships have included the hemagglutination-inhibition (HI), complement fixation (CF), and the plaque reduction neutralization (PRNT) tests. Because all flaviviruses share common antigenic determinants, identification of individual family members using these tests is difficult. The dengue viruses make up one antigenic complex within the family *Flaviviridae*. They share complex-specific antigenic determinants on both structural and nonstructural proteins. Serotypes within the dengue virus complex are most accurately and easily identified with an indirect immunofluorescent antibody (IFA) assay using serotype-specific monoclonal antibodies which react with epitopes on the structural protein. They can also be readily identified using polymerase chain reaction (PCR).

Both antigenic and biologic variation among dengue viruses have been documented. As noted above, DENV-3 viruses isolated in the Caribbean and the South Pacific in the 1960s were found to be antigenically distinct from the prototype and Asian strains of DENV-3 using PRNT. They were also biologically unique in that they did not grow as well in baby mice and mosquitoes as did Asian strains. DENV-4 viruses isolated in the Caribbean after the introduction of this serotype into that region in 1981 were antigenically distinct from DENV-4 viruses from Asia.

Field and epidemiologic evidence for natural strain variation among dengue viruses is more circumstantial. When DENV-2 was introduced into the South and Central Pacific islands in 1971 after an absence of more than 25 years, epidemics occurred on numerous islands. Marked variation was observed in disease severity, viremia levels, and epidemic potential in epidemics on the various islands. This variation was observed with both DENV-1 and DENV-2 in the Pacific and with DENV-3 in Indonesia. Some DENV strains appeared naturally attenuated, causing mild illness with low viremia levels of short duration, whereas others caused explosive epidemics with severe hemorrhagic disease and high viremia levels. Factors that could influence epidemic transmission and disease severity, other than differences in the virus strain, were ruled out as a cause of this variation. Recent studies in the American region have shown that variation among strains of DENV-2 and DENV-4 has influenced epidemic transmission.

Epidemiology

Dengue viruses occur in nature in three basic maintenance cycles (**Figure 2**). The primitive forest cycle involves canopy-dwelling mosquitoes and lower primates. A rural cycle, primarily in Asia and the Pacific, involves peridomestic mosquitoes (*Ae. albopictus* and *Ae. scutellaris* Spp.) and humans. The urban cycle, which is the most important epidemiologically and in regard to public health and economic impact, involves the highly domesticated *Ae. aegypti* mosquito and humans. The viruses are maintained in most large urban centers of the tropics, with epidemics occurring at periodic intervals of 3–6 years.

A combination of increased urbanization in the tropics, changing life styles, and lack of effective mosquito control has made most tropical cities highly permissive for transmission of dengue viruses by *Ae. aegypti*. Increased air travel by humans provides the ideal mechanism to transport dengue viruses between population centers. As a result, in the past 25 years there has been a dramatic global increase in the movement of dengue viruses within and between regions, resulting in increased epidemic activity, development of hyperendemicity, and the geographic spread and increased incidence of the severe and fatal form of disease, DHF/DSS. Once observed only in Southeast Asia, epidemic DHF/DSS has spread to west Asia, the Peoples Republic of China, the Pacific islands, and the Americas in the past 25 years.

Factors responsible for the emergence and spread of the severe form of disease, DHF/DSS, are not fully understood. The changing disease pattern described above provides support for both principal hypotheses regarding the pathogenesis of DHF/DSS, secondary infection, and virus virulence. Thus, increased movement of viruses between population centers results in increased transmission and the development of hyperendemicity, which then increases the probability of a secondary infection, of a virulent virus emerging via genetic change or being imported from another area.

Increased transmission of multiple dengue serotypes raises the iceberg further out of the water, and increases the probability that severe disease will occur, regardless of whether the underlying cause is due to increased virulence, immune enhancement, or, more likely, a combination of both (**Figure 3**).

Dengue is primarily an urban disease. Most major epidemics of DHF/DSS occur in tropical urban centers where

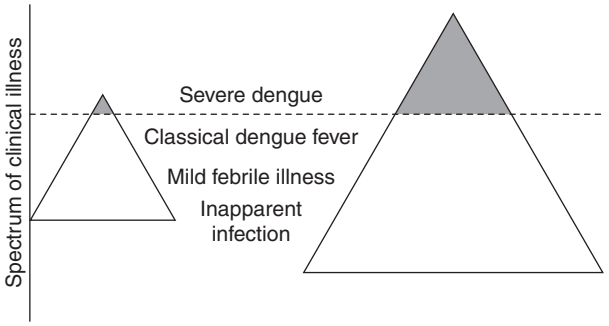

Figure 3 The iceberg concept of dengue/dengue hemorrhagic fever. The severe form of disease represents only the tip that protrudes from the water. As the incidence of infection increases, so too does the severe and fatal form of disease.

large and crowded human populations live in intimate contact with the principal mosquito vector, *Ae. aegypti*. This mosquito is a highly domesticated, day-biting species that lives and breeds in and around the home. High mosquito densities often occur in tropical cities because of water-storage practices and the accumulation of domestic trash. Primary larval habitats for *Ae. aegypti* include a variety of domestic water-storage containers such as clay jars and pots, metal drums, cement cisterns, and many other artificial containers found in the domestic environment that collect and hold rain water. The latter include, but are not limited to flower vases and pots, used automobile tires, buckets, bottles, cans, old machinery, etc.

Transmission and Tissue Tropism

Most dengue virus transmission is by the bite of an infective mosquito vector. Any of the four serotypes may cause high levels of viremia in humans ($\geq 10^8$ MID_{50} ml^{-1}) that lasts an average of 4–5 days (range, 2–12 days). If a competent mosquito vector takes a blood meal from a person during this viremic phase, virus is ingested with the blood meal and infects the cells of the mosquito mesenteron. After 8–12 days, depending on ambient temperature, the virus, and the mosquito, the virus will disseminate and infect other tissues, including the mosquito salivary glands. When the mosquito takes a subsequent blood meal, virus is injected into the person along with the salivary fluids. Dengue virus infection has no apparent effect on the mosquito, which is infected for life.

Ae. aegypti is a highly competent epidemic vector of dengue viruses. It lives in close association with humans because of its preference to lay eggs in artificial water-holding containers in the domestic environment, and to rest inside houses and feed on humans rather than other vertebrates. It has a nearly undetectable bite and is very restless in the sense that the slightest movement will make it interrupt feeding and fly away. It is not uncommon, therefore, to have a single mosquito bite several persons in the same room or general vicinity over a short period of time. If the mosquito is infective, all of the persons bitten may become infected.

In addition to transmitting the virus to humans or lower primates, the female mosquito may also transmit the virus vertically to her offspring through her eggs. Although the implications of vertical transmission are not fully understood, it is thought to be an important mechanism in the natural maintenance cycles of dengue viruses, especially in rural and forest settings.

The primary site of replication of dengue viruses after injection into humans by the feeding mosquito is believed to be dendritic cells. Other tissues from which these viruses have been isolated include phagocytic monocytes, liver, lungs, kidneys, lymph nodes, stomach, intestine, and brain, but it is not known to what extent the virus replicates in these tissues. Pathological changes similar to those observed in yellow fever, with focal central necrosis, have been observed in the liver of some patients who died of dengue virus infection. There is some evidence that the viruses also replicate in endothelial cells and possibly in bone marrow cells. Encephalopathy has been documented in dengue infection but whether dengue viruses cross the blood–brain barrier and replicate in the central nervous system is still open to question. Dengue viruses have been transmitted by blood transfusion and organ transplantation.

Pathogenicity

There is still some controversy about the pathogenesis of DHF/DSS. Evidence suggests that at least two pathogenetic mechanisms are associated with severe dengue infection. Classical DHF/DSS is characterized by a vascular leak syndrome which, if not corrected, may rapidly lead to hypovolemia, shock, and death. The underlying pathogenetic mechanism for this syndrome is thought to be an immune enhancement phenomenon whereby the infecting virus complexes with non-neutralizing dengue antibody, thus enhancing infection of mononuclear phagocytes. The latter produce vasoactive mediators, which are responsible for increased vascular permeability. Loss of plasma from the vascular compartment may range from mild and transient to severe and prolonged, the latter often resulting in irreversible shock and death. Although classical DSS is most commonly associated with secondary dengue infections, it has also been documented in primary infections, which suggest that subneutralizing levels of homologous antibody or other immune factors may also cause immune enhancement.

In vitro studies have shown that not all dengue viruses can be enhanced and that there are qualitative differences in the enhancing ability of antibody to dengue viruses. This raises the question as to whether dengue virus strains vary in their ability to stimulate production of enhancing antibody, whether this is associated with virulence, and, if so, how this relates to the immune enhancement hypothesis. Because an animal model is not available, no good data exist that demonstrate variation in virulence among dengue viruses. However, an accumulating body of both experimental and field data suggest the dengue viruses, like most other animal viruses, vary in their virulence and in their epidemic potential. When DENV-1 and DENV-2 viruses were introduced into the Pacific in the early 1970s after an absence of more than 25 years, some islands experienced explosive epidemics, with patients having high viremia levels and severe and fatal hemorrhagic disease, whereas other islands with similar ecology experienced only sporadic

or silent transmission, with low or undetectable viremias and mild illnesses. Virus strain variation was the only logical explanation for these differences. Recent laboratory evidence suggests that a major Cuban epidemic of DHF/DSS in 1981, the first of its kind in the American Region, was caused by a DENV-2 introduced from Vietnam, which was genetically distinct from the original American DENV-2. Data from this epidemic support both the immune enhancement and virus virulence hypotheses, which are not mutually exclusive. The most consistent feature associated with the emergence of DHF/DSS in an area is the development of hyperendemicity. This increases the probability of secondary infection, which is thought to be associated with DHF/DSS. However, hyperendemicity is also associated with increased transmission and movement of viruses between population centers, which increases the probability of genetic change and introduction of virus strains that have greater epidemic potential or virulence (**Figure 4**).

Patients infected with dengue viruses may also experience severe and uncontrolled bleeding, usually from the upper gastrointestinal (GI) tract. This severe hemorrhagic disease may be associated with multiple organ failure, and is more difficult to manage than classical DHF/DSS. The underlying pathogenetic mechanism for this type of bleeding is clearly different from that of the vascular leak syndrome, and involves disseminated intravascular coagulation and thrombocytopenia.

A third type of severe and fatal dengue infection, which may or may not involve overt hemorrhagic disease, is encephalopathy. Although many patients with this syndrome present clinically as viral encephalitis, conclusive evidence that dengue viruses infect the central nervous system has not yet been documented. Available data suggest that neurologic symptoms may be secondary to cerebral hemorrhage, edema, or other indirect effects of dengue virus infection.

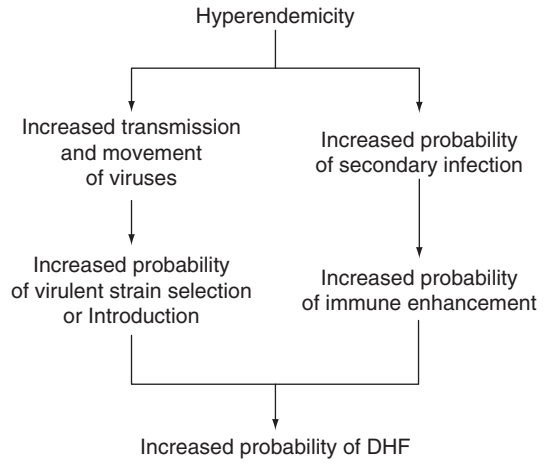

Figure 4 The cocirculation of multiple virus serotypes in a community (hyperendemicity) is the most important risk factor for the occurrence of dengue hemorrhagic fever and is compatible with the two principal hypotheses of pathogenesis, immune enhancement and virus strain variation.

Clinical Features of Infection

Dengue infection causes a spectrum of illness in humans ranging from clinically inapparent to severe and fatal hemorrhagic disease with the latter representing only the tip of the iceberg (**Figure 3**). The incubation period may be as short as 3 days and as long as 14 days, but most often is 4–7 days. The majority of patients present with mild, nonspecific febrile illness, or with classical dengue fever. The latter is generally observed in older children and adults, and is characterized by sudden onset of fever, frontal headache, retroocular pain, and myalgias. Rash, joint pains, nausea and vomiting, and lymphadenopathy are common. The acute illness, which lasts for 3–7 days, is usually benign and self-limiting, but it can be very debilitating, and convalescence may be prolonged for several weeks.

The hemorrhagic form of disease, DHF/DSS, is most commonly observed in children under the age of 15 years, but it also occurs in adults in areas of lower endemicity. It is characterized by acute onset of fever and a variety of nonspecific signs and symptoms that may last 2–7 days. During this stage of illness, DHF/DSS is difficult to distinguish from many other viral, bacterial, and protozoal infections. In children, upper respiratory symptoms caused by concurrent infection with other viruses or bacteria are not uncommon. The differential diagnosis should include other hemorrhagic fevers, hepatitis, leptospirosis, typhoid, malaria, measles, influenza, etc.

The critical stage in DHF/DSS occurs when the fever subsides to or below normal. At that time, the patient's condition may deteriorate rapidly with signs of circulatory failure, neurologic manifestations, shock and death if proper management is not implemented. Skin hemorrhages such as petechiae, easy bruising, bleeding at the sites of venepuncture, and purpura/ecchymoses are the most common hemorrhagic manifestations; GI hemorrhage may occur, usually after, but in some cases before, onset of shock.

The World Health Organization (WHO) has defined strict criteria for diagnosis of DHF/DSS, with four major clinical manifestations: high fever, hemorrhagic manifestations, hemoconcentration, and circulatory failure. WHO has classified DHF/DSS into four grades according to severity of illness: grades I and II represent the milder form of DHF and grades III and IV represent the more severe form, DSS (**Table 1**). Thrombocytopenia and hemoconcentration are constant features. However, there is some disagreement with the WHO case definition in that some patients may present with severe and uncontrollable upper GI bleeding with shock and death in the absence of

Table 1 World Health Organization classification of dengue hemorrhagic fever

Grade I	Fever accompanied by nonspecific constitutional symptoms, with a positive tourniquet test and/or scattered petechiae as the only hemorrhagic manifestation
Grade II	The same as grade I, but with spontaneous hemorrhagic manifestations
Grade III	Circulatory failure manifested by rapid, weak pulse, narrowing of pulse pressure (20 mmHg or less), or hypotension
Grade IV	Profound shock with undetectable pulse and blood pressure

From Anonymous (1997) *Dengue Hemorrhagic Fever: Diagnosis, Treatment and Control*. Geneva: World Health Organization.

hemoconcentration or other evidence of the vascular leak syndrome. These patients by the WHO criteria cannot be categorized as having DHF/DSS. In addition, hepatomegaly may not be a constant feature in all epidemics of DHF/DSS. The WHO is currently reevaluating the case definitions for dengue fever, DHF and DSS.

Dengue virus infection is associated with a variety of neurologic and psychiatric disorders, including headache, dizziness, hysteria, and depression. In addition, some patients present with clinical symptoms of viral encephalitis, but as noted above, there is no conclusive evidence that CNS infection occurs.

Treatment for DHF/DSS is symptomatic, and the prognosis of the disease depends on early recognition, initiation of corrective fluid replacement, and management of shock. Definitive diagnosis can only be made in the laboratory by serologic and/or virologic methods.

Pathology and Histopathology

The pathology of dengue virus infection is not well understood because systematic postmortem studies have not been done on patients representing all types of clinical presentations. The major pathophysiologic abnormality in classical DHF/DSS is an increase in vascular permeability which leads to leakage of plasma. Patients may have serous effusions in the pleural and abdominal cavities and a variable amount of hemorrhaging in most major organs. Studies have not revealed destructive inflammatory vascular lesions, but some swelling and occasional necrosis have been observed in endothelial cells.

Limited studies on patients with a fatal outcome have demonstrated focal necrosis of the hepatic cells, Councilman bodies, and hyaline necrosis of Kupffer cells in the liver. Changes in the kidney are suggestive of an immune complex type of glomerulonephritis. There is depression of bone marrow elements, which improve when the patient becomes afebrile. Biopsy studies of the skin rash have demonstrated perivascular edema with infiltration of lymphocytes and monocytes.

Immune Response

Persons infected with dengue viruses produce IgM and IgG antibodies, both of which appear 5–7 days after onset of illness in primary infections. The highest titers of IgM antibody are produced in primary dengue infections, but IgM antibody is also produced in secondary and tertiary infections. IgM antibody is transient and generally disappears 30–90 days after onset of illness in primary infections and after shorter periods in secondary and tertiary infections. IgG antibody, by contrast, persists for at least 60 years and probably for the life of the patient. In persons experiencing their first dengue or flavivirus infection, peak IgG titers are reached 14–21 days after onset of illness and seldom exceed 640–1280, although there are exceptions. In secondary infections, on the other hand, there is an immediate anamnestic IgG immune response to dengue complex-and/or flavivirus-specific antigenic determinants. In these patients, IgG antibody titers may exceed 20 480. Both IgM and IgG antibodies neutralize dengue viruses, and infection provides life-long immunity to that specific dengue virus serotype.

Both IgM and IgG antibodies to dengue viruses cross-react with other flavivirus antigens, including those of yellow fever, Japanese encephalitis, West Nile, and St. Louis encephalitis viruses. Cross-reactivity with viruses in the dengue complex is more extensive than with other flaviviruses, and makes interpretations of serologic results difficult. In patients with second and third flavivirus infections, original antigenic sin reactions are not uncommon. In geographic areas where several flaviviruses are endemic, therefore, definitive laboratory diagnosis can only be made by virus isolation or nucleic acid detection, and in patients with primary infection, by PRNT. Normally, a combination of laboratory (serologic and virologic), clinical, and epidemiologic data is used to make a diagnosis of dengue and other flavivirus infections.

Because IgG antibody persists for many years, its presence in a single serum sample is not diagnostic unless it occurs at high titer ($\geq$1280 by HI and PRNT, $\geq$256 by CF or $\geq$163 840 by IgG ELISA), which is considered presumptive evidence of a recent infection. Lower IgG titers simply indicate that the person has had a previous infection at some time in the past. Paired serum samples are required to confirm a current infection by demonstrating a fourfold or greater rise in IgG antibody. The presence of detectable IgM antibody in a singe serum sample is considered to be diagnostic for a recent infection because this isotype does not persist for long periods. The diagnosis is considered presumptive, and not confirmatory for a current infection, however, because IgM antibody may persist for 90 or more days.

Extensive work done in recent years has demonstrated that immunopathogenetic mechanisms play a major role in the pathophysiology of severe dengue infection. Generally, CD4+ and CD8+ T-cell responses are directed against multiple viral proteins. After primary infection, memory T cells proliferate in response to multiple dengue serotypes with both specific and cross-reactivities. After secondary infection, the T cell proliferation is of low-affinity and may be more cross-reactive to the first infecting virus serotype than the second, a phenomenon analogous to original antigenic sin seen in the antibody response.

Dengue virus infection results in the production of a number of chemokines, including IL-8, RANTES, MIP-1α, and MIP-β, which attract T cells and other inflammatory cells. Some, such as IL-8, are associated with plural effusions and may be important in inducing increased vascular permeability in patients with dengue infection.

There is accumulating evidence that cell-mediated immunity also plays a role in terminating dengue infections. Recent work suggests that dendritic cells (DCs) are likely the initial site of virus replication. Dengue virus infection stimulates DC maturation and activation, and production of TNF-α and INF-α. The DCs migrate to T-cell-rich lyphoid organs where T cells are activated, stimulating memory responses and releasing cytokines and chemokines. Circulating virus in the blood activates more T and B cells. During a second dengue infection, T-cell responses are likely to be dominated by a subset of specific memory T cells, which produce IFN-δ and CD40L, resulting in greater DC activation, T cell stimulatory capacity, IL-12 release, increased secretion of TNF-α and IFNδ, as well as potential dysregulation of cytokine responses. As viremia is cleared, the cascade of events initiated by an early type 1 cytokine response may contribute to the pathogenesis of DHF. The cross-reactive T cells that have low affinity to the second infecting virus serotype (see above) may be ineffective in clearing viremia, thus permitting a higher virus load and more severe disease.

Prevention and Control of Dengue

The options available for prevention and control of DF/DHF are limited. Although currently not available, considerable progress has been made in recent years in development of a vaccine (for DF/DHF). Effective vaccination to prevent DF/DHF will likely require a tetravalent, live attenuated vaccine. Promising candidate attenuated vaccine viruses have been developed and have been evaluated in phase I and II trials.

Progress has also been made on developing second-generation, recombinant dengue vaccines by using cDNA infectious clone technology. At least three candidate chimeric vaccines have been constructed by inserting the PrM and E genes into the backbone of yellow fever 17D vaccine virus, into an attenuated DENV-2 (PDK-53) backbone and into an attenuated DENV-4 backbone. The yellow fever 17D chimeric vaccine is further along and appears promising after phase I safety trials. The other two, plus a subunit candidate vaccine, are still in the preclinical phase.

The development of other new technology vaccines is in its infancy. Despite the promising progress, it will likely be 5–7 or more years before an effective, safe, economical dengue vaccine is commercially available. Also very promising has been the rapid progress in developing antiviral drugs that can be used in treatment of dengue infection, and perhaps, even in prevention and control programs.

Currently, the only way to prevent dengue infection is to control the mosquito vector that transmits the virus. Unfortunately, our ability to control *Ae. aegypti* is limited. For more than 25 years, the recommended method of control was the use of ultralow volume (ULV) application of insecticides to kill adult mosquitoes. Field trials in Puerto Rico, Jamaica, and Venezuela, however, showed that this method was not effective in significantly reducing natural mosquito populations for any length of time. This supports epidemiologic observations that ULV has little or no impact on epidemic transmission of dengue viruses.

The only truly effective method of controlling *Ae. aegypti* is larval control, that is to eliminate or control the larval habitats where the mosquitoes lay their eggs. Most important larval habitats are found in the domestic environment, where most transmission occurs. To have sustainability of prevention and control programs, some responsibility for mosquito control should be transferred from government to citizen homeowners. For long-term sustainability, mosquito control programs must be community-based and integrated. Persons living in *Ae. aegypti* infested communities have to be educated to accept responsibility for their own health destiny by helping government agencies control the vector mosquitoes, and thus prevent epidemic DF/DHF/DSS.

Countries with endemic dengue should develop active, laboratory-based surveillance systems that can provide some degree of epidemic prediction. Finally, prevention of excess mortality associated with DHF/DSS can be achieved by educating physicians in endemic areas on clinical diagnosis and management of DHF/DSS. As demonstrated in countries such as Thailand, early recognition and proper management are the key to keeping DHF/DSS case–fatality rates low.

Future

Continued population growth and urbanization of the tropics, changing lifestyles, increased air travel and lack of effective mosquito control have been the most important factors responsible for the dramatic increased incidence and geographic expansion of DHF/DSS in the past

25 years. DF/DHF/DSS has become a global public health problem in the tropics and it is anticipated that this trend will continue unless something is done to reverse it. More effective integrated prevention and control strategies must be developed and implemented worldwide in the tropics. Ultimately, development of an economical, safe, and effective vaccine holds the greatest promise for sustainable prevention and control.

Motivation for New Diagnostic Methods

Numerous human diseases exist for which viral etiologies are suspected, yet specific causal agents are not known. Among these are up to 20% of cases of acute hepatic failure, up to 35% of cases of acute aseptic meningitis and acute encephalitis, up to 50% of cases of acute respiratory infections, and numerous other conditions. In addition, infectious agents may be involved in the pathogenesis of a number of chronic conditions, most notably disorders such as chronic inflammation, autoimmune and degenerative conditions, as well as some forms of cancer. While it is unlikely that viruses cause all of these diseases, identifying causative agents in even a modest number of disorders will have profound implications for understanding, diagnosis, and treatment of these conditions.

New approaches to viral diagnostics and discovery are needed to overcome the shortcomings of existing methods. These methods include viral culture, electron microscopy, serology, specific polymer chain reaction (PCR)-based methods, and techniques based on subtractive hybridization. While these methods have been critical for identifying many important human and nonhuman pathogens, each of these methods has intrinsic limitations. For example, many viruses are refractory to culture. Inspection by electron microscopy may prove difficult depending on the titer and morphological features of the virus. Serology- and PCR-based techniques are highly specific methods, but their specificity frequently renders them ineffective for the detection of variant or novel viral species. In the case of PCR, there exist dozens if not hundreds of variations on the method which may extend the scope of the assay, usually through multiplexing or by the use of degenerate primers, yet the number of possible targets that can be interrogated remains small relative to the number of known viral pathogens. Finally, subtractive hybridization techniques, while unbiased, are difficult to troubleshoot and essentially impossible to scale up for high throughput.

DNA Microarrays

While there exist many different forms of DNA microarrays, produced by both researchers and corporations,

they fundamentally share the same properties. All microarrays exist as some form of solid substrate, typically glass or silicon, to which is bound different species of nucleic acid. Each microarray may contain 10^5–10^6 different species of DNA, arranged in a grid. Fluorescently labeled nucleic acid derived from any biological sample may be interrogated by hybridization to the microarray. In this manner, the abundance of thousands of different nucleic acid species may be simultaneously measured. The most common application of microarray technology is the measurement of relative gene expression, often for entire genomes. While gene expression profiling has enjoyed tremendous success over the last decade, it has long been realized that the microarray format would be amendable to the detection of exogenously derived nucleic acids for purpose of identifying the presence of pathogens in a background of host material. The general concepts and methodologies are similar to those required for expression profiling; however, there are key differences to consider for the design of the array and the mechanics of sample processing. Furthermore, most implementations of virus-detection microarrays strive only to determine the presence of viral sequences, rather than attempting to quantify the amount of virus in a particular sample. In practical terms, this allows more aggressive amplification strategies to be used during sample preparation.

Microarray Design for Viral Detection

Algorithms to guide the process of sequence selection for expression microarrays are well developed, and many of the design principles apply directly to microarrays for viral detection. The parameters shared in common include physical properties of the oligonucleotide itself, such as the propensity of the sequence to form hairpins, melting temperature, and sequence complexity. Beyond this, the design considerations for viral detection and expression profiling differ substantially. First, the majority of microarrays intended for viral detection are designed to specifically detect the products of a multiplex PCR reaction using specific primers. In this role, the array simply sorts the product of amplification. The design specifications for these types of arrays are straightforward and are primarily guided by the choice of flanking PCR primers for virus amplification. This configuration of array does not exploit the full potential of the microarray for panviral detection. However, the design parameters for a generalized virus detection chip that does not rely on specific multiplex PCR primers must take into account additional factors.

While it is essential that probes for expression arrays are unique with respect to target sequence (to prevent cross hybridization from other mRNA species), the same does not necessarily apply to viral probes. In fact, to maximize the probability of detecting any viral species from a known family, it is often desirable to choose sequences that are the most conserved among a group of viruses. For example, while there exists a large range of sequence diversity among human rhinoviruses, sequences in the 5′ UTR are highly conserved, even among more distant picornaviruses. These sequences may thus serve as a type of universal 'hook' to capture both existing and new variants of these RNA viruses. In case of novel pathogens, such as the SARS coronavirus, the use of conserved sequences was a key determinant for successful detection by microarray. Clearly, unique species-specific or even genotype-specific oligonucleotides can further augment the discrimination of the microarray. A logical extension of this strategy takes into account features of viral taxonomy. Rather than choosing all conserved, or all unique sequences, one may attempt to cover, by design, each level of the taxonomic tree for each family. Thus, some sequences would be chosen to be species specific (terminal nodes on the tree), some would be genus specific, and so on. Various bioinformatic tools, including online databases, are currently available to assist in such design efforts. In all cases, it is critical to prescreen each choice for matches within the human genome to prevent inappropriate cross-hybridization to host material.

A more simple approach is to simply tile overlapping oligonucleotides spanning the entire genome of the viruses in question. This approach is appropriate for relatively small panels of viruses since each species will result in large numbers of sequences, depending on genome length. In general, this approach becomes impractical when extended beyond a few viral species.

After satisfying the basic design requirements, more sophisticated considerations may also contribute to choice of viral sequence for representation on a microarray. For example, to enhance detection of latent herpesviruses, it may be advantageous to overrepresent sequences specific for genes specific for latent phase expression, rather than those involved in lytic processes. In this case, it is assumed that the RNA rather than DNA will be analyzed, which highlights the importance of sample processing and amplification considerations.

Sample Processing and Amplification

The protocol by which nucleic acids are isolated from specimens, and the subsequent amplification of the material, if needed, is also important to consider, as this may also affect both microarray and experimental design. In general, isolation of total RNA is the preferred and more conservative route. While this may seem biased toward RNA viruses, all DNA viruses produce mRNA as part of their lifecycle, so this choice does not exclude them. However, if viral particles are collected, or host material is removed from the specimen by filtration or other

size-selection techniques, it may be advisable to isolate total nucleic acid (both RNA and DNA) to maximize sensitivity. The origin of the sample also bears on this issue. When processing a relatively acellular material, such as cerebral spinal fluid, a total nucleic acid extraction would be appropriate, whereas in the case of a solid organ, such as liver or brain, an RNA extraction would avoid the unnecessary complexity brought by co-purifying massive quantities of the host genomic DNA.

After nucleic acid has been isolated, an amplification step is typically employed to generate sufficient quantities for successful microarray hybridization. In certain situations, where large amounts of primary material are available, the yield of nucleic may be such that an amplification step may be bypassed altogether, but these situations are the exception. The choice of an amplification strategy is closely linked to the design of the array itself. Several virus-detection microarrays have been designed to serve as detectors for the products of multiplex PCR amplification strategies, but in these cases, the broad spectrum and unbiased nature of the microarray is not realized.

For panviral microarrays, where no assumptions are made as to the probable identity of the target, a general, randomized amplification strategy is required. Numerous random amplification strategies exist, but all begin with a priming step using a randomized oligo of various lengths, ranging from 6 to 15 bp. At this point, PCR adapters may be added, either by ligation, or through priming via a common sequence linked to the random primer. Alternatively, various RNA polymerase promoter sequences may be appended which then allow linear amplification. For all these methods, contamination with previously isolated material is a critical concern and good laboratory practices and appropriate controls, such as nontemplated amplification reactions, must be an integral part of the protocol.

The overall complexity of the sample, with respect to the viral species, is a critical factor for the success of random amplification strategies. As previously noted, the ideal samples are those that contain relatively low amounts of host cellular material and high titers of virus. For many biological specimens, it may be possible to reduce the complexity by filtration, centrifugation, or by pretreatment of the raw material with various nucleases. In the latter case, free host material such as genomic DNA and ribosomal RNA may be degraded, yet viral-packaged nucleic acid will escape destruction. Such 'preprocessing' can significantly enhance the signal to noise of the final microarray assay, although these steps add both cost and complexity to the overall protocol. Potentially, the use of novel microfluidic techniques for particle size discrimination may serve as a rapid and reproducible way to deterministically reduce complexity in biological samples.

Bioinformatics

Analysis of hybridization results depends greatly on the design of the experiment and of the DNA microarray in particular. Microarrays that are narrowly targeted, for the purposes of distinguishing between strains of a particular virus species, for example, human influenza or smallpox, are subjected to different analysis techniques than are multigenus, multifamily, or even panviral arrays. The utility of DNA microarrays in all these fields is demonstrable when investigators use appropriate analysis techniques.

In strain and species typing applications there are usually ample controls available to researchers. By use of control hybridizations, characteristic species or strain hybridization patterns can be classified manually. Often these patterns are the result of iterative microarray design where features with the desired specificity are spatially clustered on the chip. These patterns can be used as templates for visual inspection of the experimental arrays where different classes of microarray features are enumerated and the input sample is thereby placed into one of the known groups or unclassified as ambiguous. Machine-learning techniques, such as probabilistic neural networks, are also sometimes used in these studies, but to date have not been show to be more accurate than simple enumerative methods.

Broader explorations of viral populations, for example, panviral studies, must face the problem that the number of control samples available is small when compared to the number of distinct viral genomes that may be encountered. Many viral targets are extremely mutable, introducing one or more mutations per virus genome for every cycle of replication. Such diversity quickly outstrips the resources of any effort to perform exhaustive control hybridizations.

In panviral studies standard methods such as hierarchical clustering and several particular bioinformatic approaches can be employed. First the microarray should be designed to include conserved regions of the target viruses to minimize the chance that a divergent but related virus will escape detection. Second, estimates of the hybridization patterns expected from the possible targets for which sequence data is available can be generated using biophysical models of hybridization. Experimental hybridization patterns can then be compared to the model profiles using a correlation metric. If a virus present in a hybridization shares homology with one of the sequences used to estimate the hybridization profiles, this similarity will be reported as a significant correlation between the profile and the experimentally observed pattern. In the last method, the intensity history of the microarray's features can be compared to an experimental hybridization. Extraordinarily strong signal at a particular feature can indicate *bona fide* virus, especially when signal

at taxonomically related features is similarly elevated. During the design stage of the experiment, it is important to consider that in multifamily, metagenomic studies it is critical to have negative controls to characterize the background of microarray designed with broad specificity, while in studies with narrower focus a significant number of positive controls are needed for each class of virus being considered.

Real-World Applications: Research and Clinical

To date, only a few studies have examined the use of viral-detection microarrays using actual prospectively collected patient samples, as opposed to viruses cultured in the lab or previously characterized retrospective samples. As of the time of this writing, no large-scale study has been published comparing the use of virus microarrays (using a random amplification) to traditional laboratory medicine diagnostics, such as commercial DFA kits and PCR assays. Preliminary data and studies using modest numbers of clinical samples suggest that a microarray-based viral diagnosis outperforms conventional DFA assays, both in terms of sensitivity and specificity. In comparison to a PCR assay using specific primer pairs, microarray assays are likely to have comparable specificity, yet the sensitivity is anticipated to be somewhat lower, depending on amplification strategy. However, microarray-based assay coupled to a random amplification protocol provides much broader detection capabilities, often including essentially every known viral pathogen. When considering the potential of DNA microarrays for clinical diagnostics, it may be the case that the microarray will serve a complementary role to specific PCR assays, especially when the latter fails to yield positive results.

For clinical cases where conventional diagnostic assays have failed, the use of a panviral microarray assay may allow identification of new, or unanticipated pathogens. In a recent case report, Chiu and colleagues reported the diagnosis of a previously healthy 28-year-old woman suffering from a severe respiratory tract infection of unknown etiology. Extensive panels of diagnostics for bacteria, fungi, and viruses failed to reveal any positive results, and all viral cultures remained negative. DNA microarray analysis of RNA isolated from endotracheal aspirate revealed the presence of human parainfluenza virus-4, a virus that is not normally included on standard DFA panels or PCR tests. Viral sequence was recovered directly from the patient sample confirming the identity of the virus, and it was further shown that the patient seroconverted during the time of the illness. While it is generally believed that human parainfluenza virus-4 causes only mild, self-limiting infections, this data taken together suggests that the spectrum of disease may extend to respiratory failure in an otherwise healthy adult. This example demonstrates an attractive feature of the microarray assay, namely, the power to detect the unexpected.

In addition to the detection of previously known pathogens, DNA microarrays have also been effective for the detection of novel viral species. In the case of SARS, total nucleic acid from a supernatant from an infected vero cell culture revealed a coronavirus signature consisting of oligonucleotides originating from avian infectious bronchitis, human and bovine coronaviruses, and, interestingly, several astroviruses. At first glance, the hybridization signal from astrovirus-derived oligonucleotides would seem to be aberrant. In fact, this is expected, since several astroviruses and coronaviruses share conserved sequences at the 3′ end of their genomes. These particular sequences were represented on the microarray since the panviral design algorithm purposely selected conserved sequences within and among viral families.

The same principles applied to a separate study in which a novel xenotropic gamma retrovirus was detected in prostate tumor biopsies of men with a mutant variant of the *RNASEL* gene. Integration sites and full-length genomes were subsequently cloned and the virus was demonstrated to be replication competent, thus validating the microarray result. Again, the broad-spectrum nature of the DNA microarray was critical to the success of the project, since there were no preconceptions that such a virus might be a candidate, given that no xenotropic gamma retrovirus had been previously observed in a human subject.

Limitations

Several important limitations of using microarrays for viral detection and discovery should not be overlooked. The most important limitation of the approach is its reliance on known viral sequences. Although most of the novel viruses discovered in the last decade share homology with previously known viruses, viruses lacking even short regions of homology cannot be detected by any hybridization-based method. In the case of profoundly divergent viruses, more brute-force approaches, such as shotgun sequencing, are likely to be applicable. Other existing and likely surmountable limitations of the microarray-based methods are their cost, the need for specialized equipment, and access to computational resources. It is likely that these limitations will become less pronounced as streamlined versions of the technology become available through academic and commercial efforts. It may also be the case that the utility of DNA microarrays may be surpassed by next-generation, massively parallel

shotgun sequencing technologies, which would permit cheap, fast, and unbiased analysis of clinical samples.

Scientific and Public Health Implications

Currently, a substantial fraction of human disease, with a presumed viral cause, goes without a clinical diagnosis. This is especially true for common ailments, such as upper respiratory tract infections, where despite advances in PCR assays, the etiology of 30–60% of infections remains unidentified. Without considering the complexities of diagnostic regulatory approvals, an unbiased DNA microarray approach to the detection of viral pathogens should substantially increase the number of successful diagnoses, and as a consequence, may lead to improved therapeutics and supportive care. It should be noted that use of a virus microarray extends beyond the analysis of clinical samples. The wide scope of detection and the power to discover new pathogens has broad application to agriculture, veterinary medicine, ecology, and environmental genomics. While it is impossible to accurately predict the number of undiscovered viral pathogens remaining on this planet, tools such as virus-detection DNA microarrays permit rapid inroads into this fascinating and important aspect of virology.

Glossary

Cylindrical inclusions (CI) CI are induced in infected cells by all viruses belonging to the family *Potyviridae*. The term pinwheel inclusion is also widely used, because it describes the typical appearance of the CI in cross sections. CI are composed of one virus-encoded 66–75 kDa nonstructural protein which aggregates to monolayer sheets forming a complicated structure in which several curved sheets are attached to a central tubule. Details of the CI architecture are specific for the virus species and can serve as an additional identification feature of the virus.

Immunosorbent techniques (e.g., enzyme-linked immunosorbent assay, immunosorbent electron microscopy) Techniques in which a viral antigen is trapped on a solid matrix by means of specific antibodies that are bound to the matrix by adsorpiton.

Plant virus vectors Plant viruses can be transmitted specifically by various vector organisms, for example, aphids, mites, nematodes, or plasmodiophorid protozoans (*Olpidium* sp., *Polymyxa* sp.).

Viroplasm Cytoplasmic inclusions induced by members of the *Caulimoviridae*, *Rhabdoviridae, Reoviridae,* and *Bunyaviridae* are about the size of nuclei and are not bound by any membrane. The viroplasm consists of amorphous and/or fibrillar material and may or may not enclose immature or mature virus particles. It is generally assumed that viroplasms are the site of virus synthesis.

Introduction

Diagnostic techniques for plant viruses are indispensable for at least three major sets of applications:

1. the identification and classification of viruses associated with 'new' plant diseases (primary diagnosis);
2. the routine detection of known viruses, for example, in
   - indexing programs designed to provide healthy plant propagation material (seeds, tubers, grafting material, etc.);
   - breeding programs designed to select virus-resistant plants; and
   - epidemiological investigations designed to monitor the spread of viruses into new areas and in quarantine tests designed to prevent this spread;
3. investigations on the functional, pathogenic, and structural properties of a virus, for example, on
   - its spread within a plant or a vector;
   - changes produced in the ultrastructure of infected cells;
   - intracellular localization of the virions and of nonstructural viral proteins;
   - the time course of the expression of various parts of the viral genome; and
   - the surface structure of virus particles, for example, the accessibility or nonaccessibility to antibodies of various parts of coat protein in the virions.

The primary diagnosis usually requires the application of a number of different techniques, whereas for routine diagnosis only one well-adapted technique is employed. For studying additional properties of a virus, in order to understand its pathogenic effects, one or several techniques may be necessary. The most important diagnostic techniques for plant viruses are based on their morphological, serological, molecular, and pathogenic properties, quite often on a combination of them.

Techniques Used for the Identification and Classification of Viruses Associated with New Plant Diseases (Primary Diagnosis)

Inspection of Symptoms

The first step in attempts to identify the causal agent of a new plant disease is usually a careful inspection of the type of symptoms present in the natural host. **Figure 1** shows some typical virus symptoms. Mosaics of green and yellow (chlorotic) tissue areas (**Figure 1(a)**) or of green and brownish (necrotic) ones (**Figure 1(c)**) or irregular yellow spots (mottling) (**Figure 1(b)**) may be seen on leaves, flowers, or fruits. Flowers may show irregular discolorations (flower break) (**Figure 1(d)**). More or less severe growth reduction (stunting) and/or malformations of either the whole plants or of individual parts, such as flowers and tubers, are also often observed.

Adsorption Electron Microscopy

A quick means to detect the presence of viruses – preferentially in symptom-showing parts of a plant – is the electron microscopical examination of a crude sap extract. In adsorption electron microscopy (**Figure 2(a)**), the virus particles are adsorbed to support films on electron microscope grids and are negatively stained, for example with uranyl acetate. Rod-shaped, filamentous, or isometric particles are readily distinguished from normal plant constituents. More than 30 different morphological types of viruses (examples in **Figure 3**) have been recognized. Particle morphology may serve as a guide for further identification, for example, by means of serology or molecular analyses (see below). Unfortunately, many viruses with very different pathogenic and other properties may be morphologically indistinguishable. Another severe limitation of this test is its rather low sensitivity. Thus, viruses occurring in low concentrations may not be detected. These drawbacks may be overcome in the immunoelectron microscopical tests described in the following sections.

Immunosorbent Electron Microscopy

In immunosorbent electron microscopy (ISEM) (**Figures 2(b), 4(a),** and **4(b)**), the electron microscope grids carrying a support film are coated with antibodies specific for viruses having the same morphology as the ones found in the electron microscopical adsorption test or with antibodies to viruses being suspected to be present in the plant material under investigation. Over a thousand times more virus particles can be detected on such antibody-coated grids than on uncoated grids or on grids coated with antibodies to an unrelated virus. This ISEM test is a very versatile technique. Its sensitivity and the broadness of cross-reactivities detected can be modulated by the length of time during which the virus-containing fluids are in contact with the antibody-coated grids. When the incubation time is short (15 min or less), mainly the homologous and very closely related viruses are trapped. However, after incubation overnight, the efficiency of virus trapping increases and more distantly related viruses are also detected. Very small amounts of antisera are needed (1 µl of crude antiserum can support 200 ISEM tests) and the quality of the antisera need not necessarily be high, since antibodies to normal host constituents do not interfere with virus-specific reactions and low-titered antisera can also be used. Since ISEM tests are labor intensive – they are not suitable for the routine detection of viruses in large numbers of samples.

Figure 1 Typical symptoms induced by plant viruses: (a) mosaic symptoms on abutilon, (b) mottling symptoms on zucchini fruits, (c) chlorotic and necrotic stripe mosaic on barley leaves, (d) flower break on lilies.

Immunoelectron Microscopical Decoration Tests

In the immunoelectron microscopical decoration test (**Figures 2(c), 4(c),** and **4(d)**), the reaction between free antibodies and viruses which have been immobilized on electron microscope support films either by adsorption or serological binding can be visualized as antibody coating of particles ('decoration'). At low antiserum dilutions (e.g., 1:50), homologous antisera produce a dense coating. Reactions with heterologous antisera may be recognized by a much weaker coating efficiency. The closeness of serological relationships may be assessed by comparing the dilution end points (titers) of antisera with homologous and heterologous viruses. The more refined immunogold-labeling technique uses antibodies that are labeled with colloidal gold particles having diameters between 5 and 20 nm. The binding of small amounts of antibodies to individual epitopes, for example, at the extremities of rod-shaped or filamentous virus particles (**Figure 4(d)**), can be visualized by means of this technique.

The immunoelectron microscope decoration tests are the most reliable means for verifying reactions between

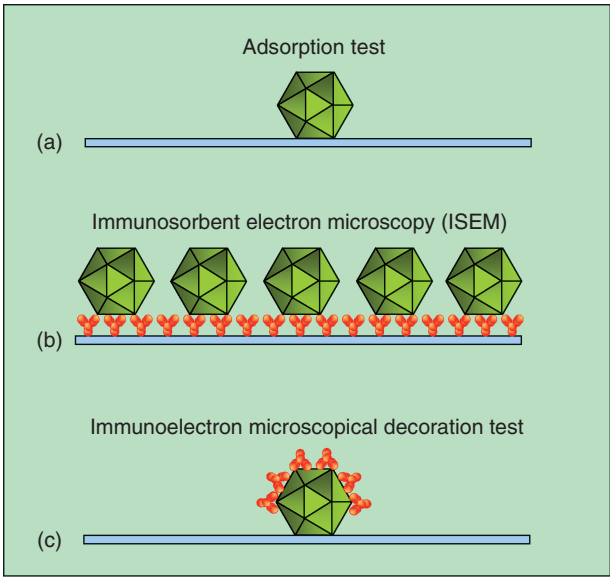

Figure 2 Schematic representation of various electron microscopical tests. For detailed explanations, see text. Adapted with permission from Koenig R and Lesemann D-E (2001) Plant virus identification. In: *Encyclopedia of Life Sciences*. Copyright 2001, © John Wiley & Sons Limited.

viruses and antibodies. Mixed infections by morphologically indistinguishable viruses are readily detected (**Figure 4(c)**). The presence of antibodies can be recognized even on a single virus particle. Thus, viruses occurring at low concentrations, as often happens in field samples, can nevertheless be analyzed directly. The detectability of viruses occurring at low concentration may be increased when the decoration test is preceded by an ISEM step. Antisera even with high host plant reactivities can be used successfully, because the specific antibody attachment to virus particles is directly visualized. The technique is not suited for detecting small antigenic differences between viruses and since it is labor intensive and cannot be automated, it is not suitable for routinely testing large numbers of samples.

Observations on Host Plant Reactions

The transmission of new viruses to experimental host plants is another helpful method to identify and characterize suspected 'new' viruses. Commonly used indicator and propagation hosts are *Chenopodium* species, for example, *C. quinoa* (**Figure 5**), and *Nicotiana* species, for example, *Nicotiana benthamiana*. These plant species are susceptible to a great number of plant viruses, but by far not to all of them. Host range studies may be helpful in finding a suitable host for propagating a new virus and for differentiating it from other similar viruses. In experimental hosts, viruses may reach higher concentrations than in their natural hosts and they may often be purified more easily from them, because natural hosts frequently contain tannins, glycosides, slimy substances, and other inhibitory compounds. Virus purification is necessary for the production of specific antisera which are needed for many diagnostic procedures, such as the above-mentioned immunoelectron microscopical techniques and many others, some of which will be described in the following sections.

Nucleotide Sequence Analyses

Nucleotide sequence analyses are the most reliable means to identify a virus either as a 'new' one or as a 'new' strain of a known virus. These analyses are more time-consuming than the above-described immunoelectron microscope tests. The latter can provide preliminary information concerning the putative genus or family membership of a new virus within 1–2 days. This preliminary information may serve as a valuable basis for further molecular studies, because it allows the design of broad specificity primers for cDNA synthesis and amplification of genome portions by means of the polymerase chain reaction (PCR). Such primers will be derived from highly conserved genome areas in the genera or families suggested by electron microscope studies.

Genome sequences of viruses with circular DNAs can be amplified directly by means of isothermic rolling-circle amplification (RCA) techniques using random primers and the DNA polymerase of *Bacillus subtilis* bacteriophage Phi29. This enzyme in addition to polymerase activity possesses strand-displacement activity, thus allowing circular DNA to be replicated to a nearly unlimited extent. Since random primers can be used, no previous sequence information is necessary. Virus variants or viruses in mixed infections can be recognized after cleavage with restriction endonucleases.

For RNA viruses, reverse transcription of the genome into cDNA is necessary. The PCR products obtained with broad specificity primers can often be sequenced directly without the need of time-consuming and costly cloning procedures. Several commercial companies offer this service. The sequences are compared with those of other viruses in the respective taxonomic group that can be obtained from gene banks, for example, 'Pubmed' or the 'Descriptions of Plant Viruses'. The latter as well as the 'ICTVdB Index of Viruses' offer additional information on previously described viruses.

If no information on the possible genus or family membership of a new virus is available from initial electron microscope studies, the double-stranded RNA (dsRNA) found as a replication intermediate in plants infected with RNA viruses may serve as a template for cDNA synthesis. Reverse transcription may be initiated by a 'universal' primer containing a sequence of about 20 defined nucleotides on its 5′ end and a 3′ tail consisting of six variable nucleotides that may bind randomly to various internal sites in the denatured dsRNA. The cDNAs

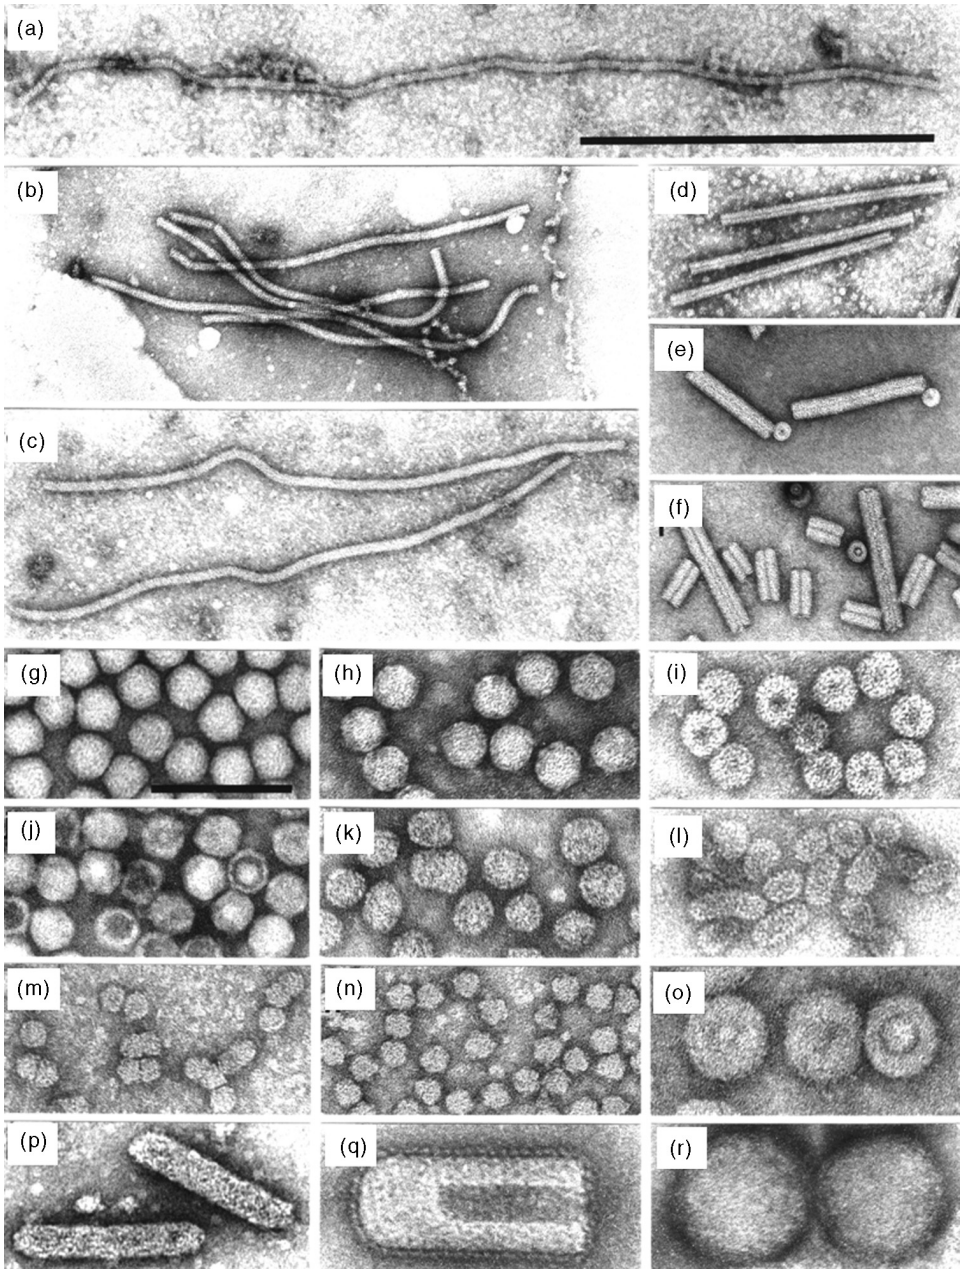

Figure 3 Various morphological types of plant viruses. Filamentous and rod-shaped particles: (a) beet yellows virus (genus *Closterovirus*), (b) potato virus X (genus *Potexvirus*), (c) potato virus Y (genus *Potyvirus*), (d) tobacco mosaic virus (genus *Tobamovirus*), (e): barley stripe mosaic virus (genus *Hordeivirus*), (f) tobacco rattle virus (genus *Tobravirus*). Isometric particles: (g) maize chlorotic mottle virus (genus *Machlomovirus*) , (h) barley yellow dwarf virus (genus *Luteovirus*), (i) cucumber mosaic virus (genus *Cucumovirus*), (j) arabis mosaic virus (genus *Nepovirus*). Irregular isometric to bacilliform particles: (k) apple mosaic virus (genus *Ilarvirus*), (l) alfalfa mosaic virus (genus *Alfamovirus*). Geminate or isometric 18 nm diameter particles: (m) tomato yellow leaf curl virus (genus *Begomovirus*), (n) faba bean necrotic yellows virus (genus *Nanovirus*). Isometric or bacilliform particles: (o) cauliflower mosaic virus (genus *Caulimovirus*), (p) cacao swollen shoot virus (genus *Badnavirus*) . Bullet-shaped or spherical particles: (q) Laelia red leaf spot-type virus (genus *Rhabdovirus*), (r) tomato spotted wilt virus (genus *Tospovirus*). The magnification bar shown in (a) equals 500 nm; the same magnification is also used in (b) to (f). obtained are rendered double-stranded and are amplified by means of PCR using a second primer that contains only the sequence of the 20 defined nucleotides forming the 5′ end of the 'universal' primer. The many different PCR products obtained will form a smear after electrophoresis in an agarose gel. The more slow-moving fraction of this smear is eluted from the gel. It contains the larger-sized PCR products that are cloned into a suitable

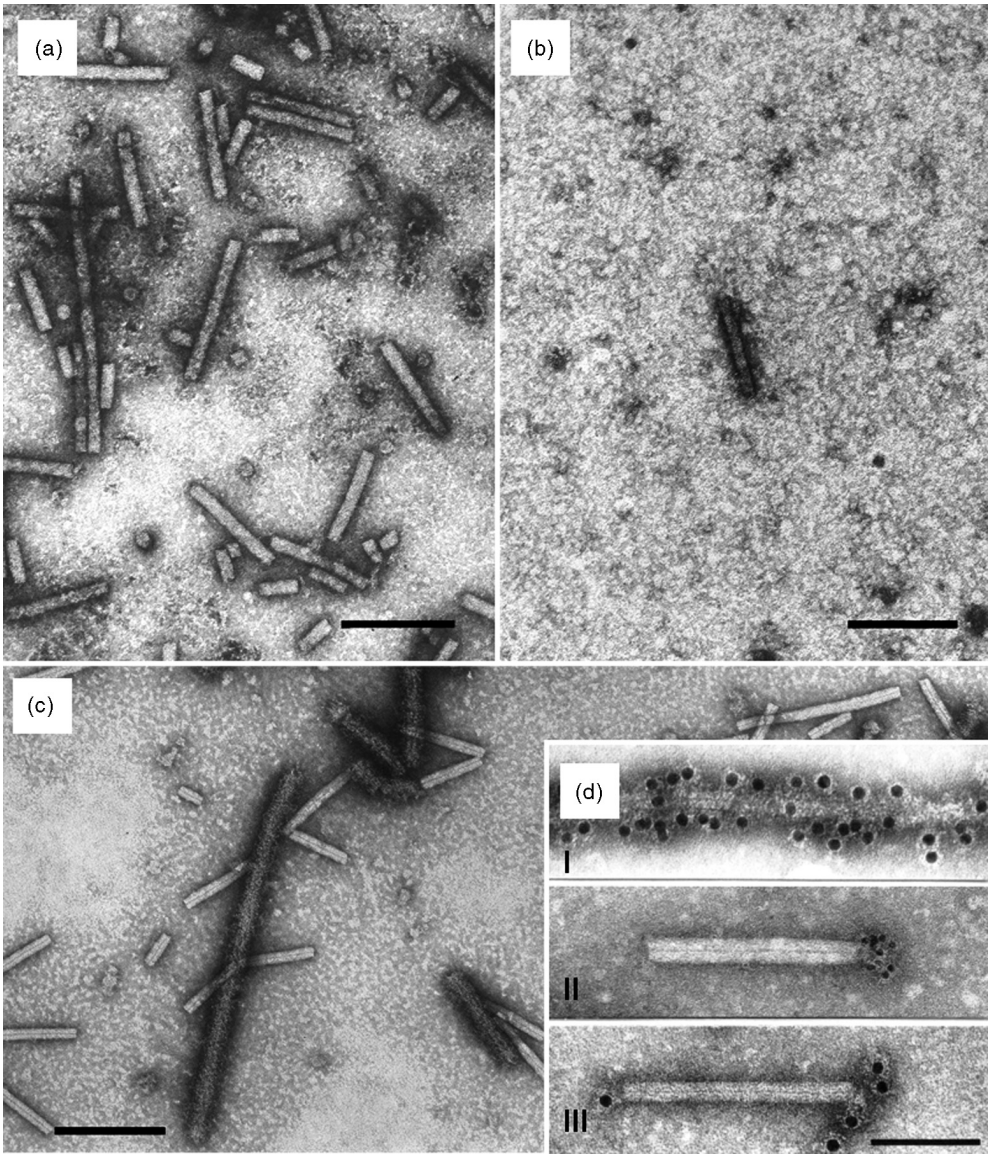

Figure 4 Immunoelectron microscopical analyses of virus-containing fluids: (a) Many virus particles are trapped within 15 min on a grid which had been coated with the homologous antiserum. (b) Only one particle is adsorbed nonspecifically from the same extract as in (a) on a grid coated with serum from a nonimmunized rabbit. (c) Detection of a mixed infection with two morphologically indistinguishable viruses: only those virus particles are decorated for which the antiserum is specific. (d) Binding of monoclonal antibodies to virus particles visualized by immunogold labeling (10 nm gold particles in the upper and lower parts and 5 nm gold particles in the middle part of the figure, respectively). In the upper part of the figure, the antibodies are bound along the entire surface of the particle, and in the middle and lower parts of the figure, on one or both extremities of the particles, respectively. Scale = 200 nm (a–c); 100 nm (d). Adapted with permission from Koenig R and Lesemann D-E (2001) Plant virus identification. In: *Encyclopedia of Life Sciences*. Copyright 2001, © John Wiley & Sons Limited.

vector. Nucleotide sequences are determined with clones containing differently sized inserts. Gaps between individual portions of a sequence may be bridged up by means of PCRs using suitably designed primers on each of these sequences. Complete sequences may be obtained by means of various RACE techniques (rapid amplification of cDNA ends). Since genome recombinations are frequently found with plant viruses, it is important to determine the full-length or almost-full-length nucleotide sequences for newly described viruses in order to allow comparisons to be made along the entire length of the genome.

Techniques That are Especially Useful for the Routine Detection of Plant Viruses

Most of the techniques that are presently used for the routine detection of plant viruses are either based on the use of enzyme-labeled antibodies or on the amplification of portions of the viral genome by means of the PCR or other nucleic acid amplification techniques (see below). Tests based on symptom formation on indicator plants to which the viruses are transmitted either mechanically or by grafting have been used extensively as diagnostic tools

in earlier times, but they are increasingly replaced by molecular or serological techniques which provide results within 1–2 days rather than after weeks or months. In addition, these latter techniques do not require extensive greenhouse or outdoor space, are more specific, do not require the propagation of unwanted pathogens, and – very importantly – can be readily automated.

Enzyme-Linked Immunosorbent Assay

Enzyme-linked immunosorbent assay (ELISA), especially its double antibody sandwich form (DAS ELISA), is presently probably the most widely used technique for the routine detection of plant viruses. The principle of DAS ELISA is outlined in **Figure 6**. Virus particles present even in low concentrations in crude sap extracts of diseased plants are trapped by specific antibodies that have been immobilized on the surface of multiwell polystyrene plates.

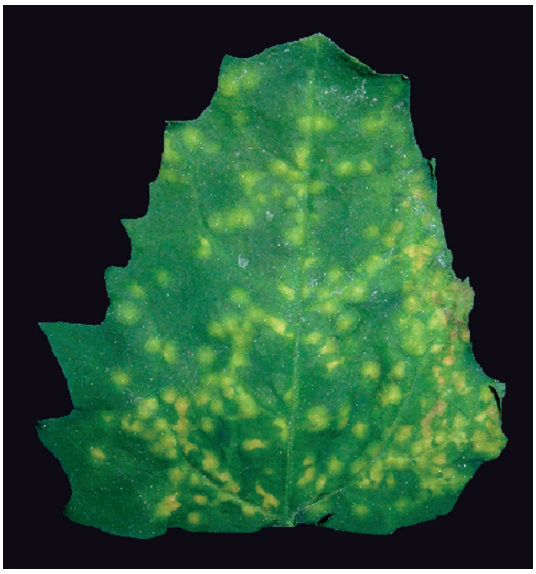

Figure 5 Chlorotic local lesions produced by a plant virus (beet necrotic yellow vein virus) on a leaf of the test plant *Chenopodium quinoa*.

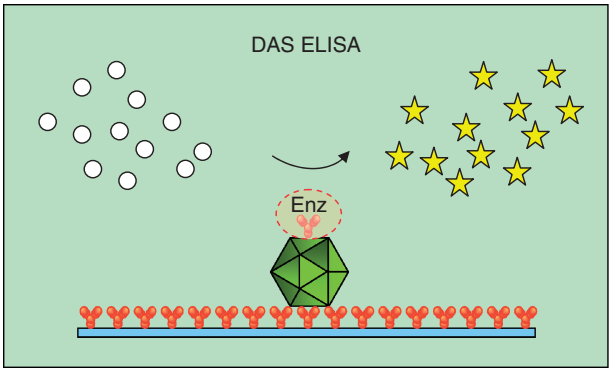

Figure 6 Schematic representation of the principle of DAS ELISA. For a detailed explanation, see text.

The trapped particles are detected by means of enzyme-labeled antibodies. The enzyme attached to these antibodies is able to convert an unstained substrate into a brightly colored reaction product. Alkaline phophatase is used most commonly for antibody labeling in plant virus work. One molecule of alkaline phosphatase attached to an antibody molecule can dephosphorylate large numbers of molecules of the colorless *p*-nitrophenylphosphate to yield the bright yellow *p*-nitrophenol. Both the initial trapping step and the dye-production step make the test more than a 1000-fold more sensitive than the previously used precipitin tests which relied on the detection of a visible precipitate formed as a result of the antigen/antibody reaction. Triple antibody sandwich ELISAs are used especially in work with monoclonal antibodies (MAbs), because the latter often lose their activity when labeled directly with an enzyme. The binding of mouse or rat MAbs is detected by means of enzyme-labeled antibodies from rabbits specific for mouse or rat immunoglobulins, respectively. This requires an additional assay step, but often results in increase in sensitivity of virus detection and a broadening of the range of serologically related viruses which can be detected.

Tissue Print Immunoblotting

In the tissue print immunoblotting assay (**Figure 7**), the surfaces of freshly cut virus-infected plant organs, for example, of leaves or roots, are firmly pressed on a nitrocellulose or nylon membrane. Viruses contained in the sap become adsorbed to this membrane and are detected by means of antibodies labeled with an enzyme that is able to convert a colorless soluble substrate into a colored insoluble product. For alkaline phospatase, 5′-bromo-4-chloro-3-indolylphosphate (BCIP) is commonly used as a substrate. Together with 4-nitrotetrazoliumchloride blue (NTB), its dephosphorylation products form an intense blue deposition of diformazan. The binding of unlabeled antibodies produced in a rabbit can be detected by means of enzyme-labeled antibodies produced against rabbit immunogloblins in a different animal species, such as goats. Small portions of a leaf are sufficient for the routine detection of a virus. The test also allows studies of the distribution of a virus in large organs, such as sugar beet tap roots.

PCR and Other Nucleic Acid Amplification Techniques

PCR techniques using specific primers have become very popular for the routine detection of plant viruses. They are in general more sensitive than serological techniques and hence can be used even for the detection of many viruses in woody plants, for example, in fruit trees, for which ELISA is usually not sensitive enough.

With RNA viruses, transcription of the RNA into cDNA prior to PCR is necessary (reverse transcription PCR, RT-PCR). Viral RNAs can be extracted from

infected tissues by means of various commercially available kits which often are based on the selective binding of RNAs to silica gel-containing membranes and microspin technology. Alternatively, virus particles can be trapped from plant sap by means of specific antibodies which have been immobilized, as in ELISA, on a polystyrene surface, for example, in an Eppendorf tube. In this immunocapture RT-PCR (IC-RT-PCR), the nucleic acid is released from the virus by heat treatment and reverse-transcribed (**Figure 8**). Fragments of the generated cDNA are amplified and converted to dsDNA by means of a heat-stable DNA polymerase in the presence of deoxynucleotide triphosphates (dNTPs) and specific upstream and downstream primers flanking the sequence. The formation of correctly sized PCR products is checked by means of electrophoresis in agarose gels which are stained with ethidium bromide.

As mentioned earlier, viruses with circular DNA can readily be detected by means of the isothermic RCA technique using the DNA polymerase of *B. subtilis* bacteriophage Phi29. RT-LAMP (loop-mediated isothermal amplification) might be a promising isothermic alternative to PCR that can be used for RNA viruses.

In multiplex PCRs, several viruses can be detected simultaneously using pairs of primers specific for different viruses. The primers are designed in a way that each virus in a mixture yields a differently sized PCR product. The sensitivity of conventional PCRs can be further increased by means of a second amplification step using nested primers that anneal to internal sequences in the first PCR product which may be present in a concentration too low for direct detection.

The technical simplicity of PCR has made it a routine procedure in many laboratories, including virus-diagnostic laboratories. However, despite the ease of the method, careful interpretation of the results and positive, internal, and negative controls are extremely important in PCR analyses. The reason is that samples may easily become contaminated during working procedures by minute amounts of cDNAs or PCR products that may be present, for example, in aerosols in laboratories. UV irradiation is a useful means to decontaminate working areas.

Real-Time PCR

Real-time PCR combines the amplification and identification of target sequences in one complex reaction. Between the upstream and downstream amplification, primers most commonly a TaqMan probe is annealed specifically to the target sequence. This probe carries a fluorophore quencher dye attached to its 3′ end and a fluorpophore reporter dye attached to its 5′ end. During PCR, the polymerase replicates the template to which the probe is bound. Due to the 5′ exonuclease activity of the enzyme, the probe annealed to the target sequence is then cleaved and the reporter is thus released from the proximity of the quencher. This leads in each cycle to an increase in the fluorescence of the reporter dye that will be proportional to the number of amplicons that have been created. Because the increase in fluorescence signal is detected only if the target sequence is complementary to the probe, nonspecific amplification is not detected.

Real-time PCR is an attractive alternative to conventional PCR because of its rapidity, sensitivity, reproducibility, and the reduced risk of carryover contamination. In addition, it is cost effective when employed in high-throughput diagnostic work where it can be conveniently automated. As other PCR-based techniques, real-time PCR permits the differentiation of strains or pathotypes that differ in a few nucleotides only. With the possibility of quantification, real-time PCR is a highly versatile molecular technique for routine virus detection and identification.

Microarrays

The simultaneous identification of a number of viral nucleotide sequences, theoretically comprising all possible virus targets in a given sample, is possible by means of microarray analysis, a technique originally designed for gene expression studies with large numbers of nucleic acid sequences. With the availability of rapidly increasing viral sequence data, sequences conserved in all members of a genus or, alternatively, sequences highly specific for one or a few isolates can be defined and used in such hybridization analysis. PCR products or nowadays rather oligonucleotides less than 50 nt in length complementary to informative conserved or discriminatory sequences in virus genomes are printed on glass slides. Several hundred to a few thousand oligonucleotide spots which act as capture probes are compiled on a so-called DNA chip. The target sequences, for example, cDNA for the total RNA of a virus-infected plant, are labeled with fluorescent dyes, for example, cyanine 3/cyanine 5, during reverse transcription and are hybridized to the probe sequences on the slide. Their ability or failure to bind to the probes is subsequently analyzed using specific laser scanners and image analysis software.

Microarray analysis permits the parallel detection of a large number of pathogen sequences in one plant sample and can be useful, for example, in quarantine assays for identifying the 'array' of pathogen sequences present in one sample. The technique is commonly used for the detection and genotyping of human viruses, for example, HIV and hepatitis virus C. Its application in plant virology, however, is still at the level of proof of principle and its use for high-throughput testing is still limited by the high cost of chip production and target labeling. Also, preamplification steps may be necessary to enrich target sequences present in low concentrations.

Techniques That are Especially Useful for Studying Functional, Physical, and Structural Properties of Plant Viruses

Western Blotting

The correct sizes and the time course of the expression of structural and nonstructural proteins of a virus can be determined by means of Western blotting. In this technique, the proteins present in a plant extract are first separated by means of sodium dodecyl sulfate (SDS) polyacrylamide electrophoresis and are then transferred electrophoretically to a nitrocellulose or nylon membrane where the viral proteins are detected by means of enzyme-labeled antibodies as described above for tissue print immunoassay.

Epitope Mapping by Investigating the Binding of MAbs to Overlapping Synthetic Oligopeptides and Subsequent Immunoelectron Microscopical Studies

Epitopes, that is, binding sites of viral coat proteins recognized by antibodies, can be identified by studying the ability or inability of MAbs to bind to a series of overlapping synthetic oligopeptides corresponding to the amino acid sequence of the viral protein. The binding sites of those MAbs which have reacted with one or several of the oligopeptides are subsequently checked on the native virus particles by means of immunoelectron microscopical decoration tests using the sensitive immunogold-labeling technique (see above). By this means, information can be obtained on the accessibility or nonaccessibility of antibody-binding sites in the intact virus particles (**Figure 4(d)**).

Methods for Studying the Distribution of a Virus within a Plant or a Vector

The distribution of a virus inside a plant or a vector can be investigated macroscopically or by means of a light microscope using the above-mentioned tissue print

immunoassay or by means of antibodies labeled with fluorescent dyes. Alternatively, the coding sequences for the green fluorescent protein (GFP) or other fluorescent tags can be attached to the coding sequences for structural or nonstructural viral proteins, provided that infectious cDNA clones of a virus are available. Investigations on the movement of a tagged virus or its tagged nonstructural proteins, such as of movement proteins, between different cell compartments are best performed by means of confocal laser scan microscopy (CLSM), which produces blur-free high-resolution images of thick specimens at various depths as well as computer-generated three-dimensional (3-D) reconstructions.

Studies on the Ultrastructure of Infected Host Cells by Means of Conventional Electron Microscopy

Alterations of the fine structure in infected host cells are studied by means of conventional electron microscopy in ultrathin sections that are obtained from plant tissues after chemical fixation, dehydration, and embedding in resin-like polymers such as epoxides or methacrylates (Epon, Araldite, Spurr's resin, LR White, or LR Gold). Cryosectioning after rapid freezing procedures is used less frequently. Cytological alterations are easily detected in ultrathin sections from well-selected tissue samples. The preparation of the sections, however, is time consuming and requires special equipment and expertise. Also, not all plant viruses induce characteristic cellular alterations.

Cytological alterations appearing as unusual inclusions may be recognized in infected cells also by means of light microscopy, especially after appropriate staining. However, details of their fine structure and the complete spectrum of cellular alterations can be analyzed only in ultrathin sections. Tissues from plant organs showing macroscopically visible symptoms like chlorosis and necrosis may show pathological alterations of various cell organelles, for example, chloroplasts, mitochondria, peroxisomes, nuclei or membranes of the endoplasmic reticulum. These alterations may be indicative of the damaging physiological effects induced by the infection in incompletely adapted host plants, rather than of virus-specific effects on cytology. However, virus-specific alterations may also be recognized in infected cells. They are most clearly seen in cells of hosts which do not produce pronounced macroscopically visible symptoms (latent infections).

Characteristic inclusions may be formed by accumulated virus particles (**Figure 9**(**a**)), nonstructural viral proteins (e.g., in the typical cylindrical inclusions induced by potyviruses; **Figure 9**(**b**)), proliferated host membrane elements, or they may be composed of complex

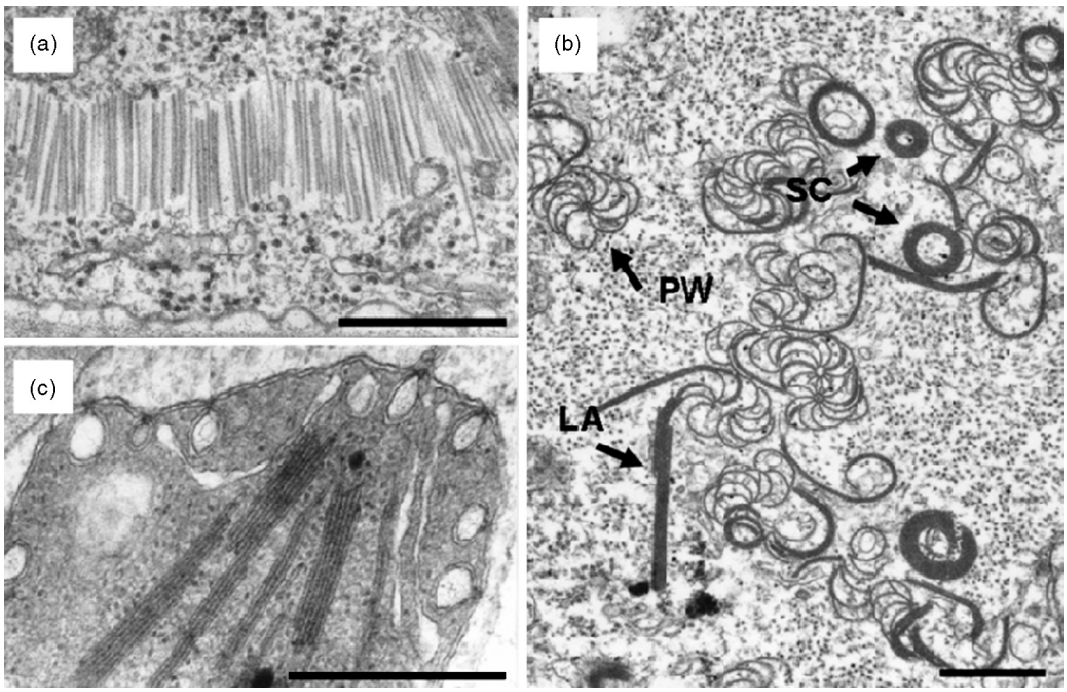

Figure 9 Electron-microscopically visible cytological alterations due to virus infections. (a) Plate-like cytoplasmic aggregate formed by the particles of a rod-shaped virus (cross section) – the highly regular *in vivo* arrangement with particle ends in register has been disturbed during fixation. Scale = 500 nm. (b) Ultrathin cross sections of pinwheels (PWs), scrolls (SCs), and laminated aggregates (LAs) formed by a nonstructural protein of a potyvirus. (c) Flask-shaped vesicles associated with the peripheral membrane of a chloroplast typical for tymovirus infections; the fibrillar content of the vesicles suggests the presence of dsRNA. Scale = 500 nm. Adapted with permission from Koenig R and Lesemann D-E (2001) Plant virus identification. In: *Encyclopedia of Life Sciences*. Copyright 2001, © John Wiley & Sons Limited.

aggregates of one or more of these components with host cell constituents. The particular structure and composition of such inclusions may be characteristic for a virus. Members of the Sindbis-like supergroup of positive-stranded single-strand RNA (ssRNA) viruses may induce virus-specific or genus-specific membrane-associated vesicles (**Figure 9(c)**), whereas members of the picorna virus-like supergroup may induce accumulations of free vesicles. Both types of vesicles contain dsRNA and are believed to be associated with viral RNA replication. Viruses with genomic nucleic acids other than positive-stranded ssRNA may induce viroplasm-like inclusions presumably involved in virus replication.

The fine structure of virus particle aggregates is usually determined by the morphology of the viruses (see **Figure 9(a)**) and is, thus, mostly specific for a virus genus. Occasionally, however, the particle arrangement may be specific for a certain virus strain. Inclusions composed of nonstructural viral proteins may exhibit very diverse and sometimes virus-specific shapes and fine structures (see **Figure 9(b)**). Proliferated membrane inclusions and membrane-associated vesicles are also species or genus specific (see **Figure 9(c)**).

Outlook: New and Neglected Techniques with Promise for Plant Virus Work

New technical developments that are promising for plant virus work include the use of liquid arrays and Padlock probes. A useful technique for RNA quantification that has been widely neglected by plant virologists is the RNase protection assay.

Liquid Arrays

Instead of applying antibodies to different viruses as an array to a planar surface, differently colored plastic beads are coated with different antibodies and serve as a basis for a miniaturized DAS ELISA in which the second antibody is labeled with a green fluorescent dye. In ELISA plates, mixtures of such beads carrying different antibodies allow the simultaneous testing of up to 100 different antigens. The assay is demultiplexed by means of a flow-through fluorescence reader that identifies by means of a laser beam on the basis of the color of a bead the antibody that has been used for coating the bead. Subsequently, a second laser beam shows how much fluorescent antibody has been bound to a specific type of bead because of the presence of the antigen in the testing material.

Padlock Probes

Padlock probes are DNA molecules whose 3′ and 5′ ends are complementary to adjacent parts of the target sequence (**Figure 10**). They become circularized in a ligation reaction when they fit the target sequence completely. In addition, they contain forward and backward primer-binding regions (P1 and P2) which can be used for amplification using unlabeled (**Figure 10(c)**) or labeled primers (**Figure 10(b)**). The probes also contain a ZipCode region which can be used either for hybridizing

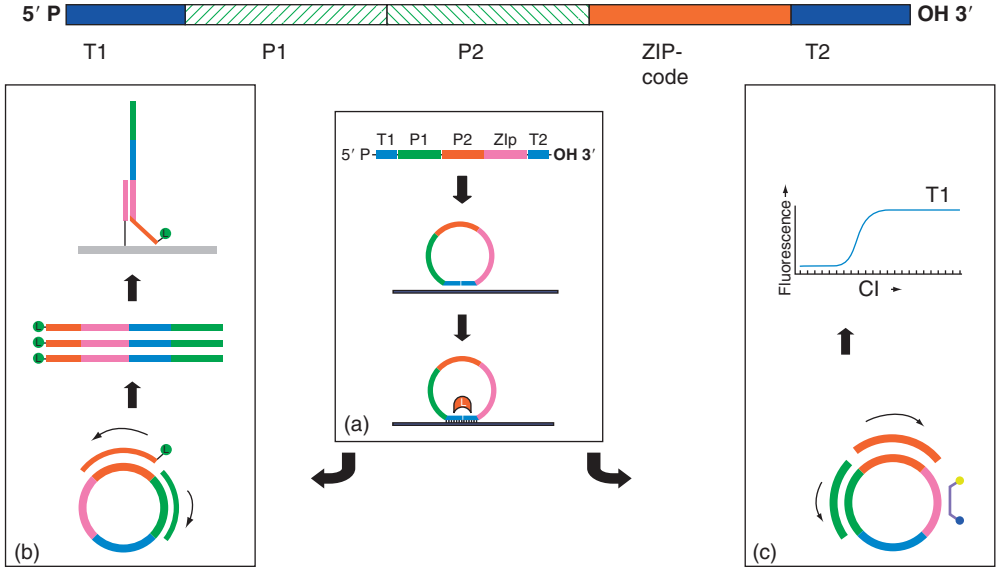

Figure 10 The Padlock probe, structure, and application for nucleic acid-based detection. The top drawing shows the construction of a Padlock probe. It consists of the two target-specific regions T1 and T2, the primer-binding regions P1 and P2, and the ZipCode, which serves as identification sequence. The probe is hybridized to the target and in case of a complete fit it is circularized (a). Subsequently the probe can serve either as a template for PCR amplification using fluorescent-labeled primers (b). In this case, the labeled amplicons are hybridized via the ZipCode to oligonucleotide arrays for differential detection (b). Alternatively, the circularized probe can be used for quantitative PCR with a TaqMan probe directed against the ZipCode (c). Courtesy of C. D. Schoen and P. J. M. Bonants, Plant Research International BV, Wageningen, The Netherlands.

the labeled Padlock amplicons to oligonucleotide arrays (**Figure 10(b)**) or as binding region for a TaqMan probe or a molecular beacon in quantitative real-time PCR (**Figure 10(c)**).

RNase Protection Assay

These tests offer a simple and cheap method to quantify RNA without PCR. They are especially useful when several RNAs have to be quantified simultaneously. Discrete-sized complementary RNAs are labeled, for example, by radioactive isotopes, and are hybridized in solution with the target RNAs to yield labeled dsRNAs. After RNase digestion of the unhybridized probe and target RNAs, the labeled dsRNAs are separated electrophoretically in a denaturing polyacrylamide gel and are visualized and quantified according to the label used.

Diagnostic Techniques: Serological and Molecular Approaches

R Vainionpää, University of Turku, Turku, Finland
P Leinikki, National Public Health Institute, Helsinki, Finland

© 2008 Elsevier Ltd. All rights reserved.

Glossary

EIA Enzyme immunoassays are methods used to estimate virus-specific IgG and IgM antibodies or virus antigens by enzyme-labeled conjugates.

PCR By the polymerase chain reaction (PCR) and with specific primers, DNA sequences can be multiplied.
RT-PCR For RNA, nucleic acid has to be transcribed with reverse transcriptase (RT) enzyme to complementary DNA prior to PCR.

Introduction

Specific virus diagnostics can be used to determine the etiology of acute viral infection or the reactivation of a latent infection. Two approaches can be used: demonstration of a specific antibody response or of the presence of the virus itself. Serological methods are used for measuring the antibody response while the presence of virus can be demonstrated by cultivation or demonstration of specific antigens or gene sequences. For the latter, molecular diagnostic methods have become more and more widely applied.

In this article, we briefly describe the principles of the most important serological methods and molecular applications that are used to provide information about the viral etiology of the clinical condition presumed to be caused by a viral infection.

The diagram of the course of acute virus infection (**Figure 1**) indicates the optimal methods for viral diagnosis. Following transmission, the virus starts to multiply and after an incubation period clinical symptoms appear with simultaneous shedding of infectious virus. Virus-specific antibodies appear somewhat later (from some days to weeks, called a window period). When the virus-specific antibody production reaches the level of detection, at first immunoglobulin M(IgM) antibodies and some days later immunoglobulin G(IgG) antibodies appear, and the amount of infectious virus starts to decrease. If this is the first encounter with this particular virus, that is, a primary immune response, IgG antibody levels can stay at a relatively low level, whereas in a later contact with the same antigen, that is, in secondary response, IgG levels increase rapidly and reach high levels while IgM response may not be detectable at all. Antibodies are usually investigated from serum samples taken at acute and convalescent phase of the infection. In selected cases other materials such as cerebrospinal fluid and other body fluids can also be analyzed.

The presence of infectious virus or viral structural components can be investigated directly from various clinical specimens either by virus isolation, nucleic acid detection assays, or antigen detection assays. In order to reach the best diagnosis for each patient, it is important to select the most suitable method using the right sample collected at the right time.

Principles of Serological Assays

During most primary infections IgM antibody levels peak at 7–10 days after the onset of illness and then start to decline, disappearing after some weeks or months. An IgM response is usually not detected in reactivated infections or reinfections. The production of IgG antibodies starts a few days after IgM response and these antibodies often persist throughout life.

Serological diagnosis is usually based on either the demonstration of the presence of specific IgM antibodies or a significant increase in the levels of specific IgG antibodies between two consecutive samples taken 7–10 days apart. The antigen for the test can be either viable or inactivated virus or some of its components prepared by virological or molecular methods. Isotype-specific markers or physical separation are used to demonstrate the isotype of the reacting antibody. In some cases, even IgG subclass specificities are determined although they have limited value in diagnostic work.

During the early phase of acute infection the specific avidity of IgG antibodies is usually low but it increases

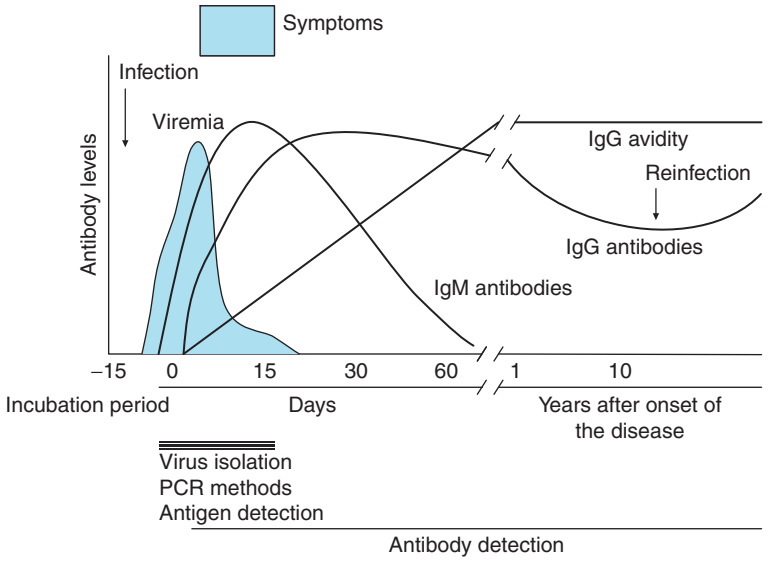

Figure 1 The course of virus infection. The shedding of infectious virus after incubation period and typical antibody response. Recommended diagnostic laboratory methods have been marked.

during the maturation of the response. Diagnostic applications of the measurement of the avidity of IgG antibodies against specific antigens have been developed to help distinguish serological responses due to acute infections from those of chronic or past infections.

Serological assays are useful for many purposes. In primary infections they often provide information about the etiology even after the acute stage when infectious virus or its components can no longer be demonstrated in the samples. They are widely used for screening of blood products for the risk of certain chronic infections, evaluation of the immune status, and need for prophylactic treatments in connection with certain organ transplantations. They are also widely used for epidemiological studies, determination of vaccine-induced immunity, and other similar public health purposes.

Serological assays have their limitations. In some infections the antibody response is not strong enough or the limited specificity of the antigens used in the assay does not allow unambiguous interpretation of the results. In infections of newborns the presence of maternal antibodies may render the demonstration of the response in the baby impossible. In immunocompromised patients the serological response is often too weak to allow the demonstration of specific responses. In these cases other virological methods should be considered.

Other clinical specimens than sera can be used for antibody assays. IgM and IgG antibody determinations from cerebrospinal fluid are used for diagnosis of virus infections in the central nervous system although new molecular methods are increasingly replacing them. Recently, increasing attention has been given to the use of noninvasive sample materials such as saliva or urine. They are becoming important for public health purposes but their value for diagnosing individual patients is still limited.

Principles of the Most Common Serological Tests

Neutralizing Antibody Assay

Antibodies that decrease the infectious capacity of the virus are called neutralizing antibodies. They are produced during acute infection and often persist during the entire lifetime. They are also useful as an indication of immunity. Both IgM and IgG antibodies participate in the neutralization.

In the assay, known amounts of infectious virus are mixed with the serum sample and incubated for a short period after which the residual infectivity is measured using cell cultures or test animals. This infectivity is then compared with the infectivity of the original virus and the neutralizing capacity is calculated from this result. Today, neutralizing antibody assays are often done by plaque reduction assays with better accuracy but with somewhat more complex technical requirements.

Neutralizing antibody assay is specific and sensitive, but time-consuming and laborious, and therefore it is not widely used in routine diagnostic services.

Hemagglutination Inhibition Test

Many viruses bind to hemagglutinin molecules found at the surface of red blood cells of various animal species and this can cause aggregation of red cells in suitable conditions. Prevention of this aggregation, called hemagglutination inhibition, by specific antiviral antibodies in the patient's serum has been widely used for diagnostic purposes. The test, known as hemagglutination inhibition test, has important diagnostic and public health applications in certain infections, most notably in influenza where antibodies measured by this test show additional specificity compared to other tests and therefore provide more detailed information about the immunity and past infections of individuals. However, for the diagnosis of individual patients, the assay is no longer widely used and is replaced by more modern immunoassays.

In the test, a virus preparation with a predetermined hemagglutinating capacity is mixed with the serum sample and after proper incubation the residual hemagglutination capacity is measured. Both IgM and IgG antibodies are able to inhibit hemagglutination.

Complement Fixation Test

The complement fixation test (CFT) is a classical laboratory diagnostic test, which is still used for determination of virus antibodies in patient sera or cerebrospinal fluid samples during an acute infection. The test mainly measures IgG antibodies.

The test is based on the capacity of complement, a group of heat-labile proteins present in the plasma of most warm-blooded animals to bind to antigen–antibody complexes. When the complexes are present on the surface of red blood cells, complement causes their lysis which can be visualized by a suitable experimental setup.

In the actual test, the complement in the patient's serum is first destroyed by heating; the serum is then mixed with appropriate viral antigen and after incubation; when the antigen–antibody complexes are formed, exogenous complement (usually from fresh guinea pig serum) is added. This complement then binds to the complexes and having been 'fixed', it is then no longer able to cause lysis of added indicator red cells. Usually, sheep red cells coated with antisheep red cell antibodies are used as indicator to measure the presence of any residual complement. The effect is measured by a suitable test protocol. Serial dilutions of the patient serum are used

and the highest dilution where the serum can still prevent complement activity in the indicator system is taken as the CFT titer of the sample. The tests are usually carried out on microtiter plates and the results are observed by eye.

CFT is still used for diagnosis of acute virus infection. It measures certain types of antibodies which occur only during the acute phase of the infection. Therefore, CFT is not suitable for investigation of immune status. The assay procedure is quite complex, because the test is dependent on several biological variables, which have to be standardized by pretesting. The method is less sensitive than many other immunoassays. In addition, the method is very labor intensive and is not amenable to automation. The use of CFT in virus diagnostics is increasingly replaced by modern immunoassays.

Immunoassays

In immunoassays, antibodies binding to specific immobilized antigens can directly be observed using bound antigens and proper indicators such as labeled anti-immunoglobulin antibodies. The antigens can be immobilized to plastic microtiter plates, glass slides, filter papers or any similar material. Different immunoassays are nowadays widely used to measure virus-specific IgM and IgG antibodies. The most recent formats of immunoassays make it possible to detect simultaneously both antigens and antibodies decreasing significantly the window period between infection and immune response. Numerous commercial kits with high specifity and sensitivity are available. Automation has made immunoassay techniques more rapid, accurate, and easier to perform.

In the basic format of solid-phase immunoassays, virus-infected cells, cell lysates, purified or semipurified, recombinant viral antigens or synthetic peptides are immobilized to a solid phase, usually plastic microtiter wells or glass slides. Patient's serum is incubated with the antigen and the bound antibody, after washing steps, is visualized using labeled anti-immunoglobulin antibodies ('conjugate') (**Figure 2(a)**). If the label used is an enzyme, the test is called enzyme immunoassay (EIA) or enzyme-linked immunosorbent assay (ELISA) and the bound antibody is detected by an enzyme-dependent color reaction. If a fluorescent label is used, the method is called immunofluorescent test (IFT). The enzyme labels most commonly used are horseradish peroxidase (HRP) and alkaline phosphatase (AP). In HRP-EIA the color-forming system consists of ortho-phenyldiamine (OPD) as a chromogen and hydrogen peroxidase (H_2O_2) as a substrate. If the HRP-conjugate is bound to antibody–antigen complexes, the colorless chromogen becomes yellow and color intensity is measured with a photometer at a wavelength of 490–492 nm. The intensity of the color is proportional to the amount of bound conjugate and to the amount of specific antibodies in a patient serum sample. If the serum contains no specific antibodies, the conjugate is not bound and no color reaction occurs. By using either anti-IgG or anti-IgM conjugates it is possible to determine separately immunoglobulin subclasses.

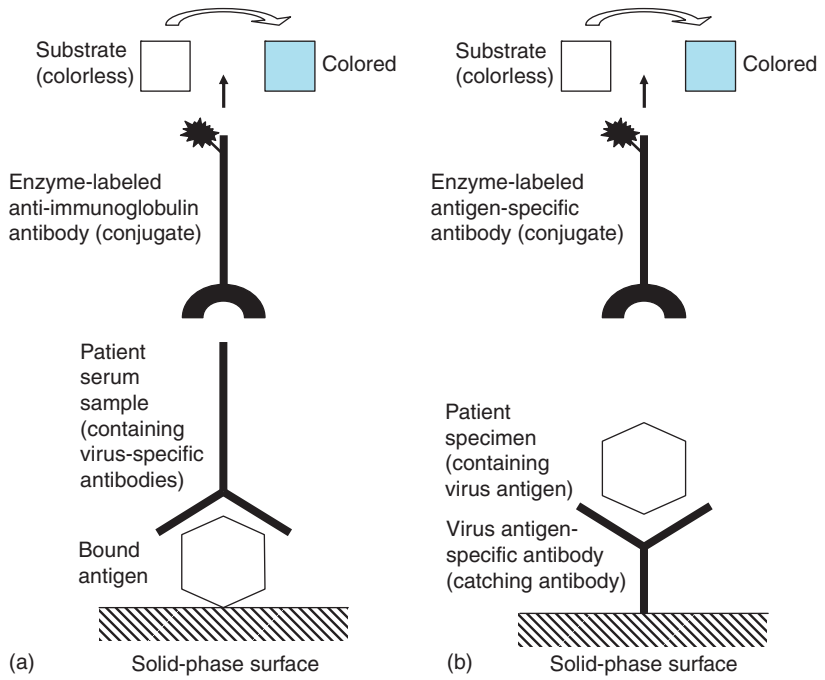

Figure 2 Enzyme immunoassay. (a) Detection of virus-specific antibodies. (b) Detection of virus antigens.

The specificity and sensitivity of these immunoassays are high. The sensitivity can be improved further, by using an additional incubation step where IgM antibodies are first enriched ('captured') in the sample by using anti-IgM immunoglobulin. Modifications to improve assay specificity by various methods of antigen handling and by using monoclonal antibodies or synthetic peptides have been developed.

Immunofluorescent tests were used in the past for measuring virus-specific antibodies, but are now replaced by EIA techniques. The principle of the method is similar to EIAs. In IFT infected cells are placed on a glass slide and bound antibodies are detected by fluorescein-labeled anti-immunoglobulin antibodies. The glass slides are examined under a fluorescence microscope. The method is specific and sensitive, but quite labor intensive and reading the test demands considerable experience.

Immunoblotting

In some infections (e.g., that caused by human immunodeficiency virus (HIV)), antibodies against certain components of the virus are more informative than other less-specific antibodies and they are detected by immunoblotting assays. Different virus antigens, prepared by gel diffusion or other techniques, are absorbed as discrete bands on a solid strip of cellulose or similar material and the strip is incubated with the patient's serum. Antibodies present in the serum bind to specific antigens and are detected using an HRP-conjugate and nitroblue tetrazolium as the precipitating color chromogen. The color reaction is observed and compared to positive and negative control samples assayed on separate strips.

Lateral-Flow and Latex Tests

A technique known as lateral-flow technology has also been used to identify antibodies or antigens. These tests involve application of serum or other samples directly on a strip of suitable material such as cellulose, where the antibodies are diffused laterally and eventually reach a site in the strip where appropriate antigen has been applied and chemically fixed. Specific antibodies become bound to the site while nonreacting antibodies diffuse out from the area. The presence of antibodies is visualized using labeled conjugates.

Although such tests are not quantitative, they are valuable for infections where the presence of specific antibodies is indicative, such as HIV infection. Performance of the test is often very simple and the result is available in a few minutes or a few hours, making such tests suitable for bed-side screening. In more advanced tests, several different antibodies can be detected by a single assay and the test conditions can be modified further so that antigens can also be detected. Many such tests have become commercially available in recent years.

For some applications, coated latex particles have replaced strips with fixed antigen as the solid phase. Binding of specific antibodies can be visualized with chromogenic or otherwise labeled indicator antibodies or a positive reaction can be detected by agglutination of the latex particles.

Point-of-Care Tests

Point-of-care tests (POC tests) are becoming increasingly common in clinical practice. Most of them are based on easy-to-use lateral-flow or latex particle technology and are able to give the result in a few minutes. POC tests are nowadays available for antibody screening of an increasing number of virus infections (HIV, hepatitis C virus (HCV), varicella-zoster virus (VZV), cytomegalovirus (CMV), Epstein–Barr virus (EBV)). Some authorities still question the validity of POC tests for clinical use although there is considerable evidence that many of the commercially available kits give reliable results.

Detection of Viral Antigens

The presence of viral antigens in clinical specimens, such as nasopharyngeal aspirates, fecal specimens, vesicle fluids, tissue specimens, as well as serum samples can be demonstrated by antigen detection assays.

In immunofluorescence tests, cells from a clinical specimen are fixed on a glass slide and viral antigens present in the cells are detected by fluorescein-labeled virus-specific antibodies. More reliable results can be obtained using enzyme immunoassay or time-resolved fluoroimmunoassay (TR-FIA). Europium-labeled monoclonal antibodies can be used as a conjugate. Solubilized antigens in clinical specimens are first captured using specific monoclonal antibodies bound to a solid phase, and are then detected with enzyme- or europium-labeled virus-specific antibodies (**Figure 2(b)**).

Antigen detection methods are especially recommended in the case of virus reactivation, for example, for herpes simplex and varicella zoster virus diagnosis where the serological response can be very weak. Antigen detection assays are also widely used in respiratory tract infections like influenza and respiratory syncytial virus infections. A simple test for the demonstration of rotavirus and adenovirus antigens in children with gastroenteritis is also available.

Nucleic Acid Detection Assays

Direct demonstration of viral nucleic acids in clinical samples is an increasingly used technique for virus diagnosis. Using the polymerase chain reaction (PCR) with specific

primers, viral sequences can be rapidly multiplied and identified. These techniques are largely replacing classical virus isolation. They are rapid to perform and in many cases more sensitive than virus isolation or antigen detection methods making earlier diagnosis possible. They have proved particularly valuable for the diagnosis of viruses that cannot be cultivated such as papillomaviruses, parvoviruses, and hepatitis viruses. Semiquantitative and quantitative applications have been developed allowing monitoring of viral load during antiviral treatment. These tests cannot distinguish between viable and replication-incompetent virus, warranting caution in the interpretation of the results in certain cases. Also, sensitivity to cross-over contamination in the laboratory has caused some problems in clinical laboratory settings.

The specificity of these tests is based on the extent of pair-matching sequences between the viral nucleic acids and the primers. Extremely high sensitivity is typical for PCR methods; 1–10 copies of viral nucleic acid can be detected in a few hours. PCR methods are available for both RNA and DNA viruses. For RNA viruses viral nucleic acid has to be transcribed with reverse transcriptase (RT) enzyme to complementary DNA (RT-PCR).

Viral nucleic acid is extracted from the sample material and amplified in three successive steps. The double-stranded DNA is first heat-denaturated and separated into single strands. The specific target fragment of DNA strand is then amplified (**Figure 3**) by pairs of target-specific oligonucleotide primers, each of which hybridize to one strand of double-stranded DNA. The hybridized primers act as an origin for heat-stable polymerase enzyme and a complementary strand is synthesized via sequential addition of deoxyribonucleotides. After annealing of the primers, extension of the DNA fragment will start. These cycles are repeated 35–40 times, each cycle resulting in an exponentially increasing numbers of copies.

After the amplification is completed, the products can be detected by several methods. Agarose gel electrophoresis combined with ethidium bromide staining of the products is a classical method (**Figure 4**). The size

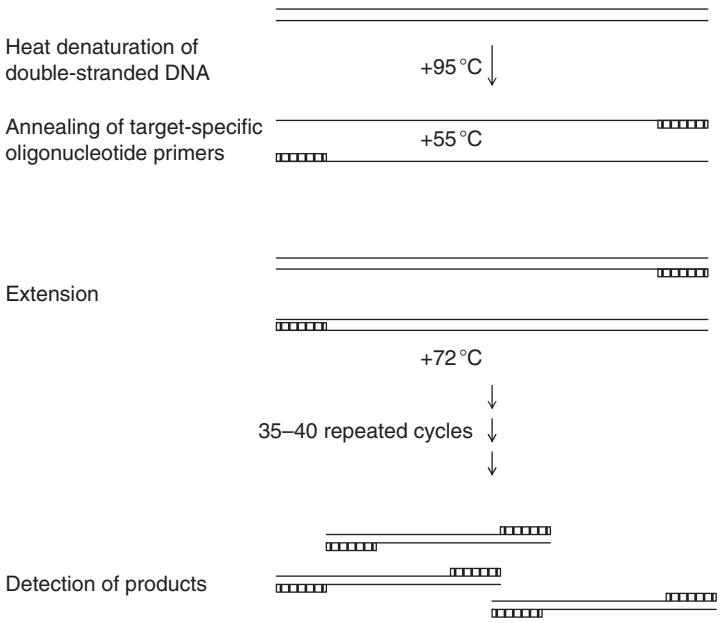

Figure 3 Polymerase chain reaction.

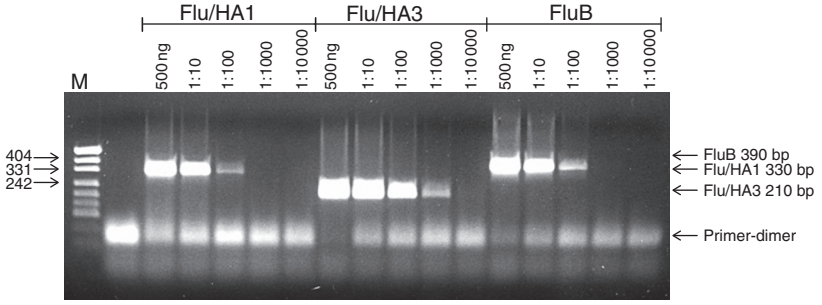

Figure 4 Detection of PCR products (amplicons) by an agarose gel electrophoresis after ethidium bromide staining.

of the amplified product is compared to control amplicons and other standards in the same gel. Various hybridization assays, based on labeled complementary oligonucleotides (probes), are also used to improve the sensitivity and specificity of the detection.

The amplified fragments can also be sequenced giving additional information about the virus. Comparison of the sequences with known virus sequences allows identification of species, strains, or subtypes that may be important for public health or medical purposes. Sequencing after RT-PCR is also the current method-of-choice for investigating the emergence of antiviral drug resistance among HIV-infected patients.

Real-time PCR instruments monitor accumulation of amplicons by measuring the fluorescence continuously in each cycle of the reaction. The earlier the amplification product becomes detectable over the background, the higher is the amount of virus in the sample (**Figure 5**). One application, based on the use of melting temperatures, allows simultaneous detection and analysis of several different nucleic acids. It also allows testing for more than one virus from the same sample (**Figure 6**).

The PCR assays are extremely sensitive and can therefore be influenced by inhibitors of the polymerase enzyme that are sometimes present in clinical samples. Internal controls can be included into reaction mixtures. Nucleases present in samples or in reagents can also cause false negative results by degrading viral nucleic acids. Furthermore, amplicons may also cause product carry-over and false positive results. Extremely high care has to be applied in handling the clinical specimens, the reagents, as well as the reaction products.

One of the great advantages of the PCR technology is its potential to detect new emerging viruses. By using primers from related viruses or so-called generic primers important information regarding the new virus can be obtained for further development of more specific tests. A good example is the severe acute respiratory syndrome (SARS) virus, for which specific diagnostic tests became available soon after the taxonomic position of the virus became known. The technology also allows safe handling and transport of virus samples, since extraction buffers added to the samples inactivate virus infectivity.

Future Perspectives

Driven by public health, scientific and commercial interests, new diagnostic tests for the laboratory diagnosis of viral infections are continuously being developed. The main area for development will probably be new molecular detection methods, where automation will provide rapid, well-standardized, and easy-to-use technology.

Use of multianalyte methods is becoming a practical reality and they might significantly change diagnostics of infectious diseases in future. They provide an opportunity to screen simultaneously for a wide range of viruses increasing the rapidity of the diagnostic procedure. A single microarray test (microchip) can contain thousands of virus-specific oligonucleotide probes spotted on a glass slide. Several kit applications for detecting viral nucleic acids and antigens or virus-specific antibodies already exist. Microarrays based on random PCR amplification can be used to detect a variety of viruses belonging to different families. Screening of some other infection markers can be also included in the same test format. Microarrays are not widely used for clinical purposes because of limited sensitivity and the difficulties of developing analytical instruments suitable for diagnostic laboratories. Another line of

Glossary

Cohort A group of similar individuals.
Dipteran A member of the insect order Diptera: true flies.
Hemipteran A member of the insect order Hemiptera: true bugs (including aphids).
Hymenopteran A member of the insect order Hymenoptera: wasps and bees.
Intergenic region Region between the two open reading frames in the dicistrovirus genome.
Lepidopteran A member of the insect order Lepidoptera: moths and butterflies.
Orthopteran A member of the insect order Orthoptera: crickets and grasshoppers.
Penaeid A shrimp from the family Penaeidae.
Picorna-like Viruses that are ostensibly like members of the *Picornaviridae*; but the term is generally used to refer to any small (*c.* 30 nm in diameter) icosahedral viruses with single-stranded RNA genomes.
Polyprotein A protein that is cleaved after synthesis to produce a number of smaller functional proteins.
Vertical transmission Transmission of virus directly from an infected mother to her offspring.
VPg A virally encoded protein covalently linked to the 5′ end of the viral genome.

Introduction

After the early 1960s, it became apparent that invertebrates, as well as vertebrates and plants, played host to a number of small (<40 nm in diameter) icosahedral viruses with RNA genomes. The initial descriptions of many of these viruses involved little more than their physical and biochemical characteristics such as diameter, density, and S-value. By the 1970s, many new invertebrate small RNA viruses were being isolated and described and even minimal characterization made it clear that new families of viruses were emerging from this assemblage of small RNA-containing viruses of invertebrates, along with apparent members of existing virus families. Two major families of viruses recognized in the late 1970s and early 1980s were the *Tetraviridae* and *Nodaviridae*. Any of the other viruses were simply considered to be 'invertebrate picornaviruses' or 'small RNA viruses of insects'.

The properties of many of the yet-unclassified viruses were found to be very similar to those of the mammalian picornaviruses. In particular, the size of the virions (*c.* 30 nm), the composition of the capsids (three major proteins of around 30 kDa), and single-stranded, positive-sense RNA genomes all suggested these were invertebrate picornaviruses and this was very much the prevalent feeling – until 1998. At this point, the first full genome sequence of one such invertebrate virus, drosophila C virus (DCV), was published and surprisingly revealed a genome organization strikingly different from the picornaviruses, and indeed quite different from any other viruses known at that time. During the next several years, the genomes of a number of insect small RNA-containing viruses were sequenced and it became clear that two organizational paradigms existed. The first group became the *Dicistroviridae* while the second has become the (currently) unassigned genus *Iflavirus*.

Taxonomy and Classification

The family *Dicistroviridae* currently comprises 12 species, most of them in the only genus recognized so far, *Cripavirus* (**Table 1**). There are a number of other potential candidates for the family but these have yet to be accepted as species by the International Committee on Taxonomy of Viruses. For the purposes of this article, we will limit our discussion to only those species shown in **Table 1**.

Biophysical Properties

Dicistroviruses appear roughly spherical under the electron microscope in negative stained preparations with particle diameters of approximately 30 nm and no envelope (**Figure 1**). The mature virions contain three major structural proteins, VP1, VP2, and VP3 of between 28 and 37 kDa, although taura syndrome virus (TSV) does appear to have one larger structural protein of 56 kDa. In many mature virion preparations, one or more minor structural components can be present which are larger than the major capsid proteins and are presumed to be the precursor(s) of structural proteins. In some viruses, a fourth smaller structural protein (VP4) – of between 4.5 and 9 kDa – is also present in the virion. A summary of the biophysical properties of dicistrovirus virions and the size and composition of the genome is given in **Table 2**.

The virions exhibit icosahedral, pseudo $T = 3$ symmetry and are composed of 60 protomers. Each of the protomers is composed of a single molecule of each of the structural proteins VP2, VP3, and VP1. The protomers are arranged so that the molecules of VP1 are set around the fivefold axes (**Figure 2**), with VP4 lying inside the virion below the molecules of VP1. Where the molecules of VP1 come together the surface of the virion shows a slightly raised crown – similar to that on the surface of poliovirus and other picornaviruses (**Figure 3**). In contrast to poliovirus, the surface of cricket paralysis virus (CrPV) does not show the characteristic deep canyon around the fivefold axes – which in the case of the former is where the receptor-binding site is known to be. The mature virions have a buoyant density in neutral CsCl of between 1.34 and 1.39 g cm^{-3} and sedimentation coefficients that range between 153S and 167S. For those viruses where physicochemical stability has been assessed, for example, CrPV, the virions are stable at pH 3.0 and are resistant to treatment with detergents and organic solvents such as ether and chloroform.

The virions contain a single molecule of linear, positive-sense, single-stranded RNA (ssRNA) of approximately 9000–10 000 nt in size. Structural studies have not revealed any ordered structure to the RNA within the virion. Terminal modifications to the RNA include a covalently linked protein at the 5′ end of the genome (referred to as the VPg) and a polyA tract at the 3′ end.

Organization of the Dicistrovirus Genome

The single-stranded genomes possess a 5′ untranslated region (5′ UTR) of 500–800 nt followed by two open reading frames (ORFs) of *c.* 5500 and 2600 nt. The ORFs are separated by an untranslated region of ~190 nt, commonly referred to as the intergenic region (IGR) (**Figure 4**).

Table 1 Members of the virus family *Dicistroviridae*. Isolate and vernacular names are shown in brackets. Accession number for whole genome sequences are also given. A recently suggested taxonomy that places ABPV, KBV, SINV-1, and TSV as unassigned species in the family is followed

Genus	*Species (isolate name)*	*Accession number*	*Abbreviation*
Cripavirus	*Cricket paralysis virus* [type species] (cricket paralysis virus)	[AUF218039]	CrPV
	Aphid lethal paralysis virus (aphid lethal paralysis virus)	[AUF536531]	ALPV
	Black queen-cell virus (black queen-cell virus)	[AUF183905]	BQCV
	Drosophila C virus (drosophila C virus)	[AUF014388]	DCV
	Himetobi P virus (himetobi P virus)	[AUB017037]	HiPV
	Plautia stali intestine virus (plautia stali intestine virus)	[AUB006531]	PSIV
	Rhopalosiphum padi virus (rhopalosiphum padi virus)	[AUF022937]	RhPV
	Triatoma virus (triatoma virus)	[AUF178440]	TrV
Unassigned species in the family	*Acute bee paralysis virus* (acute bee paralysis virus)	[AUF150629]	ABPV
	Kashmir bee virus (Kashmir bee virus)	[AUY452696]	KBV
	Solenopsis invicta virus-1 (solenopsis invicta virus-1)	[AUY634314]	SINV-1
	Taura syndrome virus (taura syndrome virus)	[AUF277675]	TSV

The virion proteins (VPs) have been shown, by direct sequence analysis, to be encoded by an ORF proximal to the 3′ end, while the more 5′ ORF encodes protein(s) that have sequence motifs lying in the order (5′–3′) Hel-Pro-Rep, a feature common among a large number of other positive-sense RNA viruses such as picornaviruses, comoviruses, sobemoviruses, caliciviruses, sequiviruses, and potyviruses.

Where present, the sequence coding for the small virion protein VP4 is in the ORF encoding the structural proteins, between the region coding for the capsid proteins VP2 and VP3 (as it is also in the iflaviruses). VP4 is cleaved from VP3 during the maturation of the virion. The VPg is encoded in the nonstructural protein-encoding region, and in most dicistroviruses there are multiple copies of the VPg coding sequence which show some degree of heterogeneity.

Virus Replication and Genome Expression

The mechanism of virus entry into susceptible cells is unknown. Initiation of protein synthesis coincides with the shutdown or downregulation of host cell protein synthesis. During infection, a large number of precursor proteins are produced which are then cleaved to produce an array of smaller polypeptides. In the case of CrPV (one of the few dicistroviruses for which a permissive cell culture system exists), the structural proteins are produced in supramolar excess relative to the nonstructural proteins. Like many positive-sense RNA viruses, no subgenomic RNAs (sgRNAs) are produced during the infection cycle.

The absence of sgRNAs indicates that the translation of ORF2 could be initiated by an internal ribosome entry site (IRES) similar to the mechanism known from picornaviruses. Experimental studies did indeed demonstrate this and that both the 5′ UTR and IGR of several dicistroviruses including CrPV, plautia stali intestine virus (PSIV), and rhopalosiphum padi virus (RhPV) can act as IRES elements to direct initiation of translation in either *in vitro* translation systems or in cultured invertebrate cells.

However, perhaps the most unique feature of the replicative strategy of dicistroviruses is the fact that translation of the structural proteins from IGR–IRES element does not require the presence of a methionine codon. Computer modeling has shown that the IGRs of all dicistroviruses have predictable stem–loop structures. While there are two basic types among the dicistroviruses (**Figure 5**), these are fundamentally the same with six stem–loops – the most 3′ of which forms a pseudoknot with the codons involved in translation initiation. The initiation of translation is thought to be mediated by the codon which forms the part of the pseudoknot with stem loop VI, immediately upstream of the triplet which encodes the first amino acid of the mature VP2 (**Table 3**). In most cases, the initiation codon is CCU (Pro) while the first codon of

Table 2 Summary of some biophysical properties of dicistroviruses

Virus	*Molecular weight of major capsid proteins (kDa)*[a]	*Buoyant density in CsCl (g ml^{-1})*	*Particle diameter (nm)*

Triatoma virus	39, 37, 33	1.39	30

[a]Minor virion components are shown in brackets. These are presumed to be precursors of VP4–VP3.

VP2 encodes an alanine residue (**Table 3**). It has been shown experimentally that the glutamine at the 5′ end of PSIV VP2 can be replaced with any other amino acid to produce a mature protein in an *in vitro* translation system.

Where cell culture systems are available, pulse-chase studies have shown that translation of dicistrovirus genomes results in the production of polyproteins that are then cleaved to produce the structural and nonstructural proteins. For the virion proteins of some dicistroviruses, the cleavage sites between proteins in the structural polypeptide have been experimentally determined and are shown in **Table 3**. These sites show some degree of conservation and point toward the involvement of cysteine proteases. While the viruses themselves encode cysteine protease-like peptides in the nonstructural region there is also some evidence, for CrPV at least, that host-cell-encoded proteases may also be involved in the processing of viral polypeptides.

(2005) *Virus Taxonomy*: *Eighth Report of the International Committee on Taxonomy of Viruses*. San Diego, CA: Elsevier Academic Press.

Host Range

To date, all members of the *Dicistroviridae* have been isolated from invertebrates, generally from a single species, or at most three closely related species. The hymenopteran viruses, acute bee paralysis virus (ABPV) and black queen-cell virus (BQCV), are known only from honeybees (*Apis mellifera*) but Kashmir bee virus (KBV) has also been isolated from the Asiatic hive bee *Apis dorsata*. It should also be noted that ABPV and KBV have been identified in the parasitic mite *Varroa destructor*, although there is no clear evidence that the virus is capable of replicating in this host. Solenopsis invicta virus-1 (SINV-1) is only known to infect the ant species, *Selonopsis invicta*.

Dicistroviruses found in homopterans and hemipterans (which includes aphids and true bugs, respectively) have slightly broader host ranges. RhPV has been isolated from laboratory and field populations of the aphids *Rhopalosiphum padi*, *R. maidis*, *R. rufiabdominalis*, *Schizaphis graminum*, *Diuraphis noxia*, and *Metapolophium dirrhodum*. Aphid lethal paralysis virus (ALPV) has only been isolated from aphids, but in this case from only three species: *R. padi*, *M. dirrhodum*, and *Sitobian avenae*. Himetobi P virus (HiPV) and PSIV are found in true bugs rather than aphids with HiPV having been isolated from the leafhoppers *Laodelphax striatellus*, *Sogatella furcifera*, and *Nilaparvata lugens*, and PSIV from the brown-winged green bug, *Plautia stali*. Triatoma virus is also a virus of hemipterans and has been found in the hematophagous triatomine bug, *Triatoma infestan*, which is also a vector of the protozoan agent that causes Chagas' disease in South America.

DCV is the only dicistrovirus with a host range restricted to dipterans and has been isolated from *Drosophila melanogaster* and the sibling species *D. simulans*. TSV is a virus of penaeid shrimps and has been isolated from a number of species including *Litopenaeus vannamei*, *L. stylirostris*, *Metapenaeus ensis*, and *Penaeus monodon*. The majority of the dicistroviruses have relatively restricted host ranges and, at most, have only been isolated from insects of a single order. CrPV is the striking exception. Originally isolated from the field crickets *Teleogryllus*

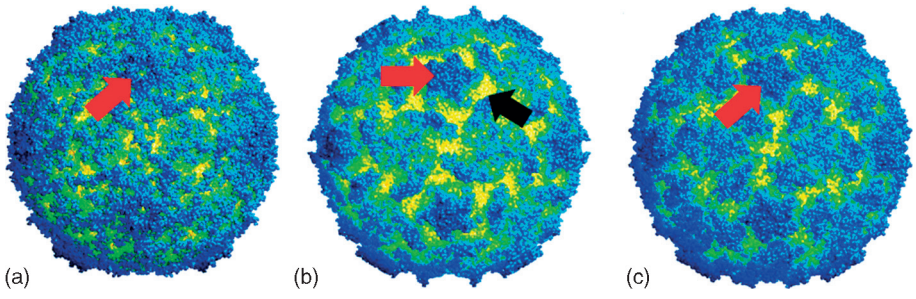

Figure 3 The surface structure of (a) CrPV, (b) poliovirus, and (c) rhinovirus 14. The red arrows show the raised crown around the fivefold axes and in poliovirus the black arrow indicates the deep canyon around this raised crown. Courtesy of John Tate.

oceanicus and *T. commodus*, CrPV has subsequently been isolated from a further 20 species belonging to five taxonomic families: *Orthoptera*, *Hymenoptera*, *Lepidoptera*, *Hemiptera*, and *Diptera*. Interestingly, while a number of other RNA-containing viruses are known from lepidopterans (moths and butterflies), that is, the iflaviruses and tetraviruses, as well as a number of uncharacterized viruses, CrPV is the only dicistrovirus isolated from lepidopterans – in fact from ten lepidopteran species.

All of the above records refer to the natural host range of the viruses. To a certain extent, studies on the experimental host range of dicistroviruses are limited and those that have been carried out have not substantially extended the known host ranges. Again the exceptions are CrPV and DCV. CrPV replicates in a number of established insect cell lines including those from *Drosophila*, the hemipteran *Agallia constricta*, and the lepidopterans *Pieris rapae*, *Plutella xylostella*, *Spodoptera ornithogalli*, and *Trichoplusia ni*. In addition to insect cell lines, CrPV has also been found to replicate readily in larvae of the greater waxmoth, *Galleria mellonella*. This is an easy insect to rear and maintain and virus yields can be very high. Apart from CrPV, the only other dicistrovirus shown to replicate in cultured cells is DCV, which multiplies in several *Drosophila* cell lines (some DCV isolates also replicate in the greater waxmoth). Reports that TSV can replicate in some mammalian cell lines have never been substantiated and may simply be attributable to the production of a cytopathic effect in the absence of virus replication.

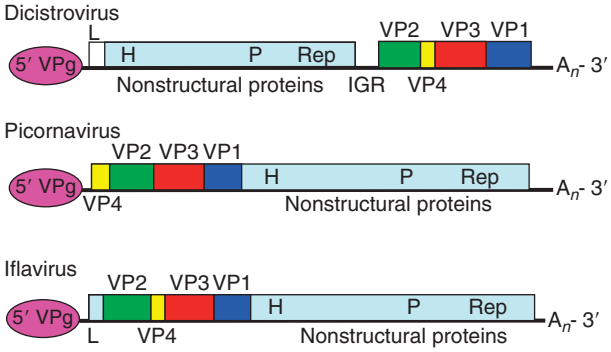

Figure 4 Diagrammatic representation of the genomic arrangement of the dicistroviruses, picornaviruses, and iflaviruses. The helicase (H), protease (P), and replicase (Rep) domains of the nonstructural proteins are indicated.

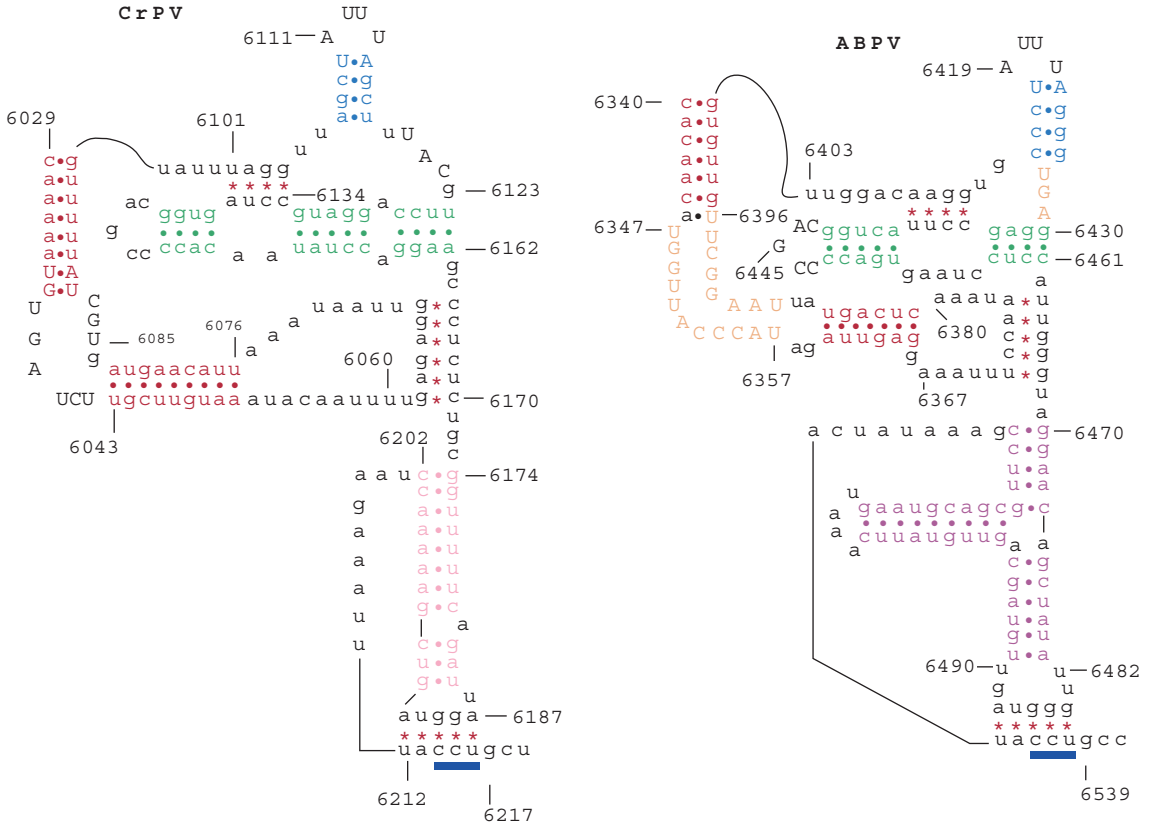

Figure 5 Predicted structure of the IGR–IRES elements of dicistroviruses. The structure represented by that of CrPV is shared by most dicistroviruses with the exception of ABPV, KBV, SINV-1, and TSV that have a structure similar to that represented by ABPV. The stem loop VI pseudoknot stuctures are shown in pink for CrPV and in purple for ABVP. The first translated codon is underlined in blue. Adapted with permission from Nobuhiko Nakashima.

Table 3 Some properties of the translation and processing of the structural polyprotein of the dicistroviruses. Only cleavage sites that have been empirically deduced from sequencing of the virion proteins are shown

Pathology and Transmission

The names of several of the dicistroviruses imply that virus infection can produce a noticeable disease symptom, that is, CrPV, ABPV, ALPV, and BQCV (potential queens die as propupae or pupae in hive cells in which the walls turn black). However, the majority of virus–host interactions produce no noticeable disease. Although BQCV kills some queens in their cells, most infected larvae, pupae, and workers appear to be completely unaffected.

Nevertheless, while disease symptoms may not be evident, in most of the cases studied, dicistrovirus infections reduce the life span of the infected individual. Or, more precisely, the presence of a dicistrovirus in a cohort (group of similar individuals) of insects coincides with a reduced life span relative to an uninfected cohort. This point is explicitly made since no studies have yet been undertaken where an invertebrate host has been nonlethally sampled for virus through its life span. In many other virus–host systems, for example, plants, mammals, or even fish and amphibians, it is possible to sample for virus without killing the host so the progress of infection can be measured at the level of the individual. With invertebrates, this has not been done and would generally be very difficult or impossible. The experimental approach has therefore been to introduce the virus into an uninfected cohort and compare the effects to a control cohort.

Despite these practical limitations, a number of studies have demonstrated the routes of virus transmission. BQCV has been detected in the eggs, larvae, and offspring of queens that were found to be infected – indicating that the virus is vertically transmitted. Similar findings have been made with ALPV which can be vertically transmitted in the aphid host, *R. padi*; this infection subsequently results in reduced longevity and fecundity. It has also been shown that ALPV RNA can be detected in the developing embryos inside infected females.

DCV is also vertically transmitted although virus is not present in the cytoplasm of the egg but is associated with the chorion on the egg surface. Infection presumably occurs when emerging larvae ingest the virus since they do not become infected if the chorion is removed. A similar phenomenon is found with CrPV and *T. oceanicus* where surface sterilization/dechorionation of eggs with dilute hypochlorite blocks the transmission of the virus to emerging nymphs.

Evidence of horizontal transmission is in many respects even more difficult to obtain than data on vertical transmission. However, experimental feeding studies indicate that dicistroviruses can be transmissed horizontally. In the case of triatoma virus (TrV) and its host *T. infestans*, infected insects excrete virus in their feces and since triatomine bugs are coprophagous and TrV is infectious *per os*, the virus can be readily spread. With DCV, it has been found that when uninfected males are placed with uninfected females, these males become infected (and vice versa). In fact, even if uninfected female flies are placed on media on which infected males have been allowed to feed for several hours, the females become infected. Such manipulations with other virus and invertebrate host systems are not as easy as those involving *Drosophila*, as it is difficult to obtain colonies free of viruses and the insects are not as easy to manipulate in the laboratory.

Evidence of vectors playing a role in dicistrovirus transmission is limited to honeybee viruses and their parasitic mite, *Varroa destructor*. It has been known for some time that the prevalence of a number of honeybee viruses increases in the presence of varroa mites. Initially, it was thought that the stress caused by varroa infestation induced the viruses to replicate. However, recently it has been shown that ABPV and KBV can be detected in mites implicating them more strongly in transmission of the viruses. In contrast, BQCV, although present at high

frequency in adult honeybees, has not been detected in mites, suggesting that they play little or no role in transmission.

Geographic and Strain Variation

Some dicistroviruses infect specific hosts with a wide geographic distribution or have been found to infect a number of species spread over a large geographic range. Several studies have looked at strain variation between geographic isolates of dicistroviruses using a variety of techniques. CrPV and DCV possess a range of biological and serological characteristics that show differentiation between geographical isolates. With CrPV, two major serogroups have been identified that separate Australian and New Zealand isolates from North American isolates. With DCV, isolates from different localities varied both in their pathogenicity and virus yield after injection into virus-free flies. Additional genetic studies on CrPV and DCV have utilized ribonuclease T1 fingerprinting and subsequently polymerase chain reaction restriction endonuclease analysis. Estimates of the maximum nucleotide divergence between isolates of CrPV and DCV were about 10%. In the case of CrPV, it was found that that the North American isolates were quite distinct from the antipodean isolates, a finding which reflects the serological data.

More recently, a number of molecular studies with the honeybee dicistroviruses and TSVs have been undertaken to determine the levels of genetic variation between isolates of these viruses. In most instances, slightly different regions of the virion protein coding regions (usually regions of VP3) have been used, which makes direct comparison between studies quite difficult. Nevertheless, ABPV isolates show levels of nucleotide identity between 90% and 100%, but isolates from the same geographic region are more closely related than isolates from more distant locations. One such study has revealed that viruses isolated from different central Europe regions were more similar to each other than to isolates from North America or from the UK. Similar patterns are also evident for BQCV and KBV with nucleotide identity within species at 90–100%. To put these values in perspective, the region used for the KBV studies is *c.* 75% identical to the same region from ABPV.

For TSV, the situation is slightly different, and it has been found that levels of nucleotide identity between isolates from North and Central America and Asia range from 95% to 100%. These lower levels of diversity may indicate that TSV has rapidly spread into many of the regions and hosts where it is now found – a hypothesis that is supported to some extent by the rapid emergence of the disease over the last two decades. There is also some evidence that there are serological differences between isolates.

Relationships within the Family

The taxonomy of the dicistroviruses currently recognizes only one genus, *Cripavirus*, into which most of the species are placed. However, comparisons of the coding sequences of the dicistroviruses reveal that they are only distantly related. For instance, the amino acid identity between the structural polyproteins of different species ranges from 19% to 66% while the amino acid similarity ranges from 37% to 80%. Using these data, the phenogram presented as **Figure 6** shows the pattern of relationships and reveals only two closely related pairs of species: CrPV and DCV (which also share a serological relationship) and ABPV and KBV. All other species are only distantly related. While the genus *Cripavirus* is currently proposed to include all but ABPV, KBV, SINV-1, and TSV, this genus will probably be divided and new genera established to accept the currently unassigned species listed above.

Similarity with Other Taxa

The dicistroviruses share various properties with a number of other positive-sense ssRNA virus genomes. Historically, these viruses have been collectively grouped as the picornavirus superfamily which has been considered to include the virus families *Comoviridae*, *Picornaviridae*, *Potyviridae*, *Sequiviridae*, *Caliciviridae*, and more recently the unassigned genera *Iflavirus*, *Sadwavirus*, and *Cheravirus* and the recently created family *Marnaviridae*. In all of the groups mentioned above, the gene order for the nonstructural proteins is the same, viz. Hel-Pro-Rep (as in **Figure 4**). When compared to other positive-sense viruses, these genes appear to be more closely related to each other

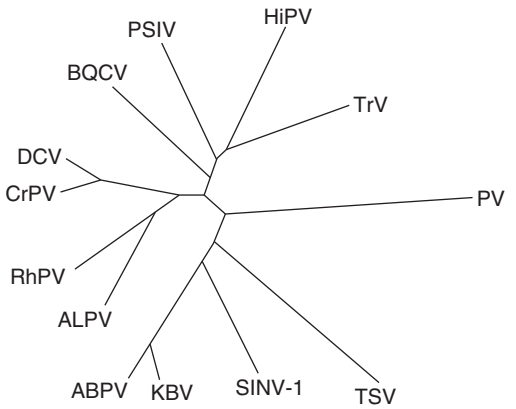

Figure 6 Phenogram showing the relationships among members of the family *Dicistroviridae,* constructed from the amino acid identity of the structural proteins encoded in ORF2. The phenogram was constructed using the neighbor-joining algorithm of the MEGA software. The sequence from Poliovirus type 3 [L23844] was used as an outgroup for the analysis. Branch lengths are drawn approximately to scale.

than to genes from other viruses, for example, coronaviruses, toroviruses, and tetraviruses. However, there is a subset of the above taxa which shares a larger set of properties: for example, isometric virus particles with pseudo $T = 3$ symmetry (formed of three units of eight-stranded β-barrel); the absence of sgRNAs during replication; and the presence of a 3–4 kDa VPg. On the basis of these properties, the grouping would exclude the *Caliciviridae* (sgRNAs, large VPg, and true $T = 3$ symmetry) and the *Potyviridae* (large VPg, rod-shaped particles with helical symmetry).

There are also a large number of other isolates of invertebrate picorna-like viruses that share some properties with dicistroviruses, for example, single-stranded postive-sense RNA genomes, isometric virions of around 30 nm in diameter, and up to three virion proteins of around 30 kDa. Further studies will undoubtedly reveal additional structural and organizational paradigms among the yet uncharacterized picorna-like viruses of invertebrates besides increasing the number of known dicistroviruses.

Glossary

Case–fatality rate Number of persons dying of an infection divided by total number of persons with the disease. Thus, CFR of 5% means that 5 of 100 persons with the infection died.

Epidemic and outbreak Most infectious disease epidemiologists do not distinguish between these terms and use them interchangeably. Generally, an outbreak is defined as a localized increase in cases, whereas an epidemic is more widespread, perhaps affecting a whole country.

GUM clinics The term GenitoUrinary Medicine clinics is often used for special clinics for sexually transmitted infections (STIs).

Incidence The rate of new infections (number by population) in a given time – for example, 5 cases of influenza per 1000 per year. Good for short-term infections.

Outbreak When an infection occurs at a frequency higher than expected for that time or place. It is basically an increased incidence which is usually unexpected. Two linked cases is also theoretically an outbreak.

Pandemic This term should be restricted to infections affecting many countries, though it does not have to be worldwide. SARS spared many countries and indeed some continents, but it was a pandemic. AIDS is undoubtedly a pandemic.

Prevalence The number of infections at any one time in a given population, expressed as a rate. Good for chronic infections and serological studies (e.g., prevalence of varicella antibody at age 15 in a given population is 95%).

Introduction

Surveillance is undoubtedly an essential – indeed critical – ingredient of any disease control program. It is used to monitor the impact of an infection, the effect of an intervention or health promotion strategy, health policy, planning, and delivery. Surveillance is the ongoing and systematic collection of routine data which are then analyzed, interpreted, and acted upon. It is essentially a practical process, which nevertheless can be useful in other ways. Its main purpose is to analyze time trends – but these can include not simply fluctuations in overall numbers, but also changes in age and sex distributions, geographical locations, and even possibly, in some of the more sophisticated established surveillance systems, at-risk groups (such as particular social, ethnic and

occupational groups). Surveillance is essential for evaluating the impact of an intervention, such as mass vaccination, on a population. It can be a fairly sensitive system for the detection of outbreaks earlier than they would have been recognized otherwise.

The word ongoing in the description of surveillance helps to distinguish it from a survey, which is usually finite, tends to focus more on one or more groups of persons, and involves a questionnaire. Nevertheless, surveillance does not have to continue forever – when it is no longer useful, it should be stopped.

To be systematic is another important ingredient of surveillance. If reporting centers are not consistent in what they report, nor regular, the data they send in will be uninterpretable, and probably useless. Defining what needs to be reported and agreeing on the criteria for making a reportable diagnosis are necessary to make sense of the data.

The collection of routine data is another important characteristic of surveillance, especially with surveillance of laboratory infections. Generally, testing of samples is done for diagnosis, not primarily for surveillance. As laboratory testing is expensive, making further use of the results by contributing to surveillance makes for more efficient use of information, and the contribution to surveillance itself can often justify further testing. Typing echoviruses or coxsackie viruses can seldom be justified on clinical grounds alone, but the surveillance of serotypes can provide valuable information on the epidemiology of these viruses, their clinical characteristics, seasonality, and age and sex distributions. Echovirus 4 for example tends to be rare, fairly localized even within a country, but, when it occurs, it has a high aseptic meningitis rate, and causes a short and sharp autumn outbreak. Echovirus 9 on the other hand is far more common, more widespread geographically when it causes an epidemic, more benign, with a macular rash, and with meningitis not an especially common manifestation.

Although surveillance is essentially a practical exercise, this article attempts to show that surveillance can also be useful in giving us clues about an infection, whether it be its natural history, etiology, severity, or outcome.

Collection of Data: Sources of Data in Surveillance of Viruses

Death Certification

In most developed and middle-income countries, deaths are certified primarily for legal reasons, but have proved to be an important data source to use for surveillance. Clearly, they tend to be useful mainly for serious infections, and may suffer from inaccuracies, but remain a useful basic data source. Diseases with a high mortality rate and a short duration of illness (the viral hemorrhagic fevers for example) will obviously be better represented by death certification, than those with a low mortality. HIV/AIDS, before the era of HAART, had a high mortality but long periods of symptomless and symptomatic infection, so that death certification data needed careful interpretation. Laboratory reporting systems can be another useful source of information on mortality from infection.

Notifications

Surveillance systems such as statutory notification tend to be based mainly on clinical features. These can be very useful for common diseases with distinctive clinical syndromes, such as measles and mumps. It is important however not to make a disease notifiable unless there is a good reason for it: 'good' reasons include a mass vaccination program (when surveillance is virtually mandatory), any other mass control program, serious diseases for which contact tracing, mass or close contact prophylaxis, or investigation into source, is necessary. Serious less common viral infections such as poliomyelitis are notifiable in most countries. This is because contact tracing and preventive measures can be taken. Broader clinical diagnoses, such as aseptic (viral) meningitis, may on the face of it be less useful to notify, as it is usually impossible at the bedside to distinguish such causes of it as, for example, the coxsackie B viruses, echoviruses, and mumps. Nevertheless, notification of aseptic meningitis can be useful because a rapid rise in notified cases may need to be investigated. Moreover, the timing of any epidemic may give a clue to etiology – mumps meningitis tends to increase in spring and is usually accompanied by a concurrent outbreak of clinical mumps, while enterovirus epidemics are more likely to occur in autumn.

Other Clinical Sources of Data

Specific general practitioner (GP) surveillance systems are useful to provide data of epidemiological value for infections that are not notifiable, such as the common cold or chickenpox (in UK). They are of course clinically based, but are nevertheless useful, and often surprisingly accurate, possibly because those GPs who subscribe to a surveillance system are motivated to do so. GP surveillance systems are often sentinel-based, that is, based on a sample of GPs in a country, region, or area. Thus, they are good for common infections which to make notifiable would possibly be wasteful, for example, chickenpox. Moreover each sentinel would normally provide complete reporting. In the English system, GPs provide data on the base populations of their practices, so that rates of infection can be provided as a routine, a feature that is almost unique among surveillance systems. GP surveillance systems also tend to be good for timeliness and completeness.

Laboratory Data

It is useful to think of laboratory data as being of qualitative rather than quantitative value as they add quality and detail to disease surveillance. Thus, in the example already used for aseptic meningitis, a precise diagnosis of mumps, echovirus, or coxsackie type is particularly useful in clustering and outbreaks. Indeed, as the enteroviruses exhibit a strong late summer/autumn seasonal pattern with each enterovirus returning to its baseline in winter, when numbers of a particular type continue to be reported at a level higher than the winter baseline, the return of this virus to cause another epidemic in the following summer can usually be safely predicted. Laboratory data are also essential in qualifying food poisoning and gastroenteritis. Separating viral from bacterial causes is a useful first step, as their management tends to be very different. Norovirus gastroenteritis can be food-borne, but also spreads very easily from person-to-person because an extremely small dose is necessary for infection to occur, and the virus being fairly resistant to the environment will survive for some time. Management therefore must concentrate on hygiene. With most bacterial causes of food poisoning, especially the salmonellas, management often depends on the removal of the offending food. Laboratory surveillance is particularly essential for unraveling the mass of respiratory viral infections that inflict humans – respiratory syncytial virus, adenoviruses, parainfluenza viruses, rhinoviruses, etc. Indeed, it is particularly useful for influenza – not only separating it from influenza-like illness, but also in identifying influenza A and B, and if A, the subtype and variant.

Surveillance of Outbreaks

Surveillance of outbreaks (as opposed to individual infections) can be revealing, and important to allow public health measures. The existence of the noroviruses was suspected in the UK many years before the organisms were identified.This was because some outbreaks which did not fit the characteristics of known infections but had characteristics of their own had occurred.

Hospital Admissions

These can be useful for certain more serious infections, such as hepatitis and encephalitis. They can be unwieldy, generally lack detail, and often are published a year or more after the events have occurred.

Serological Surveillance

Serological surveillance has become increasingly important, and is a useful tool in assessing the immunity of a population, though it can also be used to identify vulnerable individuals. The immunity of a population can be vaccine-induced, and serological surveillance is a valuable adjunct to the methods available to monitor a mass immunization program. Vulnerable age groups can be identified, and booster doses of the vaccine introduced. An example of the importance of serological surveillance in determining public health policy is included below (analysis by person).

Surveillance of Viruses in Nonhuman and Environmental Sources

To build a picture of an infection, animals, birds, and the environment have been placed under surveillance. Rabies in foxes and other wildlife, influenza in birds, pigs, and other animals, are examples of important and fairly successful surveillance systems.

Other Sources of Data

Records of sickness absence, absence from school, calls to an emergency room, if available, can provide speedy information that something has happened, but tend to be nonspecific. Surveillance of antiviral resistance will become important.

Surveillance of HIV/AIDS

The association of HIV/AIDS with stigma makes surveillance of this infection especially difficult. The uniqueness and seriousness of this infection warrants a separate section. It is an example of the importance of tailoring surveillance to a specific serious infection if it becomes necessary to do so.

In the UK and some other countries with data protection acts, HIV infection, as with other STIs, is not notifiable. Special confidential surveillance systems through clinicians and GUM clinics, as well as laboratories, are in place. These are especially important for assessing risk factors. Inclusion of risk factors is essential for targeted intervention – for example, the proportions and rates of new diagnoses attributed to men who have sex with men, heterosexual sex, mother-to-infant, blood transfusion, IVDUs, and other needlestick injury.

Laboratory reporting is essential. Death certification is useful, though it has been shown that men who have sex with men, and probably those with other risk factors, are under-represented. In the UK, matching reported cases with death certificates is very important, as it allows for detection of deaths due to AIDS (such as pneumonia) as well as deaths associated with AIDS, and which are seen now in HIV-infected individuals – these include liver and cardiovascular disease, overdoses, and malignancies.

A surveillance system, based on unlinked anonymous testing of samples of blood taken routinely from certain at-risk population or occupational groups has been shown to provide valuable information on HIV infection in these populations. Specific screening systems for blood donors, military recruits, commercial sex workers, and family planning/termination of pregnancy clinics are also useful if these populations are to be targeted. Behavioral surveillance should also be seriously considered, to assist in identifying future trends, healthcare planning, as well as for specific health promotion efforts.

Attributes of Surveillance Systems

Completeness

Incompleteness is an almost universal drawback of most notification systems. They should never be dismissed for this reason alone. Statutory notification systems can be essential for surveillance and control. For common infections completeness may not be worth striving for, because notifications (assuming consistency in reporting) will generally provide information on trends, as well as fairly accurate information on age, sex and seasonal distributions, and possibly on place. The effect of mass vaccination programs can also be monitored fairly closely with statutory notification systems, as with measles (**Figure 1**) and acute paralytic poliomyelitis (**Figure 2**) in the UK. When a mass vaccination or other universal control program reduces the incidence of an infection to low levels, completeness becomes much more essential. For serious infections also, such as SARS or Lassa fever, for which contact tracing or other control measure is necessary, completeness is essential.

In active surveillance, reporters make negative returns if they have had no cases during the reporting period, to ensure completeness. In some countries, enhanced surveillance has been used to assess more accurately the true incidence of an infection – regions or districts are chosen to report all cases of a particular infection or infections. It is a hybrid of active and sentinel surveillance.

Timeliness

Timeliness is important for infections for which urgent public health measures have to be undertaken, such as poliomyelitis and viral hemorrhagic fever, as well as any outbreak. In some instances, infections, not normally urgent, can become so as an elimination program progresses. In a country with elimination of measles as its goal, a case of indigenous or imported measles needs to be dealt with urgently, as it may lead to an outbreak if not controlled immediately. Laboratory data are often not timely, and hospital data generally even less so, but can make up in accuracy what they lose in timeliness.

Accuracy

Accuracy is clearly important, though some minor degrees of inaccuracy can be tolerated in some common infections. Clinical data are most liable to have some inaccuracies, though even laboratory data can be inaccurate. Case definitions and quality control systems can be useful to improve accuracy.

Representativeness

For surveillance to provide an accurate picture of the impact of a particular infection, representativeness is essential. It is perhaps the most important quality for any surveillance system. Having a wide coverage of reporting clinicians and laboratories, or a well-chosen sample of sentinel sites, is necessary for the data collected to be representative of an infection in a country. Sometimes it may be necessary to assess data from various sources, such as notifications/GPs (clinical), hospital, laboratory, and death certificates.

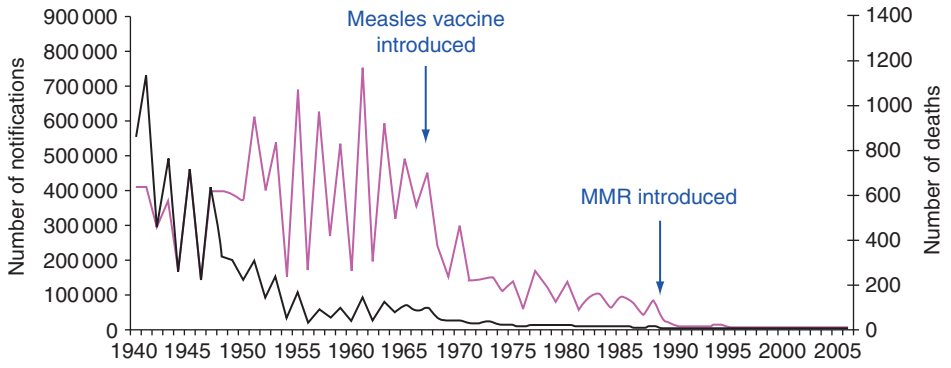

Figure 1 Measles notifications: cases and deaths, England and Wales 1940–2006. Reproduced from the Health Protection Agency (www.hpa.org.uk).

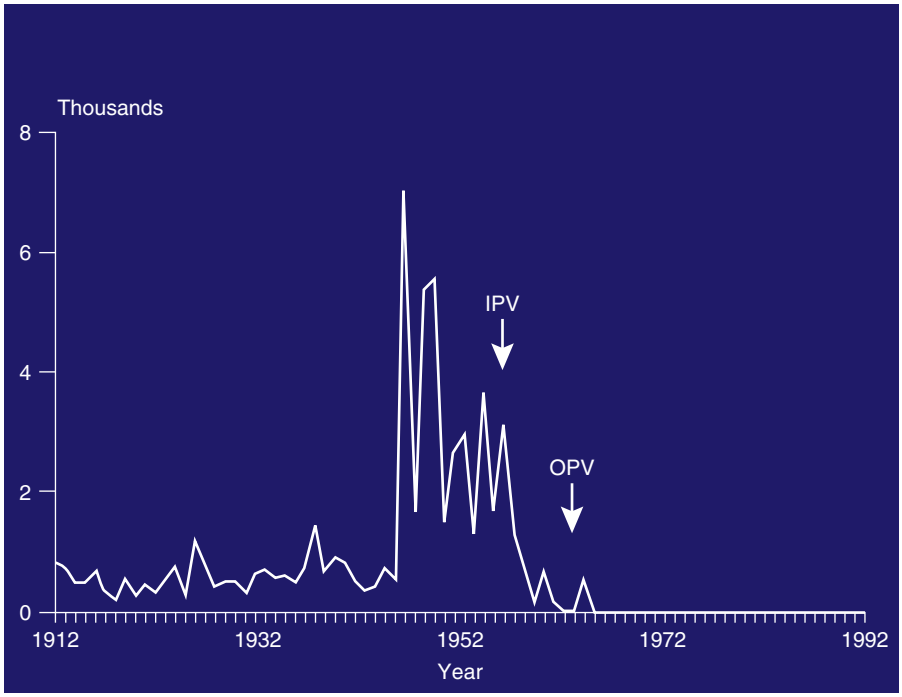

Figure 2 Notifications of acute poliomyelitis in England and Wales 1912–93. Reproduced from the Health Protection Agency (www.hpa.org.uk).

Consistency

Consistency is another crucial basic attribute of any surveillance system. Reporters must know what to report (case definition) and how often. Otherwise it will not be possible to interpret trends.

Analysis of Data

Time

The three basic analyses by time, place, and person should be routine. Computer programs have made analyses of data quicker but somewhat less flexible. There is no standard period for analysis by time. Depending on what the surveillance intends to show, yearly, quarterly, monthly, four-weekly, or weekly time intervals can be used. In surveillance, time intervals shorter than this are rarely used. Monthly intervals have the disadvantage of having unequal number of days in each month, and are difficult to use when reporting is weekly; for seasonal trends four-weekly periods are better but cannot be divided into quarterly periods. In viral surveillance, four-weekly rather than weekly intervals tend to be most useful in showing seasonal changes. There is more likely to be more variation ('noise') in weekly intervals, making for less smooth changes. For secular trends, quarterly or annual intervals are generally used. Analyzing by time can reveal regular changes in the periodicity of viruses, enabling some of them to be predicted.

A basic knowledge of seasonal and secular patterns makes it easier to detect changes that signify a possible epidemic, and to differentiate these from a random variation. It is important to remember when analyzing laboratory data that there is often an interval, which can be 2 weeks or more, between date of onset and date of reporting.

Person

Analysis by age and sex is another basic analysis in surveillance. It can identify those most affected, and vulnerable groups. Changes in age distributions may provide important clues about a changing viral infection, and the effect of mass interventions on the age distribution of an infection can be monitored. Changes in the age distribution of measles in 1994 in the UK signified that an epidemic in older children was imminent, and the vaccine schedule was changed to include an extra booster injection (MR) to children aged 5–16 years. This averted the outbreak and the booster dose became a permanent feature of the routine immunization schedule in the UK. Indeed the changes in age distribution following mass vaccination could be considered an epidemiological side effect of mass vaccination. Requests for occupational groups and travel histories should be selective. For poliomyelitis, SARS, dengue, and the viral hemorrhagic fevers, travel histories are required. Occupational group may be useful for norovirus, and hepatitis types A, B, or C. Specific risk factors may be worthwhile for HIV, hepatitis B and C.

Place

Analysis by place can pinpoint local outbreaks. Some echoviruses (e.g., echovirus type 4) can cause rare short local outbreaks, other types (e.g., types 9 and 11) are more common and more widespread. Food-borne outbreaks of hepatitis A are generally picked up locally through routine surveillance, but sometimes more extensive outbreaks caused by a more widely distributed foodstuff, including shellfish or frozen soft fruit, may be identified.

Interpretation

Collection and analysis are generally routine functions; skill is required in interpretation of the data. No statistic is perfect, and surveillance data, like all data, must be interpreted with caution. One must take into account the origins of the data – clinical, laboratory, or hospital. Not only must the reliability, or otherwise, of the data be evaluated, but what the data signify in the natural history of the infection must also be recognized.

Every viral infection has its stages and these must be recognized before surveillance data can be sensibly interpreted. At what stage are the data being collected important to understanding and interpretation? Using influenza or hepatitis A as examples, and a defined population (**Table 1**), only a proportion of persons in the defined population will be infected with the virus. They can only be comprehensively detected by screening, and serological surveillance will identify these persons, or assess population immunity (B1 in **Table 1**). In HIV/AIDS surveillance, unlinked anonymous testing of samples of blood taken routinely at say, an antenatal clinic, can give vital information on the prevalence of HIV infection, since in this infection, presence of antibody denotes infection, not immunity. A smaller proportion will be ill (B2), but only some of these will visit a doctor (B3). Surveillance systems based on GP consultation rates have now been recognized as an important addition to the spectrum of a disease, and many countries have excellent systems. Of those patients that do visit their family doctor, only some will be admitted to hospital (B4). Finally, only some will die (B5).

For laboratory data, the stages are slightly different (**Table 2**), but still important to understanding what the reported data mean. As before, only a proportion of persons will be infected (B1), a smaller proportion will be ill (B2), and a smaller proportion still visit their doctors (B3). Not all doctors will send specimens to a laboratory (B4), and only a proportion of these specimens (B5), depending on accuracy of the identification process, the method of transport, the fragility of the organism, and the swabbing or other sampling technique, will be positive. Finally, depending on the level of consistency of reporting, only some of these will be reported (B6). It is important to recognize these stages in interpreting surveillance data.

It is important moreover to recognize the biases that will inevitably occur between these stages. Collection of data in routine surveillance is not normally a scientific process as one has to rely on readily available data – data obtained mostly for other reasons, such as to make a definitive diagnosis. Only the most severe cases die, and death certification thus provides, at best, a limited view of any disease. Similarly, only certain types and severity of cases will be admitted to hospital (some admissions are for social reasons for example) or even visit their family doctor. Certain age, sex, and perhaps social or occupational groups are more likely to seek medical help, be investigated and be reported. In laboratory data, more severe cases, or children, are perhaps much more likely to be investigated in detail.

These shortcomings of surveillance data do not make them useless – but their strengths and limitations must be recognized.

Feedback

If interpretation is turning statistics into information, feedback is getting the information across to those that matter, and those that need to know, so that action – the objective of surveillance – can be taken. Without feedback, surveillance is pointless. Feedback is most likely to be informative if undertaken by those most closely involved in the surveillance cycle, and who understand the significance of the data they are receiving.

Feedback should be aimed at contributors and those in public health. Contributors will then be aware of which viruses are circulating and this will help them to know what to look for in their own tests (e.g., what echovirus or

5. Symptomatic, specimens positive
6. Symptomatic, specimens reported to surveillance system

adenovirus types are in circulation). Moreover, routine surveillance will undoubtedly uncover outbreaks of infection, which will need further investigation and control at local, national, and even international level. An interesting side effect of a flourishing microbiological/feedback surveillance system is that it often stimulates better quality control within reporting laboratories.

Regular feedback is helpful, not only to contributors, but also to those who can act for the public health. Generally, the periodicity of feedback should reflect the frequency of reporting – weekly feedback for weekly reports for example. Regular topic-based reviews are important.

Evaluation of Surveillance

A surveillance system is like a country's train system. Once the rail lines have been built, the goods that will be carried along those lines can be changed according to need. Similarly, in a surveillance network, once the lines of communication have been laid down, the data being reported can be changed according to what is most important at the time (though probably not too frequently). Nevertheless, surveillance systems should ideally be frequently evaluated for usefulness, as well as for accuracy, efficiency, and effectiveness.

They should also be sufficiently flexible, so that 'new' or emerging infections can be included in an emergency or when the need arises. The successful implementation of international surveillance for SARS was instrumental in controlling it. Emergency surveillance was also essential following the tsunami of 2004, and is also necessary for the successful management of other disasters following earthquakes, hurricanes, and floods.

Surveillance systems should be evaluated before they are set up, and again at regular intervals thereafter. Before implementing a surveillance system, is there an adequate public health and administrative infrastructure in place to take action? Are the data to be collected representative and sufficiently timely for the specific infection? Are they useful, and is action being taken on the information? If not, is the feedback inadequate?

Global and International Surveillance

The ease of modern travel, the distribution of goods (especially foodstuffs) across increasingly wide parts of the world, and the uncontrollable spread of birds and other wildlife across boundaries has made global and international surveillance essential for outbreak and infection control. Surveillance of influenza now requires the expertise of many professionals – epidemiologists, virologists, and vaccinologists, clinicians, statistical modelers, veterinarians, managers, and planners – in many different countries so that information can be exchanged, and attempts made on a global basis, to prevent the next pandemic. Only recently, a new variant of chikungunya virus jumped from Kenya, where it seems to have started, to islands in the Indian Ocean and hence to India. It has now, in 2007, even reached Italy. In Reunion alone, it affected 265 000 people, an astoundingly high incidence of 34%, and an estimated case-fatality rate of 1/1000. In India 1.3 million persons are thought to have been affected (so far, to February 2007).Two species of mosquito have been involved, *Aedes aegypti* and *A. albopictus*. Epidemics of dengue and West Nile virus have also spread widely recently. AIDS/HIV was destined to become a global problem almost from the time of its first discovery. On a more positive note, SARS was contained through the use of international surveillance; and surveillance was the backbone of the smallpox eradication program.

International surveillance can also be used for the detection of international outbreaks of food poisoning caused by the distribution of foodstuffs across a wide number of countries. An outbreak of hepatitis A in England was caused by frozen raspberries grown and frozen in another country and another outbreak of hepatitis A, this time in Czechoslovakia (before it became separate republics) was caused by strawberries used to make ice cream; the strawberries had been imported from another Eastern European country. There are now well-established trans-European surveillance systems for salmonella infections and legionnaires' disease.

The need for surveillance will never diminish or disappear. Surveillance systems will only improve, become increasingly sophisticated, and become increasingly relied upon and used. Control of infection will not be possible without it.

Glossary

Electroporation The perturbution of cell membranes by very weak electrical impulses to allow the uptake of plasmid DNA.
Th1 immune response The quality of the immune response represented by a more active cell-mediated immune response with the concomitant secretion of specific cytobines such as interferon gamma.
Th2 immune response The quality of the immune response represented by a larger humoral antibody response, with the secretion of specific cytobines such as interleukin-4.

Introduction

Although the era of vaccinology has begun over 200 years ago, some of the early advances continue to form the foundation of our most successful vaccines. For example, even though it is over 200 years since Jenner introduced the concept of vaccination, using a live virus vaccine to protect people from smallpox, the concept of vaccinating with live agents continues. Indeed, some of the most effective vaccines are live-attenuated or live-heterologous vaccines. These vaccines have been successful in eliminating smallpox, or dramatically reducing the economic impact of diseases such as measles, polio, and many animal viral infections such as rinderpest. The reason for this success is that as the agent replicates, it resembles a natural infection, thereby stimulating the appropriate immune responses, including humoral and cell-mediated immunity. Furthermore, the persistence of the infecting agent, over an extended period of time, also provides long-term memory. Approximately 100 years after Jenner, Pasteur introduced a new approach to vaccination by killing the infectious agent and introducing the killed agent into the body as a nonreplicating vaccine. Similar to the original live vaccines, killed vaccines continue to be used for many infectious agents and are an integral component of our current armamentarium for disease control. Indeed, in some cases, live vaccines, which, in many cases, are more effective than killed vaccines, can be used initially to reduce the level of circulating agent in the environment, followed by killed vaccines to 'mop up' the remaining agent. The best example of such an approach is the use of live polio virus vaccine to provide broad immunity and reduce the viral load in the environment or country of interest and then use killed polio virus vaccine as a final step in disease eradication. The reason for such a strategy is that live vaccines can revert to virulence and may have certain risks associated with their use, which are worth taking when the disease burden is high but less so when the disease burden is low.

A century after Pasteur, we embarked on a new era of vaccination, primarily driven by advances in molecular biology and biotechnology, as well as a much deeper understanding of the host immune responses and antigens of each pathogen that are involved in providing protection from infection. These advances are the underpinning of

the era of vaccination employing genetic engineering. This resulted in the development of vaccines against hepatitis B and human papillomavirus, which not only prevent infection but also reduce the development of tumors. These vaccines were genetically engineered to contain all of the critical epitopes involved in inducing protective immunity. However, they do not contain any nucleic acid, thereby making them relatively safe and they are considered to be killed vaccines. Unfortunately, they require adjuvants and generally do not induce the broadest range of immune responses often seen with live vaccines.

Since production and purification of genetically engineered subunit vaccines are generally very expensive, require strong adjuvants, and generally induce a skewed systemic Th2 response, the quest continues for the development of more effective vaccines resembling live vaccines. To combine the benefits of a subunit vaccine such as safety with the broad immune responses produced by live vaccines, the concept of introducing the gene encoding putative protective proteins in a plasmid into the host was proposed. Indeed, this was heralded as a 'third generation of vaccinology', genetic vaccination, or DNA vaccination. The major advantage of such an approach, especially for viral infections, is that the antigen is expressed endogenously and the antigens are, therefore, processed in a manner resembling a viral infection. As a result, the antigen is presented by both major histocompatibility complex (MHC) I and MHC II pathways, inducing a more balanced immune response. This article describes the progress made to date in the area of DNA vaccination, including a description of the DNA vaccines that are already licensed as well as some of the challenges faced by this technology. Furthermore, the opportunities to overcome these challenges will also be discussed.

Concept of DNA Vaccines

The major reason for continued interest in DNA-based vaccines is their simplicity in concept, ease of production, potential to develop a broad range of immune responses, as well as their perceived safety and ability to induce immunity in neonates in the absence or presence of maternal antibodies. With regards to simplicity, a DNA vaccine is comprised of a plasmid containing various regulatory elements to ensure efficient production of the plasmid in bacterial systems, such as an origin of replication and a selectable marker as well as an expression cassette containing the gene of interest under a eukaryotic promoter usually human cytomegalovirus for efficient expression of the gene inserted into mammalian cells. Since the general features of a plasmid are identical for all vaccines, the single platform makes DNA vaccines very attractive from the prospective of manufacturing. Thus, the only difference between different vaccines would be the gene insert. Thus, if a company establishes a process for manufacturing one plasmid-based vaccine, they can use the same process for production and purification of a variety of different vaccines.

Recent advances in our understanding of pathogenesis, comparative biology, molecular biology, bioinformatics, and immunology make identification of putative protective antigens to most pathogens relatively easy. Second, identifying and isolating the gene encoding a protective antigen, combined with gene sequencing to ensure the cloned gene contains the correct sequence and is correctly positioned in the plasmid, is relatively straightforward. Furthermore, the gene sequence can also be modified to optimize the codon biases for expression in the host cell of interest. Once the plasmid is constructed, the production of the plasmid is relatively simple, using well-established fermentation processes in *Escherichia coli*. Since *E. coli* grows to very high densities, the quantity of plasmid produced in this manner is very high. Combining fermentation with well-established downstream processing currently developed for plasmid purification makes this process very attractive to commercial companies. Indeed, processes for plasmid purification are considered easier to perform than protein purification used in subunit vaccine production. Currently, a number of companies have established the downstream processing steps for purifying high-quality plasmids suitable for DNA vaccine production. These processes can easily be transferred to developing countries to provide secure supplies of vaccine for the developing world, should that be necessary. Indeed, all of the processes including fermentation, plasmid purification, and quality control can occur in a time frame as short as 1 month. This is a significant advantage over current subunit vaccine protein production.

The process of inserting a gene into the plasmid is routine and once the process is developed for one vaccine, the same process can be used for inserting any gene of interest. The development of a new vaccine would not require additional skills, except knowledge of the gene of interest. As a result, extensive trials and procedures required to demonstrate the absence of reactogenic components often required for subunit or conventional vaccines is reduced to a minimum. This not only reduces the concerns for safety, but also reduces the time for reaching the market.

Safety Issues with DNA-Based Vaccines

DNA vaccines are considered to be safe since they can be highly purified to remove extraneous materials and are noninfectious. The infectious nature is a common concern with live-attenuated vaccines where reversion to virulence has occurred. Preliminary trials in animals and humans demonstrated low inherent toxicity and since

the plasmids are often administered in physiological saline, in liposome-based formulations, or various other carriers which have already been tested and used over extended periods in humans, these vaccines are considered relatively safe. Initially, there was concern regarding the potential of the introduced plasmids to integrate into somatic or germline cells. However, studies have suggested that the probability of this occurring is 3 orders of magnitude lower than spontaneous mutations. Finally, there was concern that introduction of large amounts of DNA might lead to the generation of anti-DNA antibodies. Fortunately, a number of studies designed to test this possibility have demonstrated that this is likely to be a rare event if it would occur at all. Thus, it is currently widely believed that DNA-based vaccines are relatively safe.

Attractiveness of DNA-Based Vaccines

One desirable feature of any vaccine is the ability to protect individuals against a variety of disease agents following single administration of a vaccine. Thus, multicomponent vaccines are gaining popularity, not only because of the breadth of protection they induce, but also because of improved compliance since individuals do not need to return for numerous vaccinations. One limitation of combining multiple conventional vaccines is the possibility of interference between various components in the vaccine. With DNA vaccines this is also a possibility, but it should be possible to identify which component is interfering in induction of immunity. For example, in the study of a vaccine containing nine different plasmids encoding nine different malarial antigens, reduced immune responses to various components were observed compared to responses induced by individual plasmids. Similarly, we observed interference between plasmids encoding the genes for bovine herpesvirus-1 gD, parainfluenza-3 HA, and influenza virus HA. We also showed that co-administration of BHV-1 gD reduced the immune responses to BHV-1 gB. Since in these last two instances, the gD gene was responsible for the interference, it will be necessary to re-engineer this gene to remove the interference. In contrast, the use of genes encoding the four different dengue serotypes did not result in any interference. Indeed, combining the four serotypes resulted in higher antibody levels against dengue-4 than if animals were immunized with a monovalent dengue-4 plasmid-based vaccine. Similarly, broadening of the immune response was seen with multiple DNA vaccine components of various HIV proteins. Thus, it appears that each plasmid combination may need to be investigated independently for maximal benefit.

In addition to combining plasmids encoding different genes of interest, it is also possible to introduce two different genes encoding two different proteins from either the same or different pathogens in a single plasmid, thus further reducing the cost of production since one vaccine would protect against two different agents. This can be achieved by generating a plasmid which contains two gene expression cassettes or by simply linking the genes from two pathogens and inserting them into the plasmid. In this case, the two genes would be expressed as a single protein from a single promoter. Since the conformational changes imposed by linking two proteins together may alter their immunogenicity and the stability of the plasmid may be compromised as a result of its size, a number of plasmids have been constructed with each gene driven by its own promoter or by insertion of an encephalomyocarditis virus (EMCV) internal ribosome entry site (IRES) to translate the second gene. In some of these cases, the level of expression of the second gene was not as effective as that of the first gene, whereas in other instances there was no reduction in gene expression of either gene. Using such manipulations, it should be possible to broaden the protection to induce immunity to a number of different diseases simultaneously.

Neonatal Immunization

Since many diseases occur during the first few weeks or months of life, it is critical to induce immunity from vaccines as early as possible. Unfortunately, most vaccines given to neonates are less effective than in adults. There are many reasons for this. In the case of live vaccines, the presence of maternally derived antibodies generally limit the degree of replication of the vaccine, resulting in poor immune responses due to reduced antigenic mass produced *in vivo*. In the case of killed vaccines where there is less interference by maternally derived antibodies, the immune response is generally skewed to a Th2 bias response, thought to be due to the immaturity of the immune system. Using DNA vaccines, it has been shown that not only was it possible to induce immunity in neonates, but immunity could even be induced *in utero*. Thus, sheep immunized *in utero* during the third trimester were born fully immune. More importantly, the animals developed long-term memory. Indeed, the induction of memory by DNA vaccines is a very attractive feature of these vaccines since immune memory and duration of immunity are desirable for many vaccines. Numerous other studies have also shown the induction of long-term memory of T cells and B cells following DNA vaccination. This has been shown in a variety of models including pigs, sheep, and cytomologous monkeys. Memory could be further increased by incorporating plasmids encoding for IL-12 or IL-15 with the DNA vaccine.

It is also interesting that DNA vaccines appear to be able to induce immune responses in the presence of high levels of antibody. Thus, the fact that DNA vaccines can

induce immunity in neonates in the presence or absence of maternal antibodies makes this approach to vaccination extremely attractive, especially for diseases such as herpes simplex virus-2, human immunodeficiency virus (HIV), hepatitis B, group B strep, and chlamydia which often infect children during birth or shortly thereafter.

Limitations and Clinical Applications of DNA Vaccines

Although there are over 1000 publications demonstrating the effective induction of immunity using DNA vaccines in mice which protect mice from subsequent infection, DNA vaccines have not been as successful in larger animals or humans. Possibly the greatest challenge to adopting DNA vaccination as a routine in large animals and humans is the poor efficiency of transfection leading to suboptimal induction of immunity. This has limited the introduction of vaccines into the market. However, recently two DNA vaccines were licensed for commercial use. The first was a vaccine to immunize fish against infectious hematopoietic necrosis virus, followed shortly after with one for West Nile virus in horses. Although there have been numerous clinical trials in humans, the greatest success has been when DNA vaccines were used to prime the individual, followed by booster with a recombinant or subunit vaccine. Indeed, the DNA prime, followed by protein boost is currently the method of choice for induction of the immune responses using DNA vaccines in humans. Thus, it is our contention that if better delivery mechanisms could be introduced to enhance the transfection efficiency in large animals and humans, DNA vaccines have the potential to become a critical component in our armamentarium against infectious diseases.

Vaccine Delivery

Once the plasmids are purified, they are introduced into the host (animals or humans) and the DNA is taken up by specific cells where the gene is expressed and protein is produced. Unfortunately, only a very small percentage of the DNA is internalized, which is one of the drawbacks of DNA vaccination. Even for the DNA molecules that are internalized, not all are transported to the nucleus where they express their encoded antigen. However, the few molecules that enter the nucleus are transcribed and translated to produce protein, making the animal cells a bioreactor. Thus, the vaccine antigen is produced in the animal. Even though the quantity of protein produced by the transfected cell is very low, the protein is presented to the immune system and induces a broad spectrum of immune responses including antibody- and MHC-I-restricted CTL responses. Clearly, the magnitude of the immune response as well as the quality of the immune response can be influenced by the route of delivery; intradermal delivery is generally better than intramuscular since the numbers of antigen-presenting cells are more numerous in the skin than in muscle. Indeed, muscle cells are not generally capable of presenting antigen to the immune system, although immunity occurs as a result of antigen release from myocytes leading to cross-priming. The quality of the immune response can also be modulated by the background of the plasmid. A number of groups have modified the plasmid background to incorporate sufficient and appropriate CpG motifs to stimulate the innate immune response. By stimulating the innate immune response, it is possible to recruit the appropriate cells to the site of antigen expression and create a cytokine microenvironment conducive to developing an adaptive immune response. To improve the cytokine microenvironment conducive to induction of immunity, a number of investigators have co-administered DNA vaccines with plasmids expressing cytokines, defensins, or other immune stimulator molecules to recruit dendritic cells to the vaccination site. Other constructs have contained both the antigen and the cytokine/chemokines within the single plasmid. In most cases, the immune response was enhanced by the co-administration of cytokines such as granulocyte-macrophage colony-stimulating factor (GMCSF) and interleukins IL-2, IL-12, and IL-15. In addition, the cytokine–chemokine combination plasmids could bias the immune response. For example, macrophage inflammatory protein-1 (MIP-1)β biased the immune response of Th2-like response, whereas MIP-2 and MIP-1α favored a Th1 like response. Currently, a number of studies are ongoing using IL-12 and IL-15 for enhancing immune response to HIV vaccines.

Since intracellular uptake of DNA is not a very efficient process, numerous investigators have employed a variety of methods to enhance DNA uptake into cells. One very efficient delivery system is encapsulation of DNA in liposomes or polylactide-L-glycolide (PLG) microparticles. DNA delivery by these microparticles serves two purposes. First, the encapsulated DNA is protected from degradation, and, second, the liposomes or microparticles facilitate uptake of the DNA into antigen-presenting cells. Indeed, it is even possible to deliver the microparticles orally to induce mucosal immunity as well as systemic immunity. Since encapsulation of DNA in PLG is thought to cause DNA damage due to the process of encapsulation, other investigators have attached the DNA to the surface of PLG microspheres. This process has resulted in excellent immune responses regardless of whether the PLG microparticles were given mucosally or delivered systemically, suggesting the microspheres play a crucial role in DNA uptake in the cells.

Improving uptake of DNA is thought to be critical for enhancement of immunity, and since the response is

better when more cells are transfected, significant efforts have been focused on enhancing DNA uptake by various physical methods. The earliest approach to enhancing cell uptake was the use of a gene gun. In this instance, the DNA is coated on gold particles and is propelled into the skin. Some of these particles directly penetrate cells, whereas others are taken up by antigen-presenting cells. Although this approach has been shown to be effective, the quantity of DNA that can be coated onto gold beads is generally low, thereby reducing the effectiveness of such an approach.

The limitation of the quantity of DNA that can be taken up by cells by a gene gun can be overcome by jet injection of DNA. Depending on the pressure used to deliver the DNA, the DNA can be deposited either in the epidermis, subcutaneously, or even intramuscularly. However, an even more efficient method to deliver DNA into cells is the use of electroporation. Various companies have developed devices to both inject and electroporate the DNA simultaneously. Electroporation does not only enhance DNA uptake, but it also causes localized inflammation and induces the various mediators of innate immunity, resulting in enhanced immune responses. These studies have demonstrated the importance of modifying the local environment at the site of injection since the mere enhancing of expression does not always increase the immune responses. These studies demonstrate that one requires all of the elements of the immune response to be present at the site, as well as the specific antigen for the immunity to be induced.

Future Prospects

DNA vaccines represent an exciting addition to an already impressive track record of vaccines, which have saved millions of lives and improved the quality of life of almost every individual on the planet. Furthermore, vaccines have added significant economic benefits to society. Unfortunately, individuals still suffer from many infections. The reasons for this are varied, including the cost of vaccines, politics, as well as distribution issues. One of the major challenges to distribution is the need for a cold chain. If this could be overcome, the vaccines could be distributed to even remote regions of the world. DNA vaccines offer an advantage in this regard. Furthermore, it should be possible to develop these vaccines more economically, ensuring that the poor in remote regions could be vaccinated. Unfortunately, for this dream to become a reality, it will be necessary to improve the transfection efficiency of DNA vaccines to ensure that sufficient antigen is produced to induce an immune response. Currently, improvements in DNA vaccines often have been marginal. What is required is a 10–50-fold improvement to make the vaccines economical in most veterinary species and for humans in the developing world. However, the fact that two different DNA vaccines have already been licensed provides hope that within the next decade we will see a number of new DNA-based vaccines licensed and shown to be effective in reducing both morbidity and mortality. Whether these vaccines will be comprised solely of DNA-based vaccines or will be comprised of DNA-based vaccines which will prime the immune response, followed by boosting with conventional or recombinant vaccines, remains to be determined. Indeed, we will probably see both types of vaccine configurations in the future.

History

Ebola virus (EBOV) first emerged as the causative agent of two major outbreaks of viral hemorrhagic fever (VHF) occurring almost simultaneously along the Ebola River in Democratic Republic of Congo (DRC, formerly Zaire) and Sudan in 1976 (see **Table 1**). Over 500 cases were reported, with case fatality rates (CFRs) of 88% and 53%, respectively. It was later recognized that these two outbreaks were caused by two distinct species of EBOV (*Zaire ebolavirus* and *Sudan ebolavirus*). In 1989, a novel virus, Reston ebolavirus (REBOV), was isolated from naturally infected cynomolgus macaques (*Macaca fascicularis*) imported from the Philippines into the United States. All shipments except one were traced to a single supplier in the Philippines; however, the actual origin of the virus and mode of contamination for the facility have never been ascertained. While pathogenic for naturally and experimentally infected monkeys, limited data indicate that REBOV may not be pathogenic for humans as animal caretakers were infected without producing clinical symptoms. In 1994, the first case of Ebola hemorrhagic fever (EHF) occurred in western Africa in the Tai Forest Reserve in Côte d'Ivoire (Ivory Coast). An ecologist was infected by performing a necropsy on a dead chimpanzee whose troop had lost several members to infection with Côte d'Ivoire ebolavirus (CIEBOV). A single seroconversion was later documented, suggesting another nonfatal human case in nearby Liberia. Zaire ebolavirus (ZEBOV) reemerged in Kikwit, DRC, in 1995, causing a large EHF outbreak with 81% CFR. Sudan ebolavirus (SEBOV) reemerged in 2000–01 in the Gulu District in northern Uganda. There were over 425 cases (53% CFR), making it the largest EHF epidemic documented so far. Starting in 1994, an endemic focus of ZEBOV activity became obvious in the northern boarder region of Gabon and the Republic of Congo (RC) with multiple small EHF outbreaks over the past decade. Most infections there have been associated with the hunting and handling of animal carcasses (mainly great apes). In addition, ZEBOV has virtually decimated the chimpanzee and gorilla populations in those areas. At least three laboratory exposures to EBOV have occurred; one in Russia (2004) was fatal.

Taxonomy and Classification

Filoviruses are classified in the order *Mononegavirales*, a large group of enveloped viruses containing nonsegmented, negative-sense (NNS) RNA genomes. The family *Filoviridae* is separated into two distinct genera, *Marburgvirus* and *Ebolavirus*. The genus *Ebolavirus* is subdivided into four species – *Zaire ebolavirus*, *Sudan ebolavirus*, *Côte d'Ivoire ebolavirus*, and *Reston ebolavirus*. Filoviruses are classified as maximum containment (biosafety level 4 (BSL-4)) agents as well as category A pathogens based on their generally high mortality rate, person-to-person transmission, potential aerosol infectivity, and absence of vaccines and chemotherapy.

Biological and Physical Properties of Virion

EBOV particles are pleomorphic, appearing as U-shaped, 6-shaped, circular forms, or as long filamentous, sometimes branched forms varying greatly in length (up to 14 000 nm), but have a uniform diameter of ~80 nm (see **Figures 1(a)** and **1(b)**). EBOV virions purified by ratezonal gradient centrifugation are bacilliform in outline and show an average length associated with peak infectivity of 970–1200 nm. Except for the differences in length, EBOVs seem to be very similar in morphology. Virions contain a helical ribonucleoprotein complex RNP or nucleocapsid roughly 50 nm in diameter bearing cross-striations with a periodicity of approximately 5 nm, and a dark, central axial space 20 nm in diameter running

the length of the particle. The RNP complex is composed of the genomic RNA and the RNA-dependent RNA polymerase (L), nucleoprotein (NP), and virion proteins 35 and 30 (VP35 and VP30). A lipoprotein unit-membrane envelope derived from the host cell plasma membrane surrounds it. Spikes approximately 7–10 nm in length, spaced apart at ~10 nm intervals, are visible on the virion surface and are formed by the viral glycoprotein (GP). Virus particles have a molecular weight of approximately $3–6 \times 10^8$ Da and a density in potassium tartrate of 1.14 g cm^{-3}. Virus infectivity is quite stable at room temperature. Inactivation can be performed by ultraviolet (UV) light and γ-irradiation, 1% formalin, β-propiolactone, and brief exposure to phenolic disinfectants and lipid solvents, like deoxycholate and ether.

Properties of Genome

The EBOV genome consists of a molecule of linear, nonsegmented, negative-stranded RNA which is noninfectious, not polyadenylated, and complementary to viral-specific messenger RNA. The genome amounts to *c.* 1.1% of the total virion. EBOV genomes are ~19 kbp in length and fairly rich in adenosine and uridine residues. Genomes show a linear gene arrangement in the order 3′ leader–NP–VP35–VP40–GP–VP30–VP24–L–5′ trailer (see **Figure 1(b)**). All genes are flanked at their 3′ and 5′ ends by highly conserved transcriptional start (3′-CUnCnUn-UAAUU-5′) and termination signal sequences (3′-UAAUUCUUUUU-5), respectively, all of which contain the pentamer 3′-UAAUU-5′. Most genes are separated by intergenic sequences variable in length and nucleotide composition. A feature of all EBOV genomes is the fact that some intergenic regions overlap by the conserved pentamer (UAAUU) sequence. ZEBOV and SEBOV show three such overlaps within the intergenic sequences of VP35/VP40, GP/VP30, and VP24/L, whereas REBOV shows only two between VP35/VP40 and VP24/L. Extragenic leader and trailer sequences are present at the 3′ and 5′ genome ends. These sequences are complementary at their very extremities, showing the potential to form

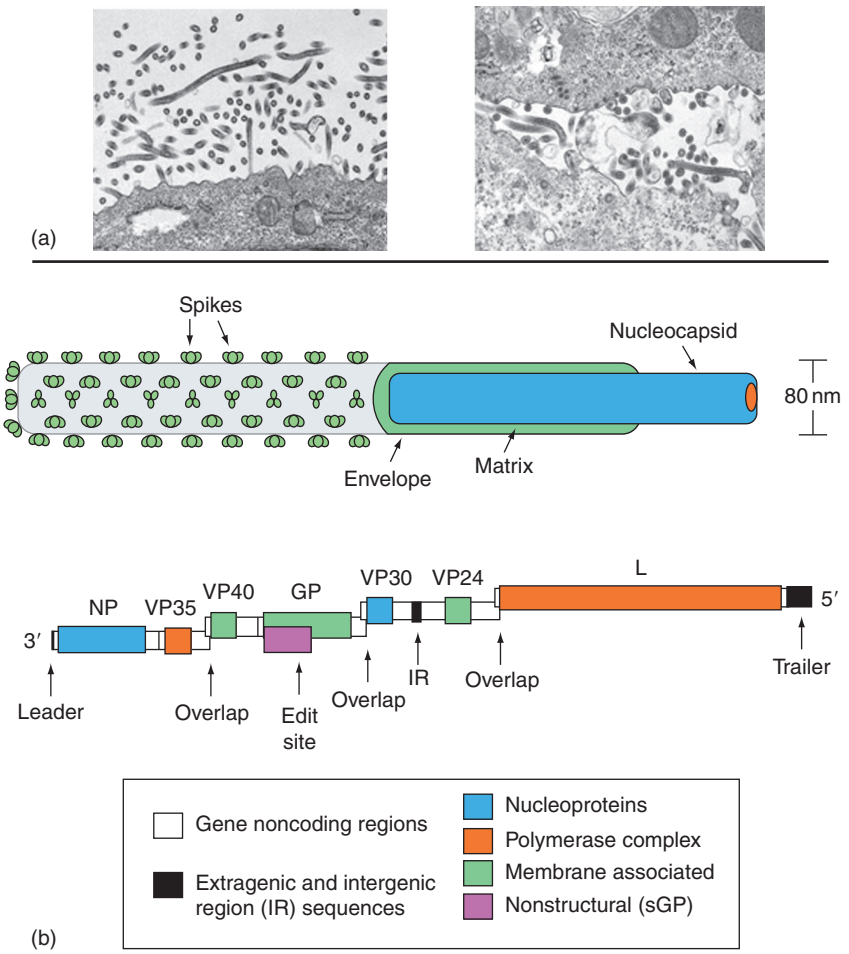

Figure 1 Particle morphology. (a) Transmission electron microscopy of Ebola virus particle. Both graphs show images of Vero E6 cells infected with Zaire ebolavirus. (b) Ebola virus particle structure and genome organization. The upper part provides a scheme of the virus particle separated into four components. The inner core consists of the nucleocapsid which is a structure formed by the single-stranded, negative-sense RNA genome associated with the two nucleoproteins (NP, VP30) and the polymerase complex (L and VP35). The matrix is built by the viral matrix protein VP40 and a minor component VP24. The envelope is derived from the infected cell during assembly/budding. The spikes consist of a homotrimer of the glycoprotein (GP).

stem–loop structures. Phylogenetic analyses on the basis of the GP gene of the different Ebola species show a 37–41% difference in their amino acid and nucleotide sequences. Analysis within one species shows remarkable genetic stability between strains (the variation in nucleotide sequences has been shown to be <7% and even <2% among distinct ZEBOV strains), unexpected for an RNA virus, but highly indicative that these viruses have reached a high degree of fitness to fill their respective niches.

Properties of Viral Proteins

Virions contain seven structural proteins with presumed identical functions for the different viruses (see **Table 2**). The electrophoretic mobility patterns of these proteins are characteristic for each species.

RNP Complex and Matrix Proteins

Four proteins are associated with the viral RNP complex: NP, L, VP30, and VP35 (see **Figure 1(b)**). These proteins are involved in the transcription and replication of the genome. NP and VP30 represent the major and minor nucleoproteins, respectively. They interact strongly with the genomic RNA molecule, and are both phosphoproteins. VP30 is also a zinc-binding protein that behaves as a transcriptional activator. The L and VP35 proteins form the polymerase complex. The L protein, like other L proteins of NNS RNA viruses, represents the RNA-dependent RNA polymerase. Motifs linked to RNA (template) binding, phosphodiester bonding (catalytic site), and ribonucleotide triphosphate binding have all been described. VP35 appears to behave in a mode similar to that of the phosphoproteins found in other NNS RNA viruses, acting as a cofactor that affects the mode of RNA synthesis (transcription vs

Table 2 Ebola virus proteins: functions and localization

Gene order[a]	*Ebola virus proteins*	*Protein function (localization)*
1	Nucleoprotein (NP)	Major nucleoprotein, RNA genome encapsidation (component of RNP complex)
2	Virion protein 35 (VP35)	Polymerase complex cofactor, type I interferon antagonist (component of RNP complex)
3	Virion protein 40 (VP40)	Matrix protein, virion assembly, and budding (membrane associated)
4 (primary)	Secreted glycoprotein (sGP) (nonstructural)	May have immunomodulatory role (secreted)
4 (secondary)	Glycoprotein (GP)	Receptor binding and membrane fusion (membrane associated)
5	Virion protein 30 (VP30)	Minor nucleoprotein, RNA binding, transcriptional activator (component of RNP complex)
6	Virion protein 24 (VP24)	Minor matrix protein, virion assembly, type I interferon antagonist (membrane associated)
7	Polymerase (L)	RNA-dependent RNA polymerase, enzymatic portion of polymerase complex (component of RNP complex)

[a]Gene order refers to 3′–5′ gene arrangement as shown in **Figure 1(b)**.

replication). VP35 is also known to be a type I interferon (IFN) antagonist; it blocks IFN-α/β expression by inhibiting IFN regulatory factor 3 (IRF-3). VP40 functions as the viral matrix protein and represents the most abundant protein in the virion. It plays a number of roles in viral infection related to assembly and budding of the viral particles. The production of VP40 by itself is sufficient to initiate the budding process for the production of virus-like particles (VLPs); however, the production of these particles is greatly enhanced by the addition of GP and NP. Recent studies have shown that EBOV hijacks the cellular protein machinery in order to mediate assembly and budding from the cellular membranes. These functions have been associated with overlapping late domain sequences (PTAP and PPEY) found in VP40. Late domains interact with cellular proteins such as Tsg101 and Nedd4 and affect a late step in the budding process. VP24 is thought to be a secondary (minor) matrix protein that, unlike VP40, is only incorporated into virions in small amounts. It has an affinity for the plasma membrane and perinuclear region of infected cells. The precise role of VP24 in replication is unclear; however, VP24 is a known type I IFN antagonist. Unlike VP35, VP24 blocks the translocation of phosphorylated STAT1 into the nucleus, subverting the antiviral response. More recently, VP24 has been associated with adaptation in rodent hosts.

Glycoproteins

The structural GP is a type I transmembrane protein inserted into the membrane as a trimer (see **Figure 1(b)**). It functions in viral entry, influences pathogenesis, and acts as the major viral antigen. The GP gene shows two open reading frames (ORFs) encoding for the precursors of GP (pre-GP) and a nonstructural secreted glycoprotein (pre-sGP), which is the primary product of this gene. Translation of pre-GP can only be achieved through mRNA editing, where one adenosine residue is added at a seven-uridine-stretch template sequence, resulting in a frameshift of the primary ORF. GP is cytotoxic when expressed at higher levels, leading to the hypothesis that mRNA editing may be evolutionarily related to the control of overexpression of this protein. The N-terminal $\sim$300 amino acids of the pre-GP are identical to those of pre-sGP, but the C termini of each protein are unique. pre-GP is translocated to the endoplasmic reticulum (ER) by an N-terminal signal sequence, and anchored by an extremely short membrane-spanning sequence at the C-terminus. The protein is glycosylated in the ER and Golgi apparatus with both N-linked and O-linked glycans. Most of the O-linked glycans are located in a mucin-like region (rich in theronine, serine, and proline residues) located in the middle of the protein. pre-GP is then cleaved by a subtilisin/kexin-like convertase such as furin, leading to the formation of disulfide-bonded $GP_{1,2}$. The smaller C-terminal cleavage fragment GP_2 contains the transmembrane region that anchors GP to the membrane. Interestingly, proteolytic cleavage of pre-GP is not required for infectivity or for virulence, indicating that the uncleaved precursor can mediate receptor binding and fusion. The production of pre-sGP differentiates EBOV from Marburg viruses, which do not express this soluble protein. pre-sGP is also translocated into the ER, modified in the secretory (e.g., oligomerization, glycosylation) pathway, and cleaved by furin near the C-terminus to release a short peptide termed delta peptide. No biological properties have been attributed to delta peptide. Recent matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) analysis suggests that sGP forms a homodimer in a parallel orientation, held together by disulfide bonds between the most N-terminal and C-terminal cysteine residues. sGP circulates in the blood of acutely infected humans. Its exact function is still unknown; however, an interaction with the cellular and

humoral host immune responses has been postulated. In contrast to GP which mediates endothelial cell (EC) activation and decreases EC barrier functions, sGP seems to have an anti-inflammatory role.

Viral Life Cycle

The viral life cycle consists of several events: binding/entry, uncoating, transcription, translation, genome replication, and packaging/budding (see **Figure 2**). EBOVs have selective tropism primarily for monocytes, macrophages, and dendritic cells (DCs), although other cell types such as fibroblasts, hepatocytes, and ECs can be infected. In contrast, lymphocytes generally do not support EBOV replication, which is believed to be due to the lack of expression of the viral receptor(s). Although several molecules have been identified as possible viral receptors in various *in vitro* systems, it is not clear if any of the identified molecules are actually used *in vivo* or the degree of requirement for infection and disease. Folate receptor alpha was the first identified possible receptor but entry was also shown to occur in the absence of the molecule. C-type lectins such as DC-SIGN, DC-SIGNR, and hMGL were shown to be able to enhance binding but are not required for infection. Expression of members of the Tyro3 family converted the poorly susceptible Jurkat T cells into susceptible cells for particles pseudotyped with ZEBOV GP and enhanced ZEBOV infection. Receptor binding results in endocytosis into endosomes, possibly via clathrin-coated pits and caveolae although some studies suggest that they may not be necessary. Acidification of the endosomes is necessary for fusion of the viral and endosomal membranes, which is mediated by a region in GP_2. Proteolysis by cathepsins B and L in the acidic endosomes might be essential for infectivity.

Transcription and genome replication seems to follow the general principles for *Mononegavirales*. There seems to

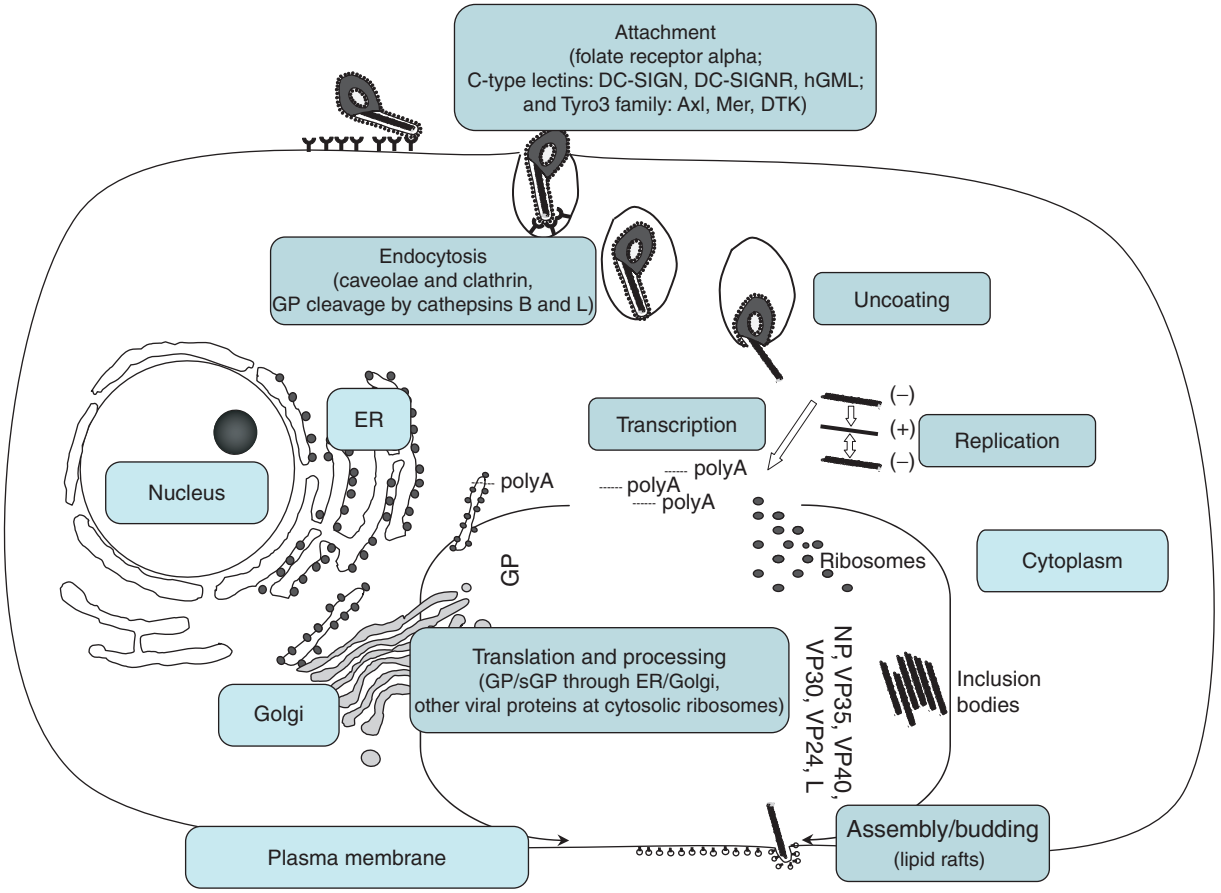

Figure 2 Ebola virus life cycle. The virus attaches to specific receptor(s) on the plasma membrane which leads to endocytosis via caveolae and clathrin-mediated pathways. The viral GP is cleaved in the endosome by cathepsins L and B. After uncoating, transcription and replication take place in the cytoplasm. All proteins except the GPs are translated on free ribosomes in the cytoplasm, while the glycoproteins are produced and modified in the ER and Golgi. Nucleocapsids formed in inclusion bodies interact with the matrix protein VP40 at the plasma membrane. Assembly and particle budding occurs at lipid rafts in the plasma membrane.

be a gradual decrease in mRNA levels from 3′ to 5′ end of the genome. The encapsidated viral genome serves as the template for transcription, which in the case of EBOV requires the L proteins, VP35 and VP30. mRNA transcripts are monocistronic, capped, polyadenylated, and contain long noncoding regions at their 3′ and/or 5′ ends. Stem–loop structures at the 5′ ends of mRNA transcripts may affect transcript stability, ribosome binding, and translation. The switch from transcription to replication seems to be triggered by an accumulation of viral proteins, especially NP, in the cytoplasm. Large amounts of NP are localized in inclusion bodies to which other viral proteins are recruited. These inclusion bodies may function as sites of RNP complex formation.

Membrane/lipid rafts have been identified as platforms for the assembly of virions; GP trimers conveyed to the surface membrane have an affinity for these rafts that is associated with palmitoylation of the membrane-spanning anchor sequence. RNP complexes interact with VP40, which is deposited at the plasma membrane via the late retrograde endosomal pathway. Abolition of the late domains in VP40 blocks particle formation, but only partially affects viral replication, suggesting that other domains or proteins must be involved. VP24 is also associated with the plasma membrane and enhances particle formation, but a specific role in particle maturation has not been identified. GP trimers seem to interact with VP40 and/or VP24 to finalize the budding process.

Host Range and Experimental Models

Natural Hosts and Geographic Distribution

EBOVs typically infect humans and nonhuman primates (NHPs); ZEBOV and SEBOV appear to be the main causes of lethal infections in humans, and thus are of primary public health concern. EBOVs appear to be indigenous to the tropical rain forest regions of central Africa (with the exception of REBOV), as indicated by the geographic locations of known outbreaks and seroepidemiological studies. The discovery of REBOV in the Philippines suggests the presence of a filovirus in Asia. Many species have been discussed as possible natural hosts; however, no nonhuman vertebrate hosts or arthropod vectors have yet been definitely identified. Epidemiological data have suggested monkeys as a potential reservoir of filoviruses; however, the high pathogenicity of EBOV for NHPs does not generally support such a concept. Similarities in biological properties to other viral hemorrhagic fever agents, such as ‘Old World’ arenaviruses, favor a chronic infection of an animal that regulates survival of the viruses in nature. More recently, viral RNA and virus-specific antibodies could be detected in African fruit bat species, suggesting that bats might be a reservoir for EBOV.

Experimental Models

Experimental hosts include monkeys (specifically rhesus and cynomolgus macaques), for which infection with ZEBOV is usually 100% lethal, guinea pigs (which show febrile responses 4–10 days after inoculation, but not uniform lethality), and newborn and immunocompromised mice when inoculated with wild-type virus. The resistance of the adult rodent models to EBOV infection has led to the production of guinea pig- and mouse-adapted ZEBOV strains (GPA-ZEBOV and MA-ZEBOV), produced through the serial passage of the virus through progressively older animals. These adapted strains are able to present uniform lethality in their respective hosts. MA-ZEBOV demonstrates reduced virulence in NHPs, whereas GPA-ZEBOV remains uniformly lethal in this model. Infected mice do not exhibit strong coagulation abnormalities (a hallmark of EBOV infection in humans and NHPs) and also slightly differ in other clinical symptoms. Mice, however, represent a good screening model for studies of antiviral and host immune responses. Infected guinea pigs do present coagulation defects that more closely resemble a human or an NHP infection. For growth in cell culture, primary monkey kidney cells and monkey kidney cell lines (e.g., Vero) are often used, but EBOV can replicate in many mammalian cell types including human ECs and monocytes/macrophages.

Clinical Features

Nonspecific, flu-like symptoms such as fever, chills, and malaise appear abruptly in infected individuals after an incubation period that ranges from 2 to 21 days, but on average lasts 4–10 days. Subsequently, multisystemic symptoms such as prostration, anorexia, vomiting, chest pain, and shortness of breath develop. Macropapular rash associated with varying degrees of erythema may also occur and is a valuable differential diagnostic feature. At the peak of the disease, vascular dysfunction signs appear ranging from petechiae, echymoses, and uncontrolled bleeding at venipuncture sites, to mucosal bleeding and diffuse coagulopathy. Massive blood loss is atypical, although it may happen in the gastrointestinal tract, and is not sufficient to lead to death. Fatal cases develop shock, multiorgan failure, and coma with death occurring between days 6 and 16. Survivors can have multiple sequelae such as hepatitis, myelitis, ocular disease, myalgia, asthenia, and psychosis. The mortality and severity of symptoms are viral species dependent, with ZEBOV causing 60–90% and SEBOV 50–60% lethality. Viremia in fatal cases can reach peak levels of 10^9 genomes ml^{-1}, while survivors have peak levels of about 10^7 genomes ml^{-1}. Viral antigen can be found systemically, although it is most abundant in the spleen and liver.

Diagnosis of EHF is based on the detection of virus-specific antibodies, virus particles, or particle components. The procedures are the same as for Marburg hemorrhagic fevers.

Pathogenicity

Most of the information available regarding pathogenicity is derived from ZEBOV infections in humans and animal models. Death seems to be the result of systemic shock due to vascular dysfunction, which is caused by a complex interaction of the immune system with vascular physiology. Three major processes – increase in vascular permeability, disseminated intravascular coagulation, and impaired protective immunological responses – are the main events that lead to shock and death. The first two processes are the product of a series of events starting with infection of primary target cells (monocytes/macrophages (Mø) and DCs) and later leading to activation and decrease of barrier function of ECs, while the third is still being actively investigated (see **Figure 3**).

Infected Mø are strongly activated, secreting pro-inflammatory molecules such as interleukin 6(IL-6), tumor necrosis factor alpha (TNF)-α, IL-1β, nitric oxide (NO), and spread the infection systemically. In contrast, infection of DCs results in impaired activation, with no upregulation of co-stimulatory molecules such as major histocompatibility complexes (MHCs) I and II, CD80, CD86, and CD40. Early interaction with primary target cells is independent of virus replication and current models suggest that GP in the repetitive context of a particle is required for activation, possibly by binding and cross-linking cellular receptors. Activation of ECs by mediators such TNF-α and NO is believed to be the main cause for the decrease in EC barrier function. TNF-α, NO, and pro-inflammatory cytokines increase vascular permeability and EC surface adhesion molecule expression, which are

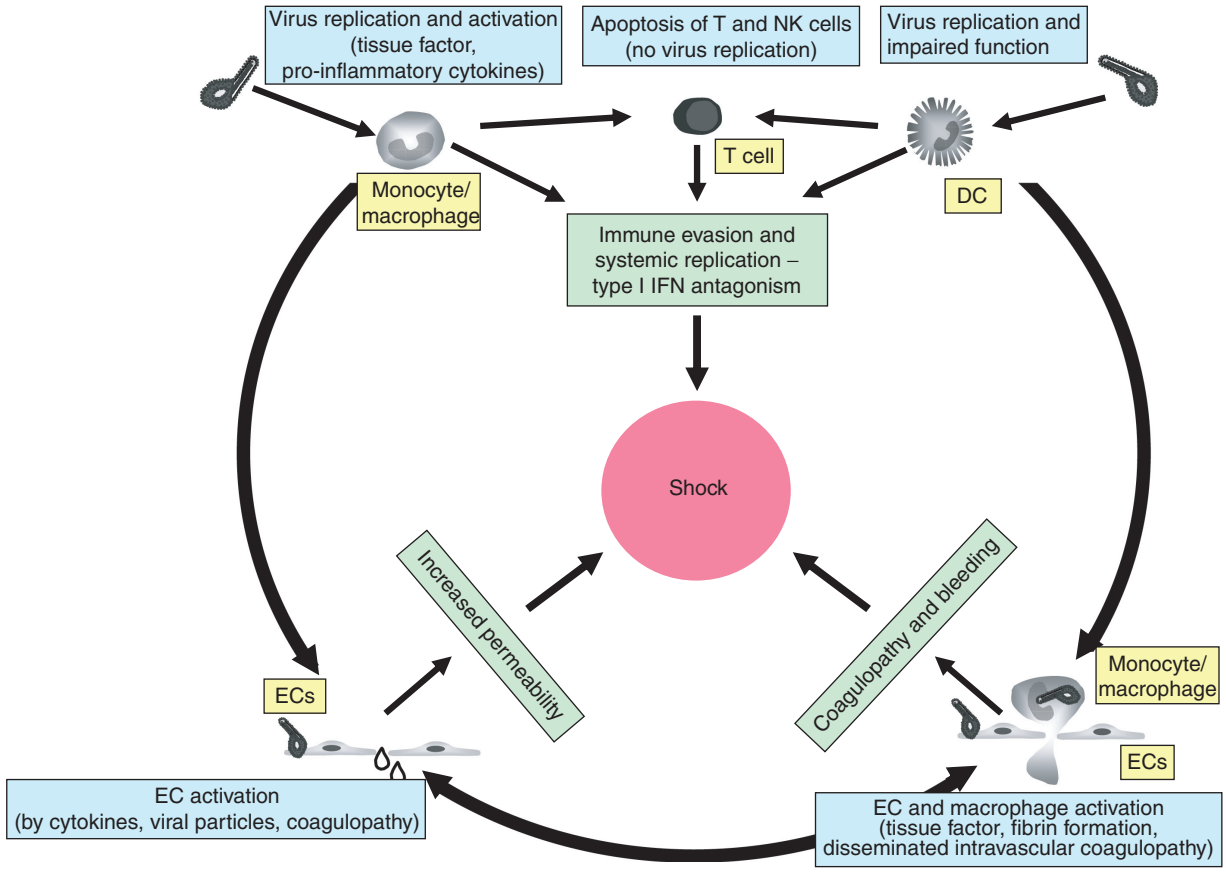

Figure 3 Ebola virus pathogenesis. Shock, the final event in severe/lethal cases, is caused by three processes, which influence each other: systemic viral replication and immune evasion, increase in vascular permeability, and coagulopathy. Infection of primary target cells such as monocytes/macrophages and DCs results in systemic spread of the virus and differential activation. Monocytes/macrophages are activated to produce pro-inflammatory cytokines and tissue factor (TF), while DC activation is impaired, leading to poor protective immune responses. Type I interferon responses are also inhibited by virus-encoded inhibitors (VP35 and VP24). Despite no infection of T- and natural killer (NK) cells, there is extensive apoptosis in those cell types. ECs are activated by pro-inflammatory cytokines and virus, which leads to increased permeability. TF expression induces coagulopathy, which is also able to increase inflammation.

necessary in extravasation of immune cells in inflamed tissue. Although these pro-inflammatory cytokines are an integral part of a normal, localized immune response by attracting and activating immune cells to the site of infection, in the context of a systemic and extensive response, they have a negative effect by inducing shock. ECs also serve as target cells and infection results in activation as indicated by upregulation of adhesion molecule expression followed by cytolysis. However, *in vivo* EC destruction can only be observed at the end stage of the disease.

Infection of Mø also results in the expression of tissue factor (TF), which can impair the anticoagulant–protein-C pathway by downmodulating thrombomodulin. TF is believed to be an important protein in the development of disseminated intravascular coagulopathy (DIC), as inhibition of TF delays death in NHPs and even protects 33% of the infected animals. TNF-α can also induce TF expression in ECs, which would further amplify coagulopathy and DIC. Coagulopathy is known to enhance inflammation, and this could lead to a vicious cycle where inflammation enhances coagulopathy, which in turn would amplify inflammation.

Rapid systemic viral replication is an integral part of the pathogenesis, as infection and even binding of particles results in not only Mø activation but also DC impairment. ZEBOV infection in humans and NHPs results in rapid massive viremia and high titers in various organs, especially spleen and liver. This correlates with an impaired innate and adaptive immune response. However, high viremia and lethality are only seen in guinea pigs and mice after host adaption or infection of various immune-deficient mice, suggesting that evasion of immune responses plays a pivotal role in pathogenesis. Mice lacking the IFN-α/β receptor or STAT1, the main signaling molecule in response to type I IFN, are extremely susceptible to ZEBOV. Treatment of NHPs with IFN-α did not protect the animals but delayed death, suggesting that type I IFN may be an important innate molecule in delaying viral replication. Interestingly, MA-ZEBOV is less sensitive to IFN-α treatment in murine macrophages compared to wild-type ZEBOV, and analysis of genomic mutations in GA- and MA-ZEBOV indicated that mutations in NP and VP24 are sufficient for a lethal phenotype. VP24 inhibits responses to interferon *in vitro*, but it is not clear yet if the mutations in the adapted strains are required for type I IFN evasion or other functions. ZEBOV is also able to inhibit IFN gene induction through VP35, and deletion of the region in VP35 involved in IFN antagonism results in a highly attenuated virus. Furthermore, comparative *in vitro* gene microarray analysis demonstrated a correlation between cytotoxicity and IFN antagonism, which was strongest with ZEBOV and weakest with REBOV.

Adaptive immune responses are also impaired during infection. As mentioned above, upregulation of co-stimulatory molecules is inhibited in DCs, which reduces activation of T cells. There is also a dramatic drop in number of T and natural killer (NK) cells despite the fact that lymphocytes do not support ZEBOV replication. It is believed that lymphopenia is caused by 'bystander' apoptosis, although the mechanism is not well understood. Activation of T cells could also be inhibited by treatment *in vitro* with a 17-amino-acid peptide present in GP_2, which has homology to a known immunosuppressive peptide in the retroviral Gag protein; yet there is no evidence that the complete ZEBOV GP has the same capabilities.

Treatment

The current treatment of EHF is strictly supportive, involving fluid and electrolyte replenishment and pain reduction. Due to the remote location of the outbreaks and limited resources available in the affected regions, treatment options have not been tested in patients. Several experimental treatment strategies have been successful in the rodent models, but failed in the NHP model, which is considered the most accurate in modeling human disease.

Therapeutic antibodies are still considered a short-term solution despite varying success in animal models and humans. Convalescent serum was used in a limited number of patients during the Kikwit 1995 ZEBOV outbreak but the success is a matter of dispute. Passive immunization with hyperimmune horse serum resulted in protection of hamadryl baboons, whereas it only delayed death in cynomolgus macaques. Monoclonal antibody treatment is successful in rodent models but has failed in preliminary NHP studies.

Currently the most feasible and promising approach relates to interference with coagulation using the recombinant nematode anticoagulant protein c2 (rNAPc2). Administration of the drug, which is already in clincial trials for other applications, as late as 24 h post infection resulted in 33% survival in the rhesus macaque model. Even more potent seems to be post-exposure treatment with a recombinant vesicular stomatitis virus (VSV) expressing the ZEBOV GP, which resulted in 50% protection when given 30 min post infection, but the mechanism of post-exposure protection is not yet understood. It is expected that approval of this attenuated replication-component vector will be difficult.

The recent advances in the understanding of EBOV pathogenesis and replication will open new avenues for intervention therapy. Novel antiviral strategies such as viral gene silencing through specific siRNA, cathepsin inhibition, and functional domain interference with small peptides showed promise in tissue culture and partially also in rodent models. Strategies targeting host responses are important alternative options and include anticytokine therapy and modulation of coagulation pathways. It should be noted that more classical approaches such as ribavirin treatment, which has been successfully used to treat other VHFs, are not indicated for EHF.

Vaccines

There are no approved vaccines against EBOV. Similar to therapeutic approaches, many initial vaccination strategies were successful in rodents but failed in NHPs. Nevertheless, there are several promising experimental strategies. Nonreplicating adenoviruses expressing the ZEBOV GP and NP were able to induce sterile immunity in cynomolgus macaques within 28 days or more post vaccination, either alone in a single shot approach or in combination with DNA priming and adenovirus boost. Although DNA priming is not necessary for protection of NHPs, it may be required to overcome the problem of preexisting immunity to human adenoviruses. DNA vaccination alone against EBOV is already in Phase I clinical trial, where it was shown to be safe and effective in inducing humoral and cellular immune responses.

Recombinant VSV expressing ZEBOV GP also induced sterile immunity when given 28 days prior to challenge of cynomolgus macaques, but was also able to protect 50% of rhesus macaques when administered 30 min post challenge. These results, together with the fact that prior immunity against the vector is extremely low, and the only target of neutralizing antibodies, VSV G protein, is removed from the vaccine vector, indicate that this platform may be successful in humans if licensing for the replication-competent vector can be achieved. Human parainfluenza virus-based vectors and VLPs are successful in protecting rodents, and preliminary results suggest that they even show efficacy in NHPs. Safety testing of vaccine vectors and the establishment of immune correlates is a priority for all these and future vaccine platforms.

Note: Investigation of an ongoing hemorrhagic fever outbreak in southwestern Uganda revealed what appears to be an additional distinct species of Ebola virus associated with this outbreak. Preliminary genome sequence analysis suggests the most closely related Ebola virus species would be the *Côte d'Ivoire ebolavirus*. Initial outbreak investigations suggest that infection with this newly discovered virus is associated with a lower case fatality than infections with Zaire ebolavirus (60–90%) or Sudan ebolavirus (50–60%) (T. G. Ksiazek, Centers for Disease Control and Prevention, Atlanta, GA, United States, personal communication).

Echoviruses

T Hyypiä, University of Turku, Turku, Finland

© 2008 Elsevier Ltd. All rights reserved.

History and Classification

Echoviruses belong to the species *Human enterovirus B* (HEV-B), in the genus *Enterovirus* of the family *Picornaviridae*. Original classification of picornaviruses was based mainly on physicochemical properties and pathogenesis in experimental animals. At the beginning of the twentieth century, poliomyelitis was transmitted to

monkeys using a filterable agent from clinical patients and 40 years later, new related human picornaviruses (coxsackieviruses), that characteristically caused disease in newborn mice, were isolated. Based on the disease signs observed in mice they were classified into A and B subgroups. After introduction of tissue cultures for virus propagation, a number of new viruses were isolated that exhibited similar physicochemical characteristics (resistance to organic solvents and low pH) with polio- and coxsackieviruses, but grew exclusively in cell culture. Since the disease association of these viruses was at that time unclear, they were grouped among ECHO viruses, which stands for enteric (isolated mainly from stool samples), cytopathogenic (cytopathic effect observed in tissue culture), human (no disease in monkeys or in newborn mice), orphan (disease association not confirmed). There are 28 distinct echovirus serotypes (EV1–33); EV1 and EV8 represent the same serotype, serotype 10 was identified to be a reovirus, serotype 28 was reclassified as a rhinovirus, and serotypes 22 and 23 were reclassified as members of a separate picornavirus genus, *Parechoviridae* (**Table 1**). Polioviruses, coxsackieviruses, and echoviruses formed human enteroviruses. Later, new enterovirus serotypes were not classified into the subgroups but were given successive numbers in the order of their identification (enteroviruses 68–71).

When sequence analysis became available, it was possible to determine the genetic relatedness of individual virus serotypes and strains. It was shown that echoviruses form a genetically rather coherent cluster and they are closely related to certain other enteroviruses. Molecular criteria replaced the previous enterovirus subgroup division in classification and currently echoviruses belong to the HEV-B species together with coxsackie B virus 1–6, coxsackievirus A9, and enterovirus 69 serotypes. More recently, identification of new enterovirus types has been exclusively based on comparison of the VP1 gene sequences, which correlate well with the previous serotype division. Currently, there are approximately 100 distinct enterovirus types, 63 of which have been assigned to serotypes. Further studies of the new members of the genus will show how many of them share biological properties with the classical echovirus serotypes.

Table 1 Summary of the molecular and clinical characteristics of echoviruses

Family	*Picornaviridae*
Genus	*Enterovirus*
Species	*Human enterovirus B*
Serotypes	1–7, 9, 11–21, 24–27, 29–33
Virus capsid	Nonenveloped, icosahedral, contains 60 copies of each of the capsid proteins VP1–4
Genome	Single-stranded, infectious RNA, approximately 7400 nt
Viral proteins	Cap-independent translation utilizing the internal ribosome entry site; translated as a polyprotein (2200 amino acids); the capsid proteins are at the N-terminus and the C-terminal part of the polyprotein contains the nonstructural proteins (2A, 2B, 2C, 3A, 3B, 3C, and 3D)
Receptors	
Most echoviruses	Decay-accelerating factor (CD55)
Echovirus 1	$\alpha 2\beta 1$ integrin
Echovirus 9 (Barty)	αV integrins
Entry route	Endocytosis
Replication	Viral RNA synthesis takes place on cytoplasmic membranes
Clinical manifestations	Meningitis, encephalitis, generalized infections of newborns, myocarditis, rashes, respiratory infections, severe infections in immunocompromised patients
Diagnosis	RT-PCR, virus isolation, serology

Molecular Characteristics and Replication

Virus Particle

In general, echoviruses share the basic properties of other representatives of the enterovirus genus, where polioviruses are considered as the type members. Enteroviruses are composed of a protein capsid consisting of 60 copies of each of the four structural proteins (VP1–4) and enclosing a single-stranded infectious RNA genome, approximately 7400 nt in length. The diameter of the icosahedral virus particle is around 30 nm and the RNA genome represents about 30% of the molecular mass of the virion. VP1–3 are exposed on the surface of the virus particle and they all share the eight-stranded antiparallel β-barrel structure. These capsid proteins are responsible for the recognition of the cellular receptors and they contain the neutralizing B-cell epitopes, located in the variable loops connecting the β-strands and in the C-termini of the proteins. VP4 is located inside the virion and it contains a myristic acid, covalently linked to the N-terminus. Five VP1 molecules form a star-shaped structure around the fivefold symmetry axis that is surrounded by a surface depression (a canyon), while VP2 and VP3 molecules alternate around the threefold axis. The structural subunits are a protomer, composed of one copy of each of the capsid proteins and a pentamer including five protomers. The three-dimensional structure of at least two echovirus serotypes (EV1 and EV11) have been determined by X-ray crystallography and some additional serotypes have also been studied by cryoelectron microscopy. In general, the detailed architecture of these echoviruses closely resembles that of other enteroviruses. Structural, immunological, and other biological

reasons for the existence of almost 30 distinct echovirus serotypes in contrast to three polioviruses are currently not known.

The organization of the echovirus genome is analogous to other enteroviruses and the functions of the proteins have been mainly predicted on the basis of the findings reported for polioviruses. The capsid proteins are located at the N-terminal part (P1 region) of the polyprotein encoded by the viral RNA and the nonstructural proteins, necessary for replication, are at the C-terminal part (P2 and P3 regions). The 5′ noncoding region (NCR) contains around 750 nt, and it includes the structured elements important in translation (internal ribosome entry site, IRES) and genome replication. A small viral protein (3B, also known as VPg) is covalently linked to the 5′ terminus of the genome. The length of the 3′ NCR, also containing predicted secondary structures, is approximately 100 nt and it is followed by a poly(A) tract. The variation in the lengths of all echovirus genomes is in the range of 100 nt. The maximum difference between the 5′ NCR sequences is less than 25%; the capsid protein genes are rather variable (around 60–80% identity between the amino acid sequences of VP1), and less diversity is found at the nonstructural region (80–100% amino acid identity).

Replication Cycle

In most picornaviruses, the interaction with a specific cellular receptor takes place through structures located on the bottom of the canyon with the terminal domains of immunoglobulin (Ig) superfamily molecules. This interaction leads to conformational changes which give rise to further uncoating and release of the genome into the cytoplasm. Instead, many echoviruses attach to decay-accelerating factor (DAF, CD55) that belongs to a family of regulatory proteins protecting the cells from autologous complement-mediated lysis. DAF contains four short consensus repeat domains and is anchored to the surface of the plasma membrane. DAF-binding echoviruses interact mainly with the consensus repeat domain 3 but may also recognize binding sites in domains 2 or 4. Interaction of DAF with echoviruses does not lead to similar alterations in the conformation of the virus particle that are observed after interaction of the Ig superfamily member receptors. Structural studies have revealed that the binding site of DAF in echovirus 7 is located in the VP2 protein close to the twofold symmetry axis in contrast to the binding site of the Ig superfamily molecules in the canyon. DAF is also recognized by certain coxsackie A and B viruses but the binding mechanisms are different and the conformational changes in these viruses are induced by subsequent interaction with members of the Ig superfamily molecules. Therefore, it is thought that additional cellular factors are also needed for successful internalization and uncoating of the DAF-binding echoviruses. Candidate molecules include β2-microglobulin, complement control protein CD59, and heparan sulfate.

Sequence analysis of the mouse-pathogenic echovirus 9 Barty strain revealed that there was a 10-amino-acid-long insert to the C-terminal end of the VP1 protein when compared to the Hill strain of the same serotype which does not cause disease in mice. This insert contains an arginine-glycine-aspartic acid (RGD) motif, known to interact with αV integrins, and this sequence has also been found in clinical isolates. Interestingly, coxsackievirus A9, another mouse-pathogenic member of the HEV-B species, contains a functional RGD motif in a similar position and recognizes αV integrins.

Echovirus 1 is the only picornavirus that is known to interact with α2β1 integrin (a collagen receptor) on the cell surface. The virus binds to the I (inserted) domain in the α2 subunit which is also recognized by collagen but there are remarkable differences between these interactions. The binding site has been localized to the outer wall of the canyon. As in the case of DAF interaction with other echoviruses, binding of the α2I-domain to EV1 does not bring about the conformational changes needed for uncoating *in vitro*. Attachment of the virus to the integrin gives rise to clustering of the receptor molecules which is known to be able to induce signaling events which may play an important role in the subsequent internalization processes.

Entry of echoviruses has been studied in serotypes 1 and 11. The integrin interaction of EV1 is followed by endocytosis of the virus–receptor complex into cytoplasmic structures which are rich in caveolin-1. This internalization process is initiated in lipid rafts and, subsequently, the virus entry can occur either in caveolae or through a faster route into caveosomes, which are preexisting intracellular organelles. How the EV1 genome is released from the caveosomes to the cytoplasm, is currently not known. Echovirus 11 appears to use similar mechanisms during entry. In the plasma membrane, DAF is present in lipid rafts, which are cholesterol-rich domains, and it has been shown that cholesterol depletion inhibits DAF-mediated echovirus infection. The virus can also be copurified with components found in lipid rafts.

When released to the cytoplasm, the picornavirus genome is infectious and it can act directly as an mRNA encoding a large polyprotein that is subsequently processed to the mature viral polypeptides. Based on similarity echovirus nonstructural proteins with those of poliovirus, viral replication cycles are evidently very similar. The proteolytic cleavages take place as a cascade and some of the intermediate products (2BC, 3AB, and 3CD) exhibit also specific activities. 2A is a protease responsible for the cleavage between the VP1 and 2A proteins and, in addition, it causes shut-off of host-cell protein synthesis

by cleaving a cellular factor needed for cap-dependent translation. Proteases 3C and 3CD are responsible for other proteolytic processing events except the cleavage between VP4 and VP2 which may be autocatalytic.

In the infected cells, the viral nonstructural proteins associate with host-cell membrane compartments and modify these to establish a specialized complex for viral RNA synthesis. In these replication complexes, containing almost all the nonstructural proteins with multiple interactions with each other and viral RNA, the genome is copied through a complementary template to new genomic strands. 3D is an RNA-dependent RNA polymerase responsible for the synthesis of the positive and negative strands. Due to the deficient proof-reading activity of the viral RNA-dependent RNA polymerases, errors are frequently generated during the replication and in picornaviruses every new genome contains approximately one mutation. 3B (VPg), found at the 5′ termini of the RNA strands during replication but not during translation, plays a role in the priming of the RNA synthesis. The role of the 3AB protein is thought to be anchoring of VPg to the membranes for priming. The exact role of the 2B protein in the replication cycle is not known. It increases membrane permeability that may facilitate release of the mature viruses from the cells and it also interferes with cellular protein secretion. The 2C protein contains three motifs found in NTPases/helicases. Moreover, 2C and some other nonstructural proteins are involved in rearrangements of intracellular vesicles during formation of the replication complexes. In the assembly of infectious virions, the protomers form pentamers which can associate to form empty capsids. It is not clear whether the viral genome can be inserted into these particles or if they represent a reservoir of the structural units, finally assembling around viral RNA. The mature viruses are released as a result of the lysis of the cells.

Viral replication has dramatic effects in the host cell, including inhibition of cellular protein synthesis and secretion, interference with RNA synthesis and transport, and activation of other processes that together induce the cytopathic effect. Both apoptotic and anti-apoptotic effects, caused by enterovirus replication in cells, have been reported and also more detailed alterations can be detected. In EV1-infected cells, approximately 2% of the studied genes were induced whereas around 0.5% were downregulated. The activated genes included immediate-early response genes as well as genes involved in apoptotic pathways and cell growth regulation. Viral macromolecule synthesis was also observed to activate protein kinases known to control expression of several cellular genes. Further studies on the events during the infection may reveal cellular activities that are necessary for the infection or play a crucial role in the pathogenesis and they can become new potential targets of chemotherapy.

Clinical Manifestations

In general, the disease pattern caused by echoviruses is highly variable and most of the infections are evidently subclinical like those caused by other human enteroviruses. No specific disease condition can be directly associated with a certain echovirus and different serotypes cause identical clinical illnesses, while the same serotype can have a different clinical outcome in patients during the same epidemic.

Members of HEV-B species are among the most common causes of meningitis that may occur as sporadic cases as well as large epidemics. Typically, the symptoms and signs include fever, headache, nausea, stiffness of the neck, and may be associated with respiratory illness, rash, or myalgia. The manifestations may also exhibit signs of meningoencephalitis. Paralysis is a rare consequence of echovirus infection although some cases have been reported.

In neonates, a severe generalized infection, often clinically indistinguishable from bacterial sepsis, can include meningitis or meningoencephalitis, myocarditis, and hepatitis. A similar syndrome is caused by echoviruses and coxsackie B viruses. The transmission occurs transplacentally or soon after delivery from the mother but can also originate from other infected infants. Immunocompromised patients may develop serious chronic echovirus infections, like meningoencephalitis, occasionally with fatal outcome. These complications occur in individuals with B-cell deficiencies and gammaglobulin has been used for the prevention and treatment of the infections.

Echoviruses are associated with mild respiratory infections (e.g., common cold, bronchiolitis, and herpangina) that cannot be clinically distinguished from illnesses caused by other viral respiratory pathogens. Entroviruses cause maculopapular rashes with similar manifestations caused by other infections. Roseola-like skin manifestations can also occur during enterovirus infections and the 'Boston exanthem', caused by echovirus 16, was the first one of these infections recognized. Although echoviruses and other enteroviruses replicate in the gastrointestinal tract and nausea as well as diarrhea can be associated with the infection, they are not considered as major causative agents of acute viral gastroenteritis. Echoviruses have been isolated from individual cases of conjunctivitis but their role in the disease compared to enteroviruses causing epidemics (coxsackievirus A24 and enterovirus 70) is not important. Epidemics of uveitis, a severe eye infection, caused by echoviruses 11 and 19, have been described in Russia.

Myocarditis is often associated with coxsackie B viruses but other enteroviruses are evidently also responsible for this disease where specific diagnosis is usually difficult. Although neonatal myocarditis can be fatal, the manifestations of the disease in older age groups are often nonspecific, and the cardiac involvement is usually suspected

on the basis of ECG findings and severe symptoms are uncommon. There is also evidence that enteroviruses could have an etiological role in the development of dilated cardiomyopathy.

Members of the HEV-B species have also been associated with the development of type 1 diabetes. This is based largely on seroepidemiological studies but, for instance, echoviruses have also been isolated from prediabetic and diabetic individuals and enterovirus genomes have been detected in the blood of patients with recent onset of diabetes. However, the role of enteroviruses in the process leading to type 1 diabetes remains unknown today. Echoviruses and other enteroviruses have also been suspected to have a role in amyotrophic lateral sclerosis, a chronic progressive neurological disorder, but further studies are required to clarify this association. Involvement of viruses, including enteroviruses, in the chronic fatigue syndrome has also been suspected, but this disease is still poorly characterized and the pathogenesis is not understood. It is known that echoviruses can cause chronic infections in cell culture models and availability of new animal models will further clarify their pathogenesis in the future. Sensitive and specific molecular methods will also cast light in the occurrence of echoviruses in diseases where the etiology is presently unknown.

Based on the observations about the protective effects of the inactivated poliovirus vaccine and appearance of severe chronic enterovirus infections in agammaglobulinemic patients, it is thought that protective immunity in enterovirus infections is mainly antibody mediated. It seems that the response is largely serotype specific and systemic infections may result in life-long immunity. Cell-mediated immunity against enterovirus infections is still rather poorly understood but there is evidence that cross-reactive epitopes between virus serotypes may exist.

Laboratory Diagnosis

Echoviruses can be detected from the cerebrospinal fluid (CSF) and respiratory tract samples during the acute phase of infection, but they may be excreted in stool samples for weeks or even months after the infection. Identification of enteroviruses has been classically based on isolation in cell culture followed by neutralization typing using antiserum pools. Although the advantage of the methods is that it gives information about the serotypes, the problem is the time and labor required. In spite of accelerated protocols, based on immunological staining of the infected cells, the isolation method is of limited use when specific diagnosis is required at the acute phase of the illness.

Introduction of the reverse transcription-polymerase chain reaction (RT-PCR) methods for the molecular detection of human picornaviruses revolutionized rapid diagnosis of the enterovirus infections, in particular those affecting the central nervous system. By this means, it is possible to obtain the results in a few hours which has an important impact in the differential diagnosis and treatment of the illness. Currently used RT-PCR methods take advantage of the conserved regions in the 5′ noncoding region of the genome and do not therefore allow further typing of the detected enteroviruses. However, it has been shown that sequences of the VP1 gene correlate well with the current enterovirus serotypes which makes it possible to obtain more detailed information about the individual virus types. Often amplification of the VP1 sequences, utilizing less well-conserved primers, is not possible directly from the clinical material and requires a cell culture enrichment step. In the future, multiplex RT-PCR and microarray methods may provide us with new tools where the high sensitivity of the molecular methods can be combined with an informative collection of data about the pathogen.

There are no highly sensitive and specific standardized serological assays available for enteroviruses. Neutralization assays are serotype specific, but due to the large number of different viruses, the usage of this method is restricted to epidemiological studies. In-house methods, based on enzyme immonoassays or complement fixation tests, are widely used in diagnostic laboratories. The antigens are usually heat-treated to increase cross-reactivity and synthetic peptides containing conserved sequences are also in use. The presence of enterovirus-specific IgM antibodies or an increase in antibody titers between samples collected at the acute and convalescent phase of the illness are considered as a sign of acute infection.

Epidemiology

Transmission of echoviruses occurs through the respiratory and gastrointestinal routes and the epithelial tissue at these sites is the primary location of replication. This can be followed by viremia and infection of secondary target organs. It is possible that respiratory transmission may predominate in areas with improved hygiene. Several nosocomial outbreaks have been described in neonatal units. In addition to direct contact with infected individuals, the infection can be obtained from contaminated water and food. There is no evidence of animal reservoir for these viruses.

In many studies, echoviruses have been the most commonly isolated enteroviruses and there is an extensive number of reports of outbreaks from different geographical areas during several decades in the literature. Most frequently, the echoviruses have been isolated from children of less than 5 years of age that can be understood for immunological reasons and because of the increased risk of transmission. The occurrence of the infections in this

age group does not necessarily correlate with the appearance of disease, since, for instance, meningitis may be detected more frequently in older children. Approximately half of the isolations originate from infections of the central nervous system and isolation from respiratory and gastrointestinal infections are more rarely used. One of the reasons for this is most probably that in mild infections specific diagnostic procedures are more rare. EV4, EV6, EV7, EV9, EV11, and EV30 have been among the predominating serotypes.

Enterovirus infections occur typically during the late summer and early autumn months in temperate climates while elsewhere, the viruses often appear to circulate through the year. The infections are more common in males and in individuals with lower socioeconomic status. Due to the high number of serotypes and the population immunity, there are considerable differences between the epidemiological periods, and variation from small local outbreaks to widespread epidemics is seen. There is also extensive fluctuation in the occurrence of the serotypes during the years and, for instance, echovirus 30 that has been responsible for large meningitis epidemics worldwide may sometimes represent almost half of the isolations but be absent during another epidemic season.

The epidemiological studies during the twentieth century were based on virus isolation and subsequent typing which provided information about the circulating serotypes. Since the RT-PCR assays only can give information about the presence or absence of enteroviruses in clinical samples, this epidemiological surveillance is significantly changing its character. However, introduction of molecular epidemiological analysis, based on the comparison of genomic sequences, has given new information about the circulation and evolution of the virus strains. The approach has been used in studies of, for example, echovirus 30 and the investigations have shown that there has been one predominant genotype with several distinct lineages circulating in Europe and in Northern America since 1978. These strains are clearly different from those isolated some decades ago and some genetic lineages seem to have completely disappeared during this time.

It has become clear that recombination is a frequent phenomenon in the evolution of enteroviruses. It has been mostly found to occur among the members of the species and in particular in the genome region encoding nonstructural proteins. Since the virus isolates are identified primarily on the basis of the serotype, based on the capsid region sequences, this heterogeneity of the genomes has not previously been observed in the epidemiological studies. Therefore, future studies may give a new picture about the circulating and reemerging genetic lineages. Although it is clear that the nonstructural gene region is evolving rapidly, the rules for the appearance of genetically mosaic strains which become predominant by their superior fitness and other properties remain still unclear. The importance of these events in the generation of new pathogenic strains would be highly important to understand and molecular epidemiological approaches and studies on picornavirus evolution in general will hopefully be able to cast new light on these questions.

Future Perspectives

There are currently no vaccines available against other human picornaviruses except polioviruses and hepatitis A virus. The number of echovirus and other enterovirus serotypes makes vaccine development particularly challenging, since the protection from infection is primarily thought to be mediated by serotype-specific neutralizing antibodies. The most promising chemotherapeutic agent developed against clinical picornavirus infections so far has been pleconaril, a capsid-stabilizing small molecule. It has been successfully used in severe enterovirus infections but due to side effects observed in a treatment study against common cold it is not in general use. Other molecules, based on a similar principle, as well as inhibitors of the virus-specific proteases have also been developed, and they are likely to become tools for the treatment of enterovirus infections in the near future. Since echoviruses, with a few exceptions, do not replicate in experimental animals, testing of antiviral drugs is problematic. However, there are promising results showing that the infection can be successfully transmitted to transgenic mice expressing human receptors for an echovirus.

An interesting application in cancer therapy is the use of naturally occurring or modified viruses. For instance, adenovirus-based systems have been used for this purpose. There are also enteroviruses that have been reported to have such an effect. An example is EV1 shown to exhibit tropism for human ovarian cancer cells.

As illustrated by these few examples, increasing knowledge of echoviruses and their replication is likely to provide us with new tools for the treatment of these infections in the future. New disease associations may also be found by using the improved diagnostic methods. Development of an enterovirus vaccine is a particularly important and demanding goal. Understanding of the cell tropism and detailed multiplication mechanisms of these viruses in the body may also provide us with new tools for the development of tools against clinical illnesses.

Glossary

Adsorption Phage diffusion and attachment to a bacterium.

Burst Release of phage from a bacterium (usually upon lysis). Burst size is the number of phage released per bacterium.

Chronic release The continuous release of phage progeny from infected bacteria in a manner that does not involve bacterial death or infection loss.

Community The species (more than one) found within a given environment.

Ecosystem The sum of the biotic (living community) and abiotic (nonliving) components of a single environment, such as a lake or a field.

Epifluorescent microscopy Microscopic observation of light reemitted from specimen-bound dyes.

Extracellular search The diffusion-mediated movement of a phage virion from the point of release from an infected bacterium through the irreversible attachment of a phage to a susceptible bacterium. The extracellular search for new bacteria to infect may be thwarted by virion decay.

Flow cytometry Technique involving detection of suspended particles (such as bacteria) as they flow through a laser beam.

Latent period The time beginning with phage adsorption to a bacterium and ending with phage release from a bacterium.

Metagenomic sequencing The isolation and sequencing of genomic nucleic acid from whole communities including bacteriophage communities such as those found within a sample volume of seawater.

Population A geographically associated group of interbreeding, potentially interbreeding, or clonally related individuals. A localized grouping of individuals of a single species.

Pseudolysogeny A latent phage infection in which penetration of the phage genome into the bacterial cytoplasm has occurred but subsequent steps towards either productive infection or lysogeny are delayed. Pseudolysogeny is thought to occur primarily when phage infect bacteria that are in a significantly starved state.

Pulsed-field gel electrophoresis A technique for gel separation of large DNA molecules such as the whole genomes of bacteriophage.

Single-step growth A technique involving adsorption of phage to bacteria that is followed by a determination of the timing of phage-progeny release from the now-infected bacteria as well as the total number of phage released per bacterium. The word ‘single’ (or ‘one’) is used to indicate that the released phages are prevented from infecting (or adsorbing to) subsequent bacteria within the experimental vessel.

Spatial structure Environmental impediments to mixing, diffusion, and organism motility such that the present spatial position of an organism serves as a good predictor of future spatial position. In the microbiology laboratory spatial structure is often imposed upon cultures via the addition of agar to growth media.

Introduction

Bacteriophages are viruses of bacteria. An enormous number of bacteriophages are found the world over, on the order of 10^{30} or more. By way of comparison, 10^{30} is approximately the weight of the Sun, in pounds. This chapter presents an overview of the interaction between bacterial viruses and their environments: phage ecology. Phage ecology is a process- or mechanism-centered exploration of how bacteriophages exist in the wild and of their impact there.

Phage Existence within Environments

Phage populations have been documented in numerous environments. With the availability of modern molecular, microscopic, and flow-cytometric techniques, it is relatively easy to obtain direct counts or to molecularly characterize uncultured phage virions obtained from environmental samples. A variety of techniques may also be employed to study viral infection/production (aka, proliferation) within environments, though none of these methods are ideal. Estimations of lysogeny in environments are possible but similarly are not ideal.

Determination of phage numbers by viable (typically plaque; **Figure 1**) count originally dominated phage environmental endeavors. Direct microscopic counts, however, are generally much higher than viable counts, for example, by as much as 10 000-fold. For isolation of viable phage from environmental samples, selective enrichment techniques are often employed. Representative phage (more generally, virus) numbers by direct counts range from 1×10^4 to 2×10^7 per ml seawater. Assuming virion degradation between sampling and enumeration in the above estimations, these numbers are estimated to be as high as $(3–100) \times 10^6$ per ml. Sediment and terrestrial counts can be even higher than phage numbers in open water.

Especially using epifluorescence microscopy, direct counts are accomplished more easily than is either phenotypically characterizing environmental phage or demonstrating phage environmental impact on specific bacteria. Partially making up for these deficiencies, the various molecular approaches – including pulsed-field gel electrophoresis and metagenomic sequencing of phage environmental populations – allow characterization of phage environmental diversity, especially at the level of genotype. While electron microscopy of environmental samples does allow some phenotypic characterization, particularly of virion morphology, none of these approaches are substitutes for phenotypic analysis of individual phage in at least 'phage' pure cultures. In most cases such characterization is not possible because the majority of presumptive phage hosts cannot be cultured in the laboratory.

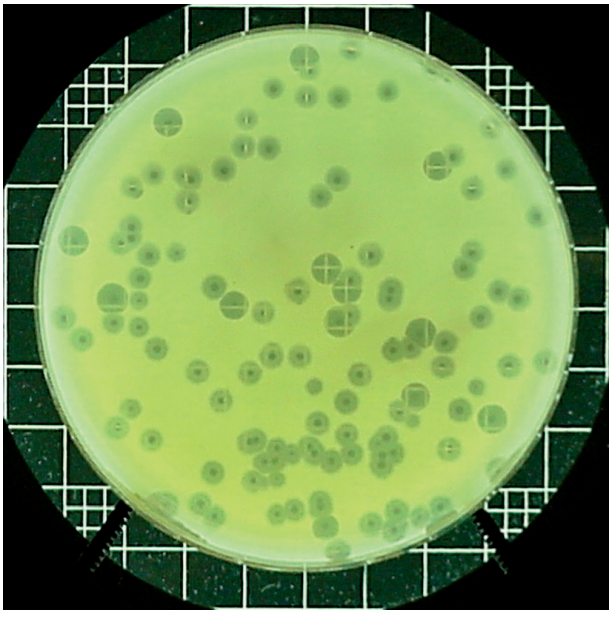

Figure 1 Bacteriophage plaques. Shown are two strains of phage RB69 as grown on the host bacterium *Escherichia coli* CR63. The larger plaques are made by a mutant, called sta5, which displays a significantly shorter latent period than the smaller-plaqued wild type. To accentuate the plaque-size differential, incubations were done at room temperature for 2 days.

Phage Ecology

The science of ecology may be differentiated into a number of more-or-less distinct subdivisions. These include organismal, population, community, ecosystem, and landscape ecologies. Also included, especially under the heading of organismal ecology, are physiological and evolutionary ecologies. Though important to an understanding of ecology in general, in most cases little effort is made within the phage ecology literature to distinguish among these various categories, plus there exist numerous overlaps among these categories. Indeed, phage biologists (including this author) often are trained first as microbiologists (or molecular geneticists, etc.) and only later or much less so as ecologists. As a consequence, phage publications relevant to our understanding of phage ecology typically will not describe their contents from a classically ecological perspective. A major goal of this entry, therefore, will be to expose readers to phage ecological thinking as organized within a more general ecological framework, presented in overview as follows.

Phage organismal ecology considers phage adaptations within environments, with emphasis on phage survival, reproduction, and dissemination. Phage physiological ecology considers the impact of environments on phenotypes, which for phage would be manifested either

through modifications in the physiology of bacterial hosts or in the environmental impact on virion properties. Phage evolutionary ecology considers the selective benefits of phage adaptations especially from an evolutionary perspective.

Phage population ecology considers phage intraspecific interactions, particularly in terms of how those interactions control phage population size, dispersion, and growth rates. Phage community ecology considers phage interactions with other species, especially with bacteria but also with other types of phages as well as with biotic components of the greater bacterial environments, for example, such as in terms of phage-encoded exotoxins which impact the eukaryotic hosts of bacteria. Phage ecosystem ecology considers phage impact on nutrient cycling and energy flow within ecosystems, which by necessity represents a much more abiotic emphasis than other approaches. Phage landscape ecology, which has been little considered at least explicitly within the phage literature, would consider the phage impact on interactions between distinct ecosystems, such as between a pond and a surrounding forest, a sewage treatment plant and downstream environments, or an animal (serving as an ecosystem itself) and the extra-animal environment. Note that these various means of looking at phage ecology build upon one another such that ecosystem ecology builds upon community ecology which builds upon population ecology which builds upon organismal ecology which, finally, is understood best in light of a strong molecular appreciation of phage biology.

Phage Organismal Ecology

Phage organismal ecology may be considered from the perspective of environmental impacts on phage 'growth' parameters, as well as the impact of these parameters on phage ecological success as measured in terms of reproduction, dissemination, and survival. 'Growth' parameters include things such as adsorption rates, infection timing, productive-infection versus lysogeny decisions, burst sizes, and virion decay rates. Since our understanding of phage growth parameters is derived from the laboratory characterization of phages, in this section the author describes this aspect of phage ecology employing a very much laboratory-centered emphasis.

The traditional means of studying most phage growth parameters are single-step growth experiments and phage adsorption determinations. We can fit these growth parameters into a generalized scheme of the phage life cycle, and then consider how variation in the assorted steps of this life cycle can impact phage ecological success. These steps, in order, include (**Figure 2**) (1) a diffusion-driven phage-virion extracellular search for bacteria to infect, (2) the phage adsorption process during which a relatively

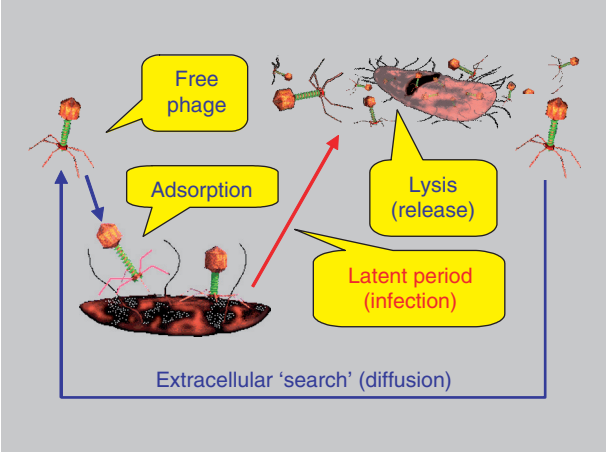

Figure 2 Lytic bacteriophage life history. Images © James A. Sullivan, used with permission.

inert phage-virion and adsorption-susceptible bacterium are together converted into a phage-infected bacterium, (3) the phage infection which can vary in its phenotypic expression from restricted to abortive to productive to pseudolysogenic (or 'carrier state') to lysogenic, and (4) some means of phage-virion release into the extracellular environment. The latter, depending on the phage, may or may not involve host-cell and infection death (i.e., via lysis versus chronic/continuous release, respectively).

Consideration of how variation in these assorted steps can impact phage ecological success is presented in the following sections. For example, we can expect rapid virion adsorption – particularly rapid phage attachment given encounter with a phage-susceptible bacterium – to be favored over less-rapid adsorption unless phenotypes conferring rapid adsorption interfere with phage survival or fecundity. For instance, T4-like phages may enhance their survival within extra-colonic environments by taking on a temporarily adsorption-incompetent but inactivation-resistant state. Another counter to the evolution of more-rapid phage adsorption/attachment may be phage growth within relatively spatially structured environments, if there exist tradeoffs between time spent disseminating versus time spent infecting bacteria. Note that these considerations of phage adsorption rates more generally reflect differences between phage properties 'as virions' versus 'as during bacterial infection', differences which are explored more fully in the following section.

Bacteria-Like versus Virion-Like Modes of Existence

The selective advantage associated with various phage infection and release strategies, similar to phage adsorption rates, will be dependent on environmental conditions, particularly in terms of bacteria numbers, bacteria

physiology, and phage decay rates. In general, we can assume that conditions that favor bacterial growth and survival over phage population growth and survival will tend to favor more bacteria-like modes of phage replication/survival over more phage/virion-like modes; more precisely, we can expect life history biases toward phage existence infecting a bacterium rather than existence as a free virion. Thus, low bacterial densities, bacterial physiologies that poorly support significant phage fecundity, or virion-specific environmental antagonists (including phage-restricting bacteria) will tend to favor extended phage latent periods, once commitment to adsorption has occurred. These infecting states may include pseudolysogeny, lysogeny, or productive but longer-lasting infections, including infections by phage that release their progeny chronically rather than lytically. Alternatively, we can assume that conditions that favor phage population growth will tend to favor more phage-like modes of replication, that is, ones that emphasize the virion state over the infected state. This more virion-emphasizing state can include shorter, productive phage infection – especially lytic infections that favor earlier virion release over higher infection fecundity, but also more-rapid chronic release at the expense of longer-term infection survival.

The advantage of displaying a more phage-like existence under these latter conditions may be viewed from two perspectives. The first is that such conditions should allow for rapid phage-population expansion. Less intuitively, that expansion comes at the expense of bacteria survival, and therefore any phage which persists within a more bacteria-like (extended latent period) mode of infection may be more susceptible to attack by unrelated phages under conditions which are favorable toward phage population expansion (see, e.g., 'Kill the winner', below). Also favoring the virion over the infecting state, a temperate phage can increase its target number and reduce its genomic target size via lysogen induction (i.e., by changing from a single bacterial lysogen to multiple copies of phage). Such induction can occur following bacterial exposure to DNA damaging agents. In considering phage population growth and survival, we thus can envisage phage adaptation within real ecosystems as involving especially a compromise between conflicting tendencies toward greater emphasis on existence as an infection versus greater emphasis toward existence as a virion.

Phage Population Ecology

Considerations of phage population ecology may be differentiated into two categories: (1) the impact of phage adaptations and environmental conditions on phage population growth within well-mixed, fluid environments (such as within broth in the laboratory) and (2) the impact of phage adaptations and environmental conditions on phage population growth within spatially structured environments (such as within soft-agar overlays in the laboratory). These categories will be considerd in turn, emphasizing phage population growth in broth-like environments. Like phage organismal ecology, much of our understanding of phage population ecology derives from laboratory characterization of phage, but also from exercises in modeling phage population growth. We can also distinguish phage population considerations into those operating at low phage densities versus those operating at high phage densities. In both cases density refers to a single phage population since inter-(as opposed to intra-) species interactions are considered under the province of phage community rather than phage population ecology. These latter considerations are much simpler to envisage during phage broth-culture growth.

The growth of phage in broth can be considered to occur over at least four distinct steps. These are as follows:

1. Phage entrance into an environment. This entrance can be physical, in terms of phage movement from one place to another, it can be physiological in terms of the induction of an already-present lysogen, or it can be genetical in terms of phage host-range mutation (or recombination event) such that a previously phage-insusceptible bacterial population suddenly becomes susceptible to sympatric phage.
2. A period of phage-population exponential growth that spans from the point of the initial phage infection of a susceptible bacterium within an environment through to the point of transition whereby most susceptible bacteria have become phage infected.
3. The transition to and then span over which most of the phage-susceptible bacteria within a population are phage infected.
4. A postinfection period during which phage numbers greatly outnumber those of bacteria.

In many cases, each of these steps is at best a transient phenomenon for a given combination of phage, bacterium, and environment. To keep things simple, during this initial discussion assume the least complex of environments: one that is homogeneous, well-mixed, closed (e.g., not a continuous culture), and of finite volume. That is, the equivalent of a shaken or stirred broth-filled flask. Also for the sake of simplicity, assume that bacteria do not replicate nor change physiologically, other than by phage infection, over the course of phage population growth.

In general terms, once a phage virion has been released from an infected bacterium, it has entered into a period of what is described as an extracellular search for new bacteria to infect. The duration of this search will be a function of the product of the density of phage susceptible bacteria within a given environment – which in turn is a function of the range of bacterial types that a given phage

may infect – and the phage adsorption constant, which will vary as a function of phage, bacterium, and environmental parameters. The likelihood that a given phage will successfully adsorb to and infect a bacterium is additionally a function of a phage's decay rate, with higher decay rates reducing the likelihood of successful virion infection. Decay can be a function of abiotic insults that result in virion capsid or nucleic acid damage, phage adsorption to abiotic materials, biotic insults including engulfment by eukaryotes as well as restriction (i.e., death or inactivation) mediated by phage-adsorbed bacteria, or even emigration out of an environment. To a phage entering a previously phage-free environment, the likelihood that phage population growth will occur therefore is a function of bacterial numbers, rates of phage adsorption per bacterium, and rates of phage decay.

If a successful adsorption occurs, the likelihood that phage population growth will continue beyond this first adsorption will additionally be a function of phage burst size, with each additional phage produced per infection essentially possessing an additional, nearly identical likelihood of successful bacterial adsorption. Extending this point, we can assume with either higher bacterial numbers, more-effective/rapid virion adsorption per bacterium, lower rates of decay, or higher initial phage numbers that there will be a greater likelihood that phage population growth will be initiated upon phage entrance into a new environment. The potential for a phage population to grow within a given environment can be described as its existence conditions.

Once phage population growth has begun, it seems unlikely that there would exist any intrinsic inhibitions on phage evolution toward faster population growth. This is not to say that there may not be blocks extrinsic to phage population growth, including various tradeoffs that could exist, such as potential conflicts between, on the one hand, the breadth of a phage's host range (more generally, niche) and, on the other hand, rates of phage population growth on any given host population (which would be a conflict between ecological generalization vs. specialization). However, both in terms of intraspecific and interspecific competition among phages, it is the phage that reaches a bacterium first that should have the greatest potential to 'claim' that bacterium for infection. Thus, a phage that grows its population fastest will have access to more bacteria sooner, and therefore enjoy among its progeny greater overall numbers of bacterial infections within a given environment. In general, we can expect faster overall population growth given greater phage burst sizes, shorter phage latent periods, or faster phage adsorption. Phage decay can also affect rates of phage population growth, and this occurs via reductions in effective phage burst size, where the qualifier 'effective' refers to the number of phage released from a given bacterial cell which go on to successfully infect a new bacterium.

Things change, within a given environment, as a phage population reaches the limits of its population growth. At this point the selective pressures on phage growth change from ones that are phage-density independent to ones which are phage-density dependent. These phage-density-dependent limits vary in their relevance, however, depending on bacterial densities along with phage fecundities. At one extreme, bacterial densities are so low, or phage fecundities (effective burst sizes) so small, that phage populations never reach densities of sufficient size to greatly affect bacterial populations. Under these conditions multiple phage adsorption to a given bacterium is of low likelihood and competition between phage for individual bacteria small. Selection here should be biased toward greater virion or infection durability, for example, rather than higher rates of phage population growth. We have this expectation because bacterial rarity presumably would put a premium on phage survival prior to bacterium encounter and also because phage potential to migrate to new bacteria-containing environments could be a function of longer-term phage survival, either as virions or as bacterial infections.

At the other extreme, bacterial densities as well as phage fecundities may be sufficiently high that a majority of phage-susceptible bacteria may become phage infected and therefore no longer available for further infection by the same phage type. Prior to this point we may expect selection to favor phage that display rapid population growth, even if such rapidity should come at the expense of effective burst size, either in terms of actual burst size or in terms of virion resistance to decay. Thus, at higher bacterial densities a phage could display faster population growth by shortening its latent period. Such shortening, however, is most easily accomplished at the expense of the overall duration of the period during which phage-progeny mature, resulting in a reduced phage burst size. Alternatively, one could envisage a loss of phage genes that otherwise could contribute to long-term virion survival should the presence of those genes come at the expense of effective phage burst size or further latent-period shortening. One possible example of such evolution could be a common loss of temperance among phage contaminating industrial dairy ferments.

Adaptation that results in declines in phage survival could be shortsighted within environments in which densities of new bacteria to infect are in rapid decline. Instead, we can envisage an advantage bestowed upon phage infections during 'final rounds' of infection – that is, at the point where most bacteria within a population have become phage infected – that would result from larger effective burst sizes. In this way more or more robust phages are produced to better assure phage survival until access to new bacterial populations occurs. Somewhat equivalently, a phage may accrue advantage by displaying a more bacteria-like lifestyle under conditions

where bacterial densities are in decline, such as via temperate-phage reduction to lysogeny rather than display of a lytic infection.

Many of these same effects take place during phage population growth within spatially structured environments, such as within bacterial lawns immobilized within soft agar, that is, as phage plaques (**Figure 1**) or as within soil. A difference, though, is that in addition to temporal differentiation between density- and density-dependent selection, there are also spatial differences. Thus, phage multiplicity is higher toward the center of plaques versus toward their periphery. In other words, at a plaque's leading edge, selection acting upon phage characteristics is more density independent than toward the center of plaques. Thus, we can expect selection for faster phage population growth to occur at a plaque's periphery, whereas, by contrast, selection at a plaque's center should be biased more toward a greater effective burst size.

Phage Community Ecology

Phage community ecology includes issues of phage predation on bacteria as well as the establishment of mutualistic-like relationships such as those between prophage and bacteria, forming lysogens. The phage community ecology literature is more closely aligned with the ecological literature, which is to say that a good deal of phage community ecology has been done by individuals trained first as ecologists who have then taken to phage as model systems rather than by individuals trained first by studying more organismal or more molecular aspects of phage biology. As such, phage community ecology has a much more theoretical basis than either phage organismal or population biologies, including the employment of simulations of phage–bacterial interactions, especially within continuous cultures (chemostats). Phage community ecology has a much more environmental emphasis than these other ecologies, as workers consider, especially, the phage impact on bacterial populations. Phage community ecology can also involve consideration of interactions between different phage species or grazing of phage by protists.

We can distill three general governing principles of phage community ecology, especially with regard to phage impact on bacteria: (1) The greater a phage population density then, all else held constant, the greater the phage impact on a bacterial population, and the faster that phage populations reach these higher densities, then the sooner their impact. (2) The greater the density of phage-sensitive bacteria, then, potential changes in bacterial physiology aside, the greater the population size that phage can grow to and the sooner they will grow to that population size. (3) Bacteria can hide in various ways from phage – numerically, genetically, physiologically, spatially – but doing so can come at a cost in terms of, for example, bacterial growth rates.

Real world applications of these concepts include that of 'Kill the winner' where it is expected that populations of same or similar bacterial types, that grow to higher densities, will tend to become more susceptible to phage-mediated population crashes. These crashes result solely from bacteria having reached these higher densities. By culling especially more successful bacterial populations, phage may serve as mediators of a frequency-dependent selection among bacterial communities that results in greater bacterial diversity than environments could otherwise sustain.

A second and related real-world consideration is that bacteria within especially eutrophic (i.e., high-nutrient) environments, where phage virions can be especially abundant, may display physiologies that represent trade-offs between rates of bacteria growth and phage-free survival. That is, bacteria may be subject to physiological and other burdens that come with deploying protective measures. Protective measures are potentially diverse and certainly include things such as restriction-modification systems. Additionally, bacteria may take on more-protective modes of existence such as within extracellular polysaccharides or biofilms.

Bacteria may also display reduced versatility because of loss (temporarily or permanently; fully or partially) of membrane proteins involved, for example, in nutrient transport, proteins which could otherwise serve as phage receptors. That is, the more proteins (or other molecules) a bacterium displays on its surface, the more phage types that bacterium may be susceptible to. Because many of these mechanisms of phage resistance can result in reduced bacterial fitness, we should expect that the strength of selection for phage resistance should be directly proportional to phage density within a given environment. Phage, in turn, can display adaptations that serve to overcome various bacterium-mediated mechanisms of phage resistance. Bacteria can also evolve to mitigate the costs associated with displaying phage resistance.

A third real-world consequence of phage impact on bacteria is as a consequence of phage-mediated transduction of bacterial genetic material. Phage do this by two basic mechanisms: generalized transduction in which bacterial DNA is incorporated into consequently defective phage virions (with essentially equal probability of incorporation across the bacterial chromosome) and specialized transduction, which traditionally involves the incorporation of the bacterial genomic DNA that flanks prophage as a consequence of imprecise prophage excision upon induction. A third means, essentially an extension of the concept of specialization transduction, is via phage 'morons', which involves the incorporation via illegitimate recombination of bacterial genes into various locations within temperate phage, which are then passed

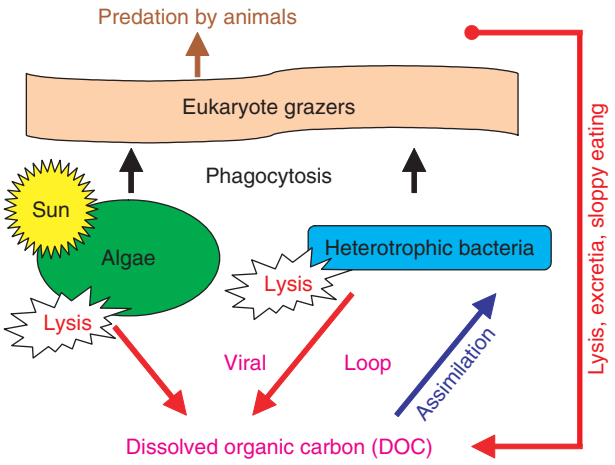

Figure 3 Microbial loop as short circuited by virus-(particularly phage-) induced lysis. The viral loop consists of generation of dissolved organic carbon via virus-induced lysis of especially heterotrophic bacteria and cyanobacteria (the latter here included under the heading, Algae), which is followed by assimilation of a fraction of that material into heterotrophic bacteria. The viral loop reduces the efficiencies by which photosynthetically fixed organic carbon is transferred to higher trophic levels, such as to aquatic animals, via the microbial loop.

on to bacteria via subsequent establishment of lysogeny. These genes, along with prophage as a whole, can impact bacterial phenotype including the fitness of lysogens, the latter at least some of the time for the better. These latter mechanisms of transduction serve as a means of transferring genetic material from bacterium to bacterium while also transferring genetic material from bacterium to phage.

Phage Ecosystem Ecology

Phage ecosystem ecology is more firmly rooted in considerations of phage environmental interactions than in the theory of phage community ecology. The primary emphasis of this field is on the impact of phage infection of prokaryotes on the movement of nutrients and energy from prokaryotes to higher trophic levels. That is, phage infection influences the acquisition of bacteria (including cyanobacteria) by bacteria-eating eukaryotes. The real-world significance of this emphasis derives from prokaryotes serving as the base of many, especially aquatic, ecosystems and the role that these bacteria play in carbon sequestration. That is, within aquatic environments most dissolved organic material becomes available to eukaryote grazers only once bacteria have assimilated it. With phage-induced bacterial lysis, however, a significant fraction, up to approximately 25% of the carbon entering these ecosystems photosynthetically, is converted to a dissolved organic state. This creates a 'viral loop' that shunts organic carbon away from what is known as the aquatic 'microbial loop', which otherwise moves carbon from prokaryotes to grazers (i.e., especially phagotrophic protists) to grazer-consuming animals (**Figure 3**). Another way of stating the significance of the phage impact on the survival of aquatic bacteria is that it is approximately equivalent to the impact of protist grazing. The impact of phage infection versus protist grazing, however, varies with habitat, with phage displaying a greater impact especially in more extreme, including low-oxygen environments.

Electron Microscopy of Viruses

G Schoehn and R W H Ruigrok, CNRS, Grenoble, France

© 2008 Elsevier Ltd. All rights reserved.

Introduction

Most viruses are too small to be observed with light microscopy and many are too large or too irregular to crystallize. Therefore, electron microscopy (EM) is the method of choice for the direct visualization of viruses and viral proteins or subviral particles. However, electrons do not travel far in air and therefore the inside of the microscope has to be under very high vacuum (10^{-5} to 10^{-8} torr). This implies that biological samples have to be dehydrated and/or fixed. It is important that the biological sample is stabilized (or fixed) so that its ultrastructure remains as close as possible to that in the biologically active material when exposed to the vacuum.

The penetrating power of electrons in biological material is also very limited, which means that the specimens must either be very thin or must be sliced into thin sections (50–100 nm) to allow electrons to pass through. This is not a real problem for the imaging of viruses because the sizes of viruses are usually in this range but if we want to study viruses interacting with cells during infection or replication, sectioning is necessary.

Contrast in the transmission electron microscope basically depends on the atomic number of the atoms in the specimen; the higher the atomic number, the more electrons are scattered and the larger the contrast. Biological molecules are composed of atoms of very low atomic number (carbon, hydrogen, nitrogen, phosphorus, and sulfur). Staining methods using heavy metal salts or image analysis have to be used to enhance the contrast in electron micrographs.

In order to make this article easier to read we will illustrate the various EM-preparation techniques with images of intact adenovirus particles, individual capsid proteins or protein complexes from adenoviruses. Adenoviruses are double-stranded DNA viruses with an icosahedral capsid with a pseudo T number of 25 and a total protein mass of around 125 MDa. The major capsid components are the hexon, a trimeric protein with a basal hexagonal shape, and the penton that is a noncovalent complex between the pentameric penton base and the trimeric fiber protein. Two hundred and forty hexons form the 20 facets of the icosahedron, whereas the pentons form and project from the 12 vertices. The fiber binds to host cell receptors with its C-terminal knob domain whereas protein loops that extend from the penton base and that contain an Arg-Gly-Asp (RGD) sequence are required to bind to a secondary cell receptor to trigger endocytosis of the virus. The capsid also contains minor components, proteins IIIa, VI, VIII and IX that glue the hexons and pentons together at specific positions in the capsid. For a schematic drawing of the virus, see **Figure 1(a)**.

Techniques for Single Particle Imaging

Before any sample preparation takes place, one should be informed about the nature of the sample: its molecular weight, some information on its physical size, and the chemical nature of the components (proteins, nucleic

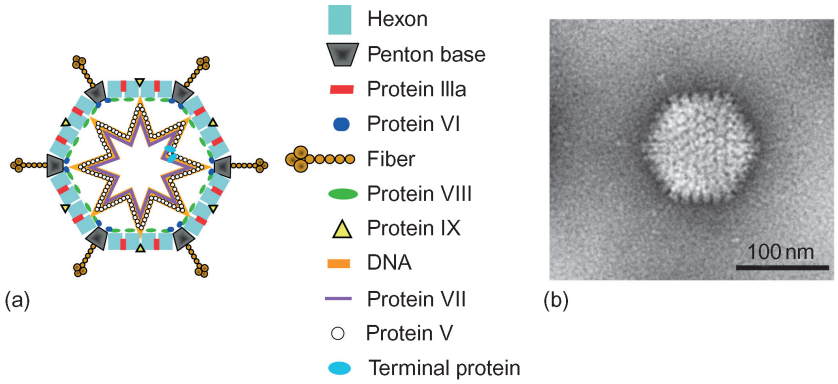

Figure 1 The adenovirus particle. (a) Schematic view of an adenovirus particle. A schematic view through a sliced adenovirus showing the different structural proteins of the virus. The adenovirus particle is an icosahedral particle with on each vertex a noncovalent complex between a trimeric fibre and a pentameric base. This complex is called the penton. (b) Electron micrograph of an adenovirus particle negatively stained with a 1% solution of ammonium molybdate pH 7.5. The particle is seen in the same orientation as in (a). The approximate molecular weight of an adenovirus is 150 MDa and the size of the particle is 1000 Å in diameter.

acids, lipid membranes). Further, it is important to verify by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS PAGE) whether the protein(s) in the sample is (are) intact and not totally or partially degraded. Information on possible contamination of protein samples with nucleic acids can be obtained by measuring the optical density spectrum at 220–350 nm. Such a spectrum can also give information on whether a protein sample contains aggregated protein since a significant absorption at wavelengths above 300 nm is then observed. Such controls are important because the imaging techniques that are described here will always lead to a picture. However, one wants to know how the picture relates to the active biological sample.

Negative Staining

For negative staining the sample is placed on a support film, bathed in a solution of a heavy metal salt that is subsequently blotted, and the sample is then left to dry in air (**Figure 2**). The stain will dry around the molecules, and the area where the molecules happen to be will appear light and the space around it dark, that is, opaque for electrons. As support films one can use plastic films, commercially available or home-made, but these films tend to become hydrophobic after some time and need to be cleaned first with a plasma cleaner. Plastic films are mechanically resistant but are often rather thick and give a high background noise in the images. Thin carbon films give better results. These films are evaporated onto the surface of freshly cleaved mica by heating carbon at high temperatures under vacuum.

For sample preparation it is important to know the concentration of the sample. For small molecules like isolated capsomer proteins, a concentration between 0.05 and 0.1 mg ml^{-1} often gives the best results. When the concentration is too low the stain will not be spread out evenly on the support film and if the concentration is too high the molecules will be one on top of the other and the picture will be difficult to interpret. For intact virus particles such as adenoviruses and influenza viruses, a concentration of 1 mg ml^{-1} should be used. Using a drawn-out glass Pasteur pipette (the sample is taken up into the pipette by capillary force) 1–2 μl of the sample is touched at the carbon–mica interface of a small piece of precut carbon on mica (**Figure 2(a)**). The surface of the carbon on the outside is hydrophobic but at the interface the carbon is clean and hydrophilic and the sample is sucked in between the carbon and mica layers. Then the carbon film with the adsorbed sample is floated off in a pool of negative-stain (usually uranyl acetate (UA), ammonium molybdate, or sodium silicotungstate, SST) and a copper EM grid is placed on the top of the floating film. The grid plus carbon film is then picked up by placing a small piece of paper on the grid and, as the paper wets, it is lifted up taking grid and carbon film up from the pool of stain. In this way the edges of the carbon film that stick out over the rim of the copper grid do not fold back onto the bottom of the grid, creating carbon layers at both sides of the grid with an inclusion of stain. The paper-grid-carbon-sample sandwich is placed on filter paper to blot and air-dry for at least 5 min before insertion into the column of an electron microscope (**Figure 2(a)**).

Different heavy atom salts that are available commercially can be used for negative staining. However, chemical reactions between the salt and the specimen are possible. When the salt binds specifically to the sample molecules one may obtain positive staining rather than negative staining. With positive staining one does not obtain an image of a clear sample molecule on a dark background but a dark molecule on a clear background. It should also be taken into consideration that some salts for staining might have non-neutral pH values. Finally, stain molecules have defined sizes and the resolution of the image may be limited by the grain size of the stain molecules.

Uranyl acetate has a low pH (pH 4.4) and is known to cross-link and stabilize fragile macromolecular assemblies. This stain is especially useful for enveloped viruses since the binding of uranyl ions to the negatively charged lipid heads stabilizes the membranes. This stain does not stay close to the support film but will also stain the top of virus particles so that one obtains a superimposed image of the surface features that touch the support film plus the features on the opposite side of the virus particle. It is not such a good stain for thin objects that lie flat on the support film because the contrast is reduced by the stain lying on top of the object. In **Figure 2** the molecules in plate C (right) were stained with uranyl acetate. Note that uranyl acetate, because of its ability to chemically react with proteins, lipids, and nucleic acids, is known to cause positive staining as well as negative staining. One serious problem with this salt is that it is no longer available in some countries since even nonenriched uranium may be considered to be of military importance. Another problem is that it is slightly radioactive. Sodium silicotungstate is a chemically inert stain with a neutral pH. The stain stays very close to the support film and outlines only those features of a virus or protein that are in contact with the film and it is therefore often used to stain small proteins. The size of the stain molecule is rather large (i.e., 10 Å in diameter) and this feature may limit the resolution of image reconstructions. The stain is often sold as silicotungstic acid. The acid needs to be solubilized in water, neutralized with NaOH and the salt is precipitated with cold ethanol. In **Figure 2** plates (b), (c) (left), and (d) were stained with SST. This stain allows visualization (and sometimes determination of their oligomeric state) of proteins as small as 60 kDa (**Figure 2(d)**).

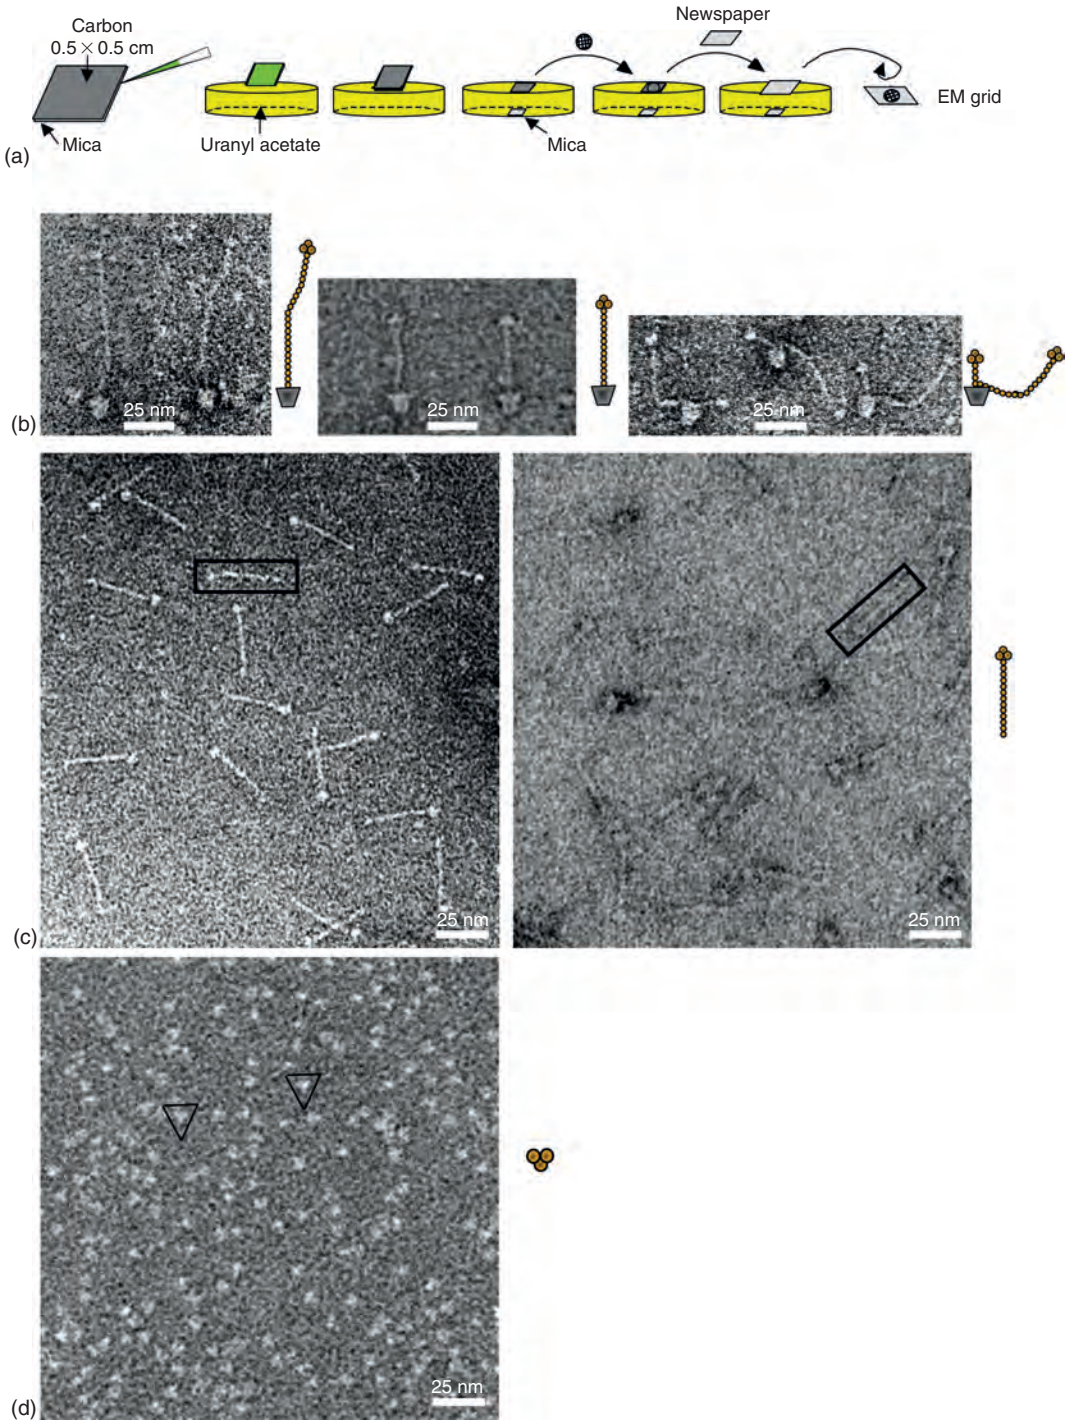

Figure 2 Negative staining technique and results. (a) The different steps of the negative staining method: the sample is adsorbed onto the carbon support film by touching a pipette with the sample to the mica and carbon interface. Then the sample/carbon is floated off the mica onto the surface of a solution of a heavy atom salt. An EM grid is placed on the surface of the carbon and then a piece of paper is used to pick up the grid with carbon film. The paper with grid, carbon, and sample is blotted on filter paper and the grid is then air-dried before observation in the microscope. (b) Electron micrographs of different adenovirus pentons negatively stained with sodium silicotungstate. From left to right one can see a bovine adenovirus 3 penton base (very long and bent fiber), a human adenovirus 41 penton with the long fiber, and an avian adenovirus penton (one base with two different fibers sticking out). The penton base is around 300 kDa is size, whereas the fiber is between 120 and 350 kDa. (c) Electron micrograph of an isolated adenovirus 2 fiber stained with sodium silicotungstate (left) and uranyl acetate (right). In each case, a single fiber is highlighted by a black rectangle. The molecular weight of one fiber is 190 kDa. (d) Electron micrograph of a recombinant canine adenovirus fiber-head expressed in *Escherichia coli*, stained with sodium silicotungstate. The molecular weight of the trimeric particle is around 60 kDa and it is sometimes possible to recognize the triangular shape of the particle (black triangles).

Phosphotungstic acid (PTA) can be used at pH values between 5 and 7. The staining characteristics are similar to those of SST although PTA often does not spread out well during air-drying and can remain in thick puddles. The stain in these puddles is so thick that protein structures cannot be visualized. This stain can be rather destabilizing for lipid membranes and enveloped viruses often show membrane blebs that are squeezed out of the regular lipid envelope during air-drying.

Ammonium molybdate has a neutral pH. During drying, the stain stays quite high on the support film. It is therefore especially useful for the staining of large particles (**Figure 1(b)**). This stain can be used for cryo-negative staining when very high stain concentrations (16%) are used. The preparation of the grids is as described below for regular cryo-microscopy. The advantage over regular cryo-microscopy is the much higher contrast. The disadvantage is that of all negative staining techniques: only the outside of the particles is visualized by negative staining without any information on the structures inside the virus particles.

Advantages and limitations

With the negative staining technique it is possible to visualize small proteins and sometimes determine their oligomeric state in a very rapid manner. The main limitation of this technique results from the air-drying step. If the sample is fragile, which is the case with enveloped viruses, some flattening can occur during drying and lipid blebs can be squeezed out. Finally, the molecular forces that act upon proteins, complexes, or viruses during the adsorption phase onto the support film can also induce conformational changes.

Cryo-Electron Microscopy

In order to overcome the adsorption step, stain artifacts and, most importantly, the drying step, Dr. Jacques Dubochet and collaborators developed a new sample preparation technique: the frozen-hydrated sample imaging or cryo-EM (**Figure 3**). For this technique the sample concentration must be much higher than that for negative staining because there is no direct support film that has a

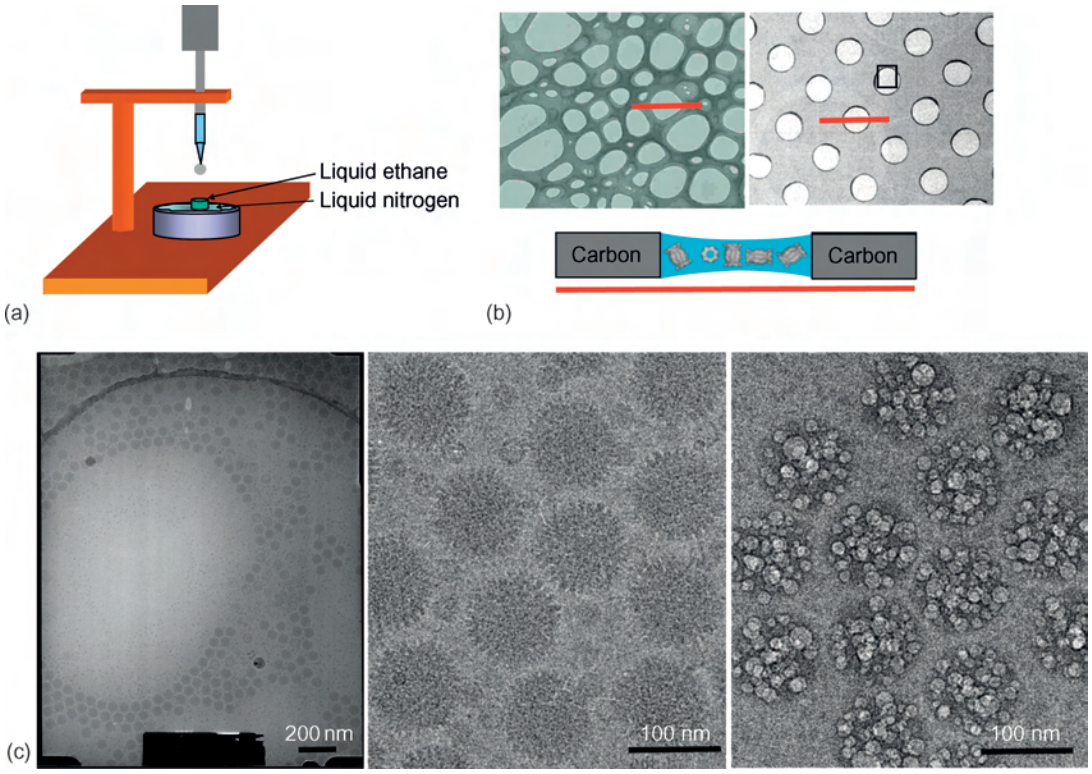

Figure 3 Cryo-electron microscopy (EM) technique and results. (a) Plunger used for rapid freezing of the sample. A grid covered with a holey carbon film is loaded with the sample just before blotting and plunging it very rapidly into liquid ethane cooled down by liquid nitrogen. (b) Examples of home-made holey carbon (left) and commercial quantifoil grid (right). The red bar represents a slice through a hole showing the sample in the frozen vitrified water (bottom). The rectangle on the quantifoil grid represents the portion of field indicated by the red bar above. (c) Cryo-EM images of adenovirus particles. The sample was prepared on a quantifoil film. The picture on the left part is an entire micrograph showing the repartition of the adenovirus particles according to the ice thickness (one part of the hole is totally empty due to the fact that the ice is too thin. The middle part shows a higher magnification of the cryo-EM micrograph. Details are visible on the virus particle; the smaller particles are adenovirus-associated viruses. On the right, the same adenovirus sample is shown after an 1 min exposure to the electron beam. Irradiation damage (bubbles on the picture) is clearly visible.

concentrating effect. The support film for the sample in solution is a carbon film with holes, either home-made (rather irregular, **Figure 3(b)**, left film) or commercially obtained (these films have very regular, evenly spaced holes, **Figure 3(b)**, right film). An aliquot of 2–4 μl of purified sample at a concentration of 0.5–1 mg ml^{-1} is pipetted onto a copper grid covered by the carbon film. Excess liquid is removed by brief blotting with a piece of blotting paper and the grid is then plunged into liquid ethane cooled by a liquid nitrogen bath (**Figure 3(a)**). The rate at which the temperature of the buffer in the holes is lowered is so high that there is no time for the formation of ice crystals; the water forms vitreous ice (also called amorphous ice). Because of the absence of ice crystals, the sample is not deformed but stays in its native state and the vitreous ice is translucent for electrons. The frozen grids have to be transferred into a cryo-holder and inserted into the microscope. The temperature of the sample has to stay very low (i.e., under −160 °C) in order to prevent the vitreous ice to transform into hexagonal or cubic ice. If this irreversible conversion occurs the structure of the sample will be destroyed. All cryo-EM work has to be done at low temperature and the microscope has to be equipped with cryo-EM tools (cryo-holder, anti contaminator blades around the specimen in the microscope in order to avoid the deposition of water and other vapors onto the sample). The ranges of salt concentration and pH that can be used are quite large and include physiological conditions.

Advantages and limitations

Because no heavy atoms are added to the sample, the contrast in the images is very low (**Figure 3(c)**) (the contrast is partly generated by the difference in density between the frozen water and the protein, i.e., 1 g/ml vs. 1.3 g ml^{-1}). This low contrast makes the use of image analysis indispensable. The combination of low contrast and noise also limits the minimum size of the protein/macromolecular assemblies that can be studied by cryo-EM to about 200 kDa. Radiation damage is also a big problem in cryo-EM. As soon as the sample is exposed to the electron beam its starts to be destroyed (**Figure 3(c)**), right). However, minimal dose systems have been developed to limit the electron dose that hits the sample by exposing it only at the nominal magnification during the photographic or charged-coupled device (CCD) camera exposure time. Basically, the electron dose has to be less than 10 e^{-}Å^{-2} in order to preserve the structure of the sample.

There have been a number of recent technological advances that have made the use of this technique easier. The blotting time of the grid is one of the important steps in sample freezing, but is also one of the less reproducible ones. The thickness of the ice in the hole has to be as close as possible to the diameter of the sample. Automated procedures for producing reproducible cryo-EM grids have been developed and commercial devices for obtaining reproducible ice thickness are now available. The introduction of support films with regularly spaced holes in parallel with automated freezing will make automated data acquisition possible.

Cryo-Electron Tomography

Electron tomography allows the study of the 3D organization of thin individual cell organelles and bacterial cells at nanometer resolutions without slicing them. This technique is also able to reconstruct the 3D structure of nonregular viruses. In contrast to all other EM reconstruction techniques, the samples are unique objects. For tomography, a tilt-series is taken from a single object (from −70° to +70°). CCD cameras are used for the recording of many images of the same sample without serious radiation damage. The second step is to align all the images coming from the tilt series in order to generate a 3D model of the object. Tomography holds the potential to routinely enable reconstructions that will allow the fitting of intermediate-resolution EM-structures or high-resolution X-ray-structures into the features of the tomography reconstruction.

Metal Shadowing

The angular shadowing of protein samples consists of evaporation under vacuum of a thin film of metal at an angle over a dried sample on support film (**Figure 4(a)**). The sample is mixed with glycerol and then deposited on the surface of a mica sheet. The mica is then introduced into an evaporator and dried. The sample is then tilted for evaporation. Different kinds of metal can be evaporated onto the surface of the sample (titanium, gold, platinum-paladium alloy). Subsequently a carbon film is evaporated onto the mica, which is then floated off on a water bath, much like the methods used for negative staining above, and the metal comes off the mica with the carbon. Different metals will lead to different grain sizes. Differences in sample height will lead to differences in metal deposit and, hence in contrast (see **Figure 4(b)**). This technique is the only technique that can determine the handedness of a helix and distinguish, for example, between icosahedral 7*d* or 7*l* surface lattices. Rotational shadowing is based on the same principle as angular shadowing but the sample is rotated during evaporation (a fixed angle of evaporation is kept). This technique is especially helpful for the visualization of small proteins or nucleic acids (**Figure 4(b)**). Note that the dimensions of shadowed proteins are difficult to interpret because the metal shadow will add significantly to the thickness of the protein.

Preparation of Cells or Very Large Particles for EM Observation

One of the most interesting aspects of virus studies is the analysis of virus infection, trafficking, and particle

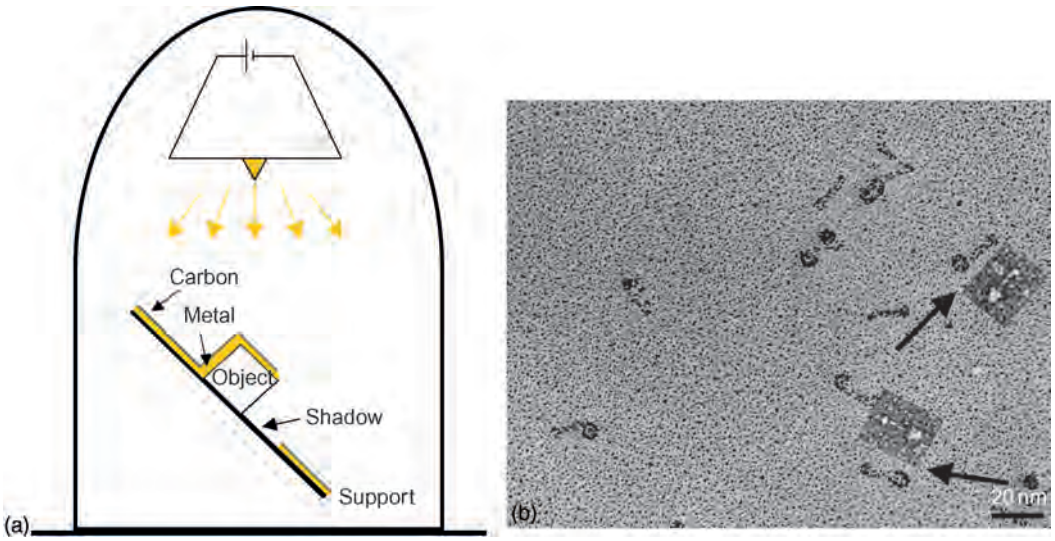

Figure 4 Principle of rotary shadowing. (a) Principle of shadowing. The shadowing process occurs under high vacuum. The specimen is in a tilted position. At the top, the metal to be evaporated is shown in yellow. It is heated until evaporation by a high-intensity current and will be deposited onto the sample. For rotating shadowing, the specimen is not fixed in a tilted position but rotated while keeping the same tilt angle. (b) Human adenovirus 3 penton base was rotatively shadowed using platinum. For comparison the same object negatively stained using sodium silicotungstate has been placed on the same figure (insets are arrowed).

formation in cells. Unfortunately, cells and tissues are generally too thick to be directly observed by EM and they first have to be sectioned.

Thin and Ultrathin Sectioning

Classical thin sectioning

The cells or tissues are first stabilized by chemical fixation (usually with aldehydes such as formaldehyde or gluteraldehyde) in order to immobilize the protein and nucleic acid components of the cell (**Figure 5**). Subsequently, fixation with osmium tetroxide will immobilize and stain the membranes of the cell. Note that all these fixatives are very toxic. Then the material is dehydrated in ethanol or acetone and embedded in plastic. Ultrathin sections (60 nm) cut with diamond knives using an ultramicrotome are floated on water, transferred to specimen support grids and examined in the transmission electron microscopy (TEM). Before observation, the sections are further contrasted with uranyl acetate and lead citrate. There are many different types of plastic resins. The hardest resins (epoxy) will best preserve the ultrastructure of the cells during sectioning but will not allow antibody labeling of sections because the antibodies have no or little access to their antigens. There exist soft or spongy resins (Lowicryl) that do permit antibody labeling but these resins are not hard enough to guarantee ultrastructure conservation.

Application: Antibody labeling

Successful immunocytochemistry is only possible when antibodies (or other affinity markers) are able to bind to their target ligands. For extracellular antigens this is not a problem, but for molecules inside cells the markers must be able to access the antigens. For EM it is important to use preparation methods that open the cells and allow introduction of antibodies without destroying the normal cellular organization. The antigens must also be preserved during the different sectioning steps.

The cryo-section technique is now one of the two most important techniques for subcellular immunocytochemistry. Specialized resin formulas have been developed specifically for use in immunocytochemistry. These include the Lowicryl resins, LR White and LR Gold, Unicryl, and MonoStep. They all have low viscosity and can be polymerized, at low temperatures, with ultraviolet light.

In practice, this method is used with electron opaque markers, which bind to the antibodies and show their location within the cell. In this way, subcellular antigens recognized by antibodies can be localized directly with TEM. Colloidal gold coupled to protein A (a protein from bacterial cell walls that binds to the Fc portion of antibodies) has been used extensively in recent years to localize antibodies on resin and frozen sections of biological materials (**Figure 5**). The ability to produce homogeneous populations of colloidal gold with different particle sizes enabled the use of these probes to co-localize different structures on the same section.

Cryo-sectioning

As for single particles, it is possible to freeze biological material fast enough to vitrify the water present inside the cells. Vitrification of water occurs when the freezing is so fast that ice crystals have no time to form. Vitrified biological material can be sectioned at low temperatures. Because no drying occurs and no salt has been added,

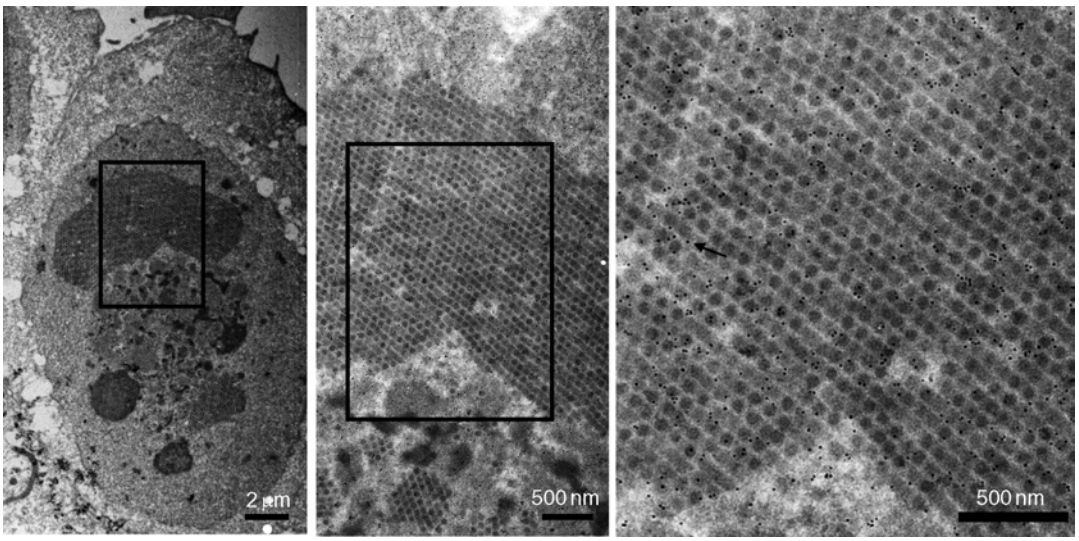

Figure 5 Thin sectioned, adenovirus infected cells. Going from left to right one can see an increase of magnification going from a general view of the infected nucleus to clearly recognizable particles. On the right, the infected cells have been labeled with anti-adenovirus-hexon (major capsid component) antibody coupled with colloidal gold (arrow). Cells were fixed with 2.5% glutaraldehyde in 100 mM HEPES buffer pH 7.4, post-fixed with 1% osmium tetraoxide and dehydrated with ethanol and then embedded in Epon prior to slicing. Grids were stained with saturated uranyl acetate in 50% ethanol and then with 1 M lead citrate.

cryo-sections better represent the native state of cells although the contrast in the sample is low. Presently, there are seven main rapid freezing methods possible:

1. Immersion freezing – the specimen is plunged into the cryogen.
2. Slam (or metal mirror) freezing – the specimen is impacted onto a polished metal (usually copper) surface cooled with liquid nitrogen or helium.
3. Cold block freezing – two cold, polished metal blocks attached to the jaws of a pair of pliers squeeze-freeze the specimen.
4. Spray freezing – a fine spray of sample in liquid suspension is shot into the cryogen (usually liquid propane).
5. Jet freezing – a jet of liquid cryogen is sprayed onto the specimen.
6. Excision freezing – a cold needle is plunged into the specimen, simultaneously freezing and dissecting the sample.
7. High-pressure freezing – freezing the specimen at very high pressure avoids the expansion of water that occurs during freezing.

CEMOVIS: Cryo-EM of vitreous sections

Dr. Jacques Dubochet in Lausanne has developed the cryo-EM of vitreous sections (CEMOVIS) technique. This technique which consists of cutting very thin sections of a vitrified sample requires good vitrification of the sample and good cutting. Progress in these two domains has been of crucial importance. The first one is high-pressure freezing, which made it possible to increase the thickness of a typical biological sample that can be vitrified from 10 to 100 µm. The second progress came from a better understanding of the cutting process which allowed optimization of the cutting. It is now possible to obtain reproducibly ribbons of homogeneous, 50 nm thick sections in which biological structures are remarkably preserved. It is also possible to observe for the first time, at a resolution approaching 2 nm, the ultrastructure of cells and tissues in their native state.

The next step using CEMOVIS is to combine it with electron tomography. Recording a large number of tilted images (typically 100) should allow the calculation of a 3D model of the specimen to a resolution approaching 4 nm. This is a real challenge for studying virus replication.

Image Analysis

As mentioned above, in tomography, about a hundred images of the same particle are combined in a computer in order to calculate a 3D reconstruction of a single particle. The resolution obtained is presently around 30 Å. However, computer analysis of images is also needed for cryo-EM images because the contrast in cryo-EM is too low. The images of thousands of particles can be combined to obtain a high-contrast model of the particle provided that all particles have the same composition and conformation. The resolution of models derived with this method can be as good as 7 Å for large protein complexes or intact virus particles. A large number of mathematical approaches are available to calculate such 3D reconstructions. Different approaches exist to calculate models of

nonsymmetrical complexes, for helical structures, and for icosahedral virus capsid structures. These techniques requires classical EM photographs to be digitized by scanning the negatives or the images have to be directly recorded in the microscope using a CCD camera.

Figure 6 shows 3D reconstructions of adenovirus type 5 particles from negatively stained particles and from cryo-EM images. The two models are identical but the cryo-model has a higher resolution (around 10 Å compared to 35 Å for the negative stain model). Because the contrast in the negatively stained images is high, such a model from negatively stained particles can be used as starting model for the cryo-reconstruction. The major difference between the two models is that in the model derived from the stained particles only the outside of the virus capsid is visualized, whereas for the cryo-model all proteins inside and outside of the capsid are visible. The cryo-EM model of the capsid was combined with the atomic resolution data derived from the crystal structure of the two main adenovirus capsomers, the trimeric hexon

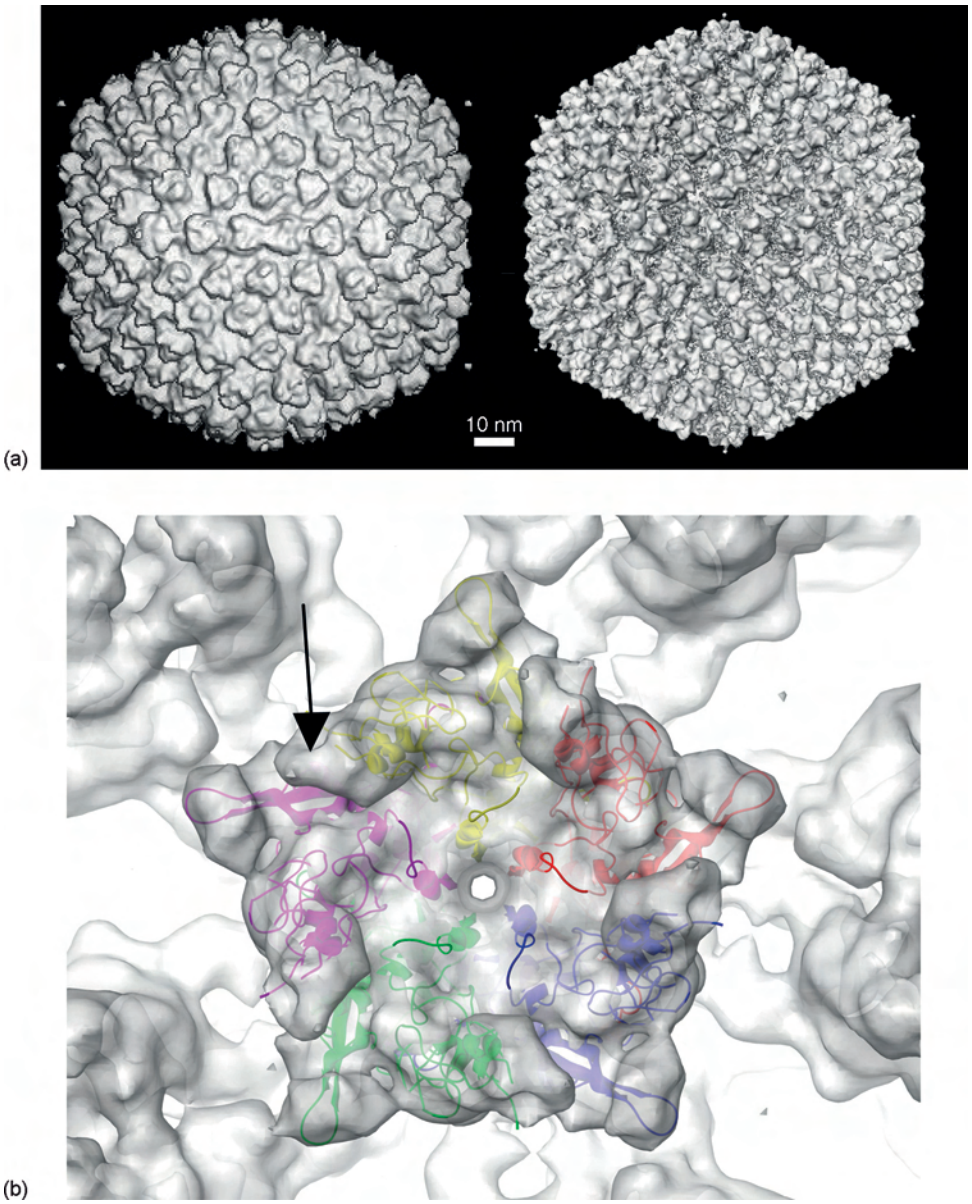

Figure 6 Image analysis and combination with other techniques (a) 3D reconstruction of adenovirus 5 particle after imaging in negative staining (left) and cryo-EM (right). Respectively 150 and 3000 individual negatively stained or cryo-EM images were combined to obtain 3D reconstructions at 35 Å (negative staining) and 10 Å (cryo-EM) resolution. (b) Combination of EM with X-ray crystallography. Fitting of the X-ray structure of the adenovirus penton base into the EM density. The arrow highlights a mobile part of the protein that is resolved in electron microscopy but not in X-ray crystallography.

and the pentameric penton base. By fitting the crystal structures into the EM density, a quasi-atomic model can be derived that describes the exact position of all capsomers and the interacting surfaces and protein loops between the capsomers. **Figure 6** shows details of the fit of the crystal structure of the penton base into a penton base from the EM model. A number of different algorithms are available to perform these fits, some of which take into account the possibility of flexibility between protein domains. The fit in **Figure 6** (arrow) shows density in the EM model that is not filled by density from the crystal structure. Some loops of the molecule are flexible and therefore invisible in the crystal structure, whereas the lower resolution of the EM model does allow imaging.

The Future

In our opinion, the future of EM in virology lies in an extended use of the combination of structural data as shown above. Fitting crystal structures of intact proteins or domains into protein complexes (viral complexes or complexes between viral and host proteins) will show how proteins interact in the infected cell. Although the EM models have a resolution of only around 10 Å, the information on the interface of the proteins in the complex is of near-atomic resolution. These techniques can be applied to regular viruses. For irregular viruses, such as influenza and paramyxoviruses, tomography will allow the construction of models with a resolution of around 40 Å that will show how the proteins in the virus particle interact. In particular, it will be interesting to see the packaging of the nucleocapsids in these viruses. At present we do not know how the DNA is packaged in adenovirus particles and it is possible that the icosahedral averaging techniques result in a loss of this information if the packing symmetry of the DNA is in fact not icosahedral. The same problem exists for capsid features that are not icosahedral such as unique capsid vertices that may be used for the packaging of DNA in adenoviruses and herpesviruses. Such problems may be overcome by using reconstruction techniques that are not based on icosahedral symmetry.

Emerging and Reemerging Virus Diseases of Plants

G P Martelli and D Gallitelli, Università degli Studi and Istituto di Virologia Vegetale del CNR, Bari, Italy

© 2008 Elsevier Ltd. All rights reserved.

Introduction

A number of RNA plant viruses constitute new threats to economically relevant vegetable crops, grapevine, and citrus. These are listed among new disease-causing agents, and are therefore denoted 'emerging or re-emerging' being often new viruses or virus strains responsible for serious diseases. The emerging plant viruses and their known vectors are quickly expanding in new areas as a consequence of the increasing international trade and the

large numbers of people traveling in many countries. Once introduced, the fitness of these viruses to new agroclimatic conditions increases, leading to the development of severe epiphytotics.

Vegetable Viruses

Pepino Mosaic Virus

Geographical distribution

Pepino mosaic virus (PepMV) was originally described in Peru on pepino (*Solanum muricatum*) and found to infect tomato and related wild species symptomlessly, in experimental trials. Since 1999, PepMV outbreaks have been reported almost simultaneously in many European countries (Austria, Bulgaria, Finland, France, Germany, Hungary, Italy, Netherlands, Norway, Poland, Slovakia, Spain, Sweden, Switzerland, Ukraine, and UK) where it is considered an emerging pathogen of tomato glasshouses. PepMV was also found in Canada, USA (Arizona, California, Colorado, Florida, Oklahoma, Texas), Ecuador, and Chile. After discovering the PepMV occurrence in tomato grown in Europe and North America, a survey carried out in central and southern Peru and Ecuador demonstrated that the virus was present in Peruvian tomato crops as well as in the following wild *Lycopersicon* species: *L. chilense*, *L. chmilewskii*, *L. parviflorum*, *L. peruvianum*, and in *L. pimpinellifolium* in Ecuador.

Disease symptoms and yield losses

In pepino, the virus causes yellow mosaic in young leaves, whereas affected tomato plants show a wide array of symptoms. These include stunting of the whole plant, bubbling of the leaf surface, interveinal chlorosis, mosaic and green striations on stem and sepals. Foliar symptoms resemble hormonal herbicide damage, while lower leaves show necrotic lesions that resemble damage caused by water that dripped onto the plant. Fruits from early infected tomato plants may show blotchy ripening and gold marbling. Ripe fruits develop yellow speckles and spots that make them unmarketable. Observations by Dutch scientists indicate that symptoms are more readily seen during autumn and winter months, and are masked during warmer months. Yield losses caused by PepMV are probably below 5%, although surveys in glasshouse-grown tomatoes reported crop reductions up to 40%. The disease spreads very rapidly and crop losses may be significant if early action is not taken to eliminate infected sources. Although Peruvian virus strains seem to be little virulent, new strains of higher virulence could arise through recombination. Because of the adverse effects on quality and yield, PepMV is becoming one of the most important tomato pathogens in Europe.

Causal agent and classification

PepMV (genus *Potexvirus*, family *Flexiviridae*) has helically constructed semirigid filamentous particles with a modal length of 508 nm and a diameter of 11 nm. Sequencing of a number of strains has shown that virions contain a single molecule of linear, positive-sense, single-stranded RNA (ssRNA) 6410–6425 nt in size. The genome organization is typical of the genus *Potexvirus*, with five open reading frames (ORFs): ORF1, encoding a putative replicase of 164 kDa; ORFs 2–4, coding for the triple gene block proteins 1–3 (TGBp) of 26 kDa, 14 kDa, and 9 kDa, respectively; and ORF5, encoding the 25 kDa coat protein (CP). Phylogenetic analyses carried out on replicase, TGBp1, and CP amino acid sequences revealed that PepMV is closely related to narcissus mosaic virus (NMV), scallion virus X (SVX), cymbidium mosaic virus (CymMV), and potato aucuba mosaic virus (PAMV) (**Figure 1**). Tomato isolates of PepMV can be distinguished from the original isolate from pepino on the basis of symptomatology, host range, and sequence data. On the other hand, tomato isolates from Europe appear very similar to each other sharing nucleotide sequence identities higher than 99% and in the range of 95–96% with PepMV from *L. peruvianum* from Peru. Nucleotide sequence comparisons between US and the European tomato isolates show only 79–82% identity. Gene-for-gene comparison between sequenced isolates suggests that TGBp1 and TGBp3 are more suitable than either the replicase or CP gene products for discriminating virus isolates.

Epidemiology

PepMV is transmitted by contact and readily spread mechanically by contaminated hands, tools, shoes, clothing, and plant-to-plant contact. The virus is thought to remain viable in dry plant material for as long as 3 months. Seed transmission or surface seed contamination in tomato is suspected but not demonstrated. In the UK, the virus is frequently found in imported fruits. Infection of other solanaceous crops such as eggplant, tobacco, and potato has only been observed in experimental trials, while infection in pepper has not been demonstrated. Cucumber can be artificially infected but the virus does not appear to spread systemically in the plant.

Alternative hosts that may serve as virus reservoirs were studied in Spain, where native plants with virus-like symptoms growing in or around tomato fields were collected and analyzed for the presence of PepMV. As many as 18 weed species were found to be infected.

Because of the high similarity of tomato virus isolates, a common origin seems likely although where this origin is located is still unclear. The extent of PepMV distribution in Peru, together with the fact that many of the wild Peruvian *Lycopersicon* populations sampled were isolated and had not been manipulated by man, led to the conclusion that this virus has been present in the region for a

long time and that other factors might be involved in its spread. *Myzus persicae* does not transmit PepMV. In southern Spain a faster spread of PepMV was observed in bumble-bee pollinated greenhouses than in those with no pollinator insects.

Control

Recommended control strategies for PepMV focus on sanitation. Use of certified seed lots, complete removal (including roots) of infected plants, limited access to affected rows, and sanitation of clothing and tools are all critical. The increasing concern caused by this new disease has led the European Commission to authorize member countries to take measures to prevent the spread of PepMV within the European Union.

Criniviruses

Criniviruses are whitefly-transmitted RNA viruses that cause plant diseases with increasingly important yield impact, consequent to the sudden explosion of whitefly populations in temperate regions in the last 10–20 years. All these viruses induce yellowing symptoms in their hosts, are generally phloem-limited, nonmechanically transmissible, and have large ssRNA genomes. Cucurbit yellow stunting disorder virus (CYSDV), tomato infectious chlorosis virus (TICV), and tomato chlorosis virus (ToCV) are important emerging criniviruses.

Cucurbit Yellow Stunting Disorder Virus

Geographical distribution

CYSDV was first observed in the southeastern coast of Spain, on melon and cucumber grown under plastic. The virus was also found in the Canary Islands, Egypt, France, Israel, Jordan, Lebanon, Mexico, Morocco, Portugal, Saudi Arabia, Syria, Texas, Turkey, and the United Arab Emirates.

Disease symptoms and yield losses

Protected crops of cucumber and melon show severe yellowing that starts as interveinal mottle of older leaves to develop into complete yellowing of the leaf lamina, except for the veins, followed by rolling, brittleness, and stunting. On the whole, symptoms are virtually indistinguishable from those caused by beet pseudo yellows virus (BPYV). Zucchini can also be infected but symptoms have not been described. Disease incidence in protected

crops can easily reach 100%. In Spain and many other countries, CYSDV is considered the prevailing virus of protected cucurbit crops.

Causal agent and classification

CYSDV (genus *Crinivirus*, family *Closteroviridae*) has a narrow host range limited to the family *Cucurbitaceae* and is confined to phloem tissues. Virions are flexuous filaments with lengths between 750 and 800 nm. Genome consists of two molecules of ssRNA of plus-sense polarity designated RNA-1 and -2. RNA-1 is 9123–9126 nt long and contains five ORFs with papain-like protease, methyltransferase, RNA helicase, and RNA-dependent RNA polymerase domains in the first two overlapping ORFs, a small 5 kDa hydrophobic protein, and two further downstream ORFs potentially encoding proteins 25 and 22 kDa in size, respectively. RNA-2 is 7976 nt long and contains the hallmark ORFs of the family *Closteroviridae*, encoding, in the order, a heat shock protein 70 (HSP70) homolog, a 59 kDa protein, the major (CP) and the minor (CPm) CP. In the 3′-terminal region, RNA-1 contains an ORF potentially encoding a protein of 25 kDa which has no homologs in any databases, and RNA-2 has an unusually long 59 noncoding region. Subgenomic RNAs were detected in CYSDV-infected plants, suggesting that they serve for the expression of internal ORFs. CYSDV can be divided into two divergent groups of isolates. One group is composed of isolates from Spain, Lebanon, Jordan, Turkey, and North America, the other of isolates from Saudi Arabia. Nucleotide identity between isolates of the same group is greater than 99%, whereas identity between groups is about 90%.

Epidemiology

Natural hosts of CYSDV are restricted to cucurbits: watermelon, melon, cucumber, and zucchini. *Cucurbita maxima* and *Lactuca sativa* are experimental host plants. The life cycle of CYSDV is dependent on its vector, the whitefly *Bemisia tabaci*, as viral outbreaks are associated with heavy infestations of whitefly biotypes A, B, and Q. Transmission of CYSDV by biotype B is more effcient than by biotype A, whereas biotype Q transmits as efficiently as biotype B. *Trialeurodes vaporariorum* was displaced *by B. tabaci* as the dominant whitefly along the southeastern coast of Spain when CYSDV took over BPYV as the agent of yellowing diseases of cucurbits. Acquisition periods of 18 h or more and inoculation periods of 24 h or more seem necessary for high transmission rates of CYSDV, which can persist for at least 9 days in the vector. The virus is not known to be seed-borne.

Control

Control of CYSDV consists in controlling *B. tabaci*, and on eliminating infection sources. Chemical control of *B. tabaci* has not been effective in preventing the spread and in reducing the incidence of the disease because the vector has a wide host range and quickly develops resistance to most of existing insecticides. Roguing infected plants and weeds that can act as hosts for the vector and removal of overwintering crops prior to the emergence of adult whiteflies may prove useful. This helps if applied over large areas and where there is no continuous cropping in glasshouses, which are the sites of whitefly survival and the source of virus spread throughout the year. Growing plants under physical barriers such as low-mesh tunnels may also have a positive effect. No resistant cultivars are currently available commercially but experimental evidence for delayed viral infection and decreased symptom severity in accessions of *Cucumis sativus* has recently been obtained.

Tomato Infectious Chlorosis Virus

Geographical distribution

TICV infections have been reported from California, France, Greece, Indonesia, Italy, Japan, North Carolina, Spain, and Taiwan. This virus may also be present in the Czech Republic but the record has not been confirmed.

Disease symptoms and yield losses

Symptomatic tomato plants in open field and greenhouses exhibit interveinal yellowing in older leaves, followed by generalized yellowing. Symptoms can be confused with nutritional disorders (i.e., magnesium deficiency), pesticide toxicity, or natural senescence as older leaves may also turn red. Necrosis and occasional upward rolling of the leaves have also been reported. On the whole, infected plants are less vigorous and with fruits that may show delayed ripening. There is no information on the effects of TICV on artichoke and lettuce crops or ornamental species known to be natural hosts. Disease incidence may vary from one or few plants to severe outbreaks, depending on the abundance of whitefly populations. In California and Greece, disease incidence between 80% and 100% was reported.

Causal agent and classification

The natural hosts of TICV (genus *Crinivirus*, family *Closterovidae*) include members of the families *Chenopodiaceae*, *Compositae*, *Ranuncolaceae*, and *Solanaceae* where the virus is confined to phloem tissue. Virions are flexuos filaments with lengths between 750 and 800 nm. Genome consists of two molecules of ssRNA of positive polarity, denoted RNA-1 and RNA-2, whose nucleotide sequence has partially been determined. Both RNAs contain the hallmark ORFs of the family *Closteroviridae.*

Epidemiology

TICV is spread by the whitefly *T. vaporariorum* but not by *B. tabaci* and it is not mechanically transmitted. Besides

tomato, natural infections have been detected in *Callistephus chinensis*, *Chenopodium album C. murale*, *Cynara cardunculus*, lettuce, *Physalis ixocarpa* (tomatillo), globe artichoke, *Nicotiana glauca*, *Petunia hybrida*, *Picris echioides*, *Ranunculus* sp., and *Zinnia elegans*.

Control

TICV has the potential to cause significant losses to tomato and other naturally susceptible crops if it becomes established. Control largely depends on the efficacy of treatments and strategies to limit populations of *T. vaporariorum*. Tomato seedlings for planting should come from disease-free stocks. The general management strategies outlined for CYSDV can also be adopted for TICV.

Tomato Chlorosis Virus

Geographical distribution

ToCV infections have been reported from the US (Colorado, Connecticut, Florida, Louisiana), Europe (France, Greece, Italy, Portugal, Spain), Morocco, Israel, Puerto Rico, South Africa, and Taiwan.

Disease symptoms and yield losses

Symptoms are very similar to those induced by TICV, that is, progressive yellowing of the whole plant. Apparently, there are no estimates of yield losses, although since its discovery, the virus represents a serious problem for tomato production in many parts of the world.

Causal agent and classification

ToCV (genus *Crinivirus*, family *Closteroviridae*) virions are flexuous filaments encapsidating two molecules of positive-sense ssRNA denoted RNA-1 and RNA-2, whose complete nucleotide sequence has been determined. RNA-1 consists of 8595 nt organized into four ORFs and encodes replication-associated proteins. RNA-2 is 8244 nt long and putatively encodes nine ORFs comprising in the order, the HSP70 homolog, a 59 kDa protein, CP, and CPm, which may be involved in determining the unique, broad vector transmissibility of the virus. Phylogenetically, ToCV is closely related to sweet potato chlorotic stunt virus (SPCSV) and CYSDV.

Epidemiology

ToCV is transmitted by *T. vaporariorum*, *B. tabaci* biotypes A and B, and *T. abutilonea*. Besides tomato, the natural host range includes pepper, *Datura stramonium*, *Physalis wrightii*, *Solanum nigrum*, and *Z. elegans*.

Control

ToCV has the potential to cause significant losses to tomato if it becomes established. Control depends on the efficacy of treatments and strategies to limit populations of its broad range of vectors. The management strategies outlined for CYSDV apply also for ToCV.

Cucumber Vein Yellowing Virus

Geographical distribution

Cucumber vein yellowing virus (CVYV) has been recorded form Greece, Israel, Jordan, Portugal, Spain, Sudan, and Turkey.

Disease symptoms and yield losses

In cucumber, CVYV causes pronounced vein clearing deformation of the leaves followed by a generalized chlorosis and necrosis of affected plants. Fruits show light to dark green mottling. Nonparthenocarpic cucumbers are symptomless carriers of CVYV while parthenocarpic cucumbers develop severe symptoms. Stunting was also observed in cucumber and melon and sudden death in protected melons in Portugal. In watermelon, symptoms are often light or not expressed, but splitting of the fruits has occasionally been observed. In zucchini, symptoms vary from chlorotic mottling to vein yellowing of the leaves, but symptomless infections have also been recorded. Symptoms severity may be increased by synergistic reactions with other viruses. Yield losses have not been quantified. CVYV could present a threat to cucurbits grown outdoors or under glasshouses, although its actual impact in the complex pathosystem affecting cucurbit crops in the Mediterranean and subtropical regions has not been determined.

Causal agent and classification

CVYV (genus *Ipomovirus*, family *Potyviridae*) has filamentous particles and is transmitted by *B. tabaci* but, unlike other whitefly-transmitted viruses, it can also be transmitted by mechanical inoculation. CVYV genome consists of a single molecule of plus-sense ssRNA of 9751 nt (ALM 23 isolate) containing most hallmarks of the genome of members of the family *Potyviridae*. The absence of a coding region for the helper component-proteinase seems to be a distinctive trait of CVYV. Two CVYV strains have been recognized from Israel and Jordan, that is, CVYV-Is and CVYV-Jor. The two strains induce similar vein-clearing symptoms in cucumber and melon, but CVYV-Jor infections in cucumber are more severe. CVYV is more closely related to *Sweet potato mild mottle virus* (SPMMV) than any other species in the family *Potyviridae*.

Epidemiology

CVYV naturally infects cucumber, melon, watermelon squash, and zucchini and several weed species are also natural hosts of the virus (e.g., *Ecballium elaterium*, *Convolvulus arvensis*, *Malva parviflora*, *Sonchus oleraceus*, *Sonchus asper*, and *Sonchus tenerrimus*). All experimental hosts belong to the

family *Cucurbitaceae* and include *Cucurbita moschata*, *Cucurbita foetidissima*, and *Citrullus colocynthis*. CVYV is semipersistent in its white-fly vector (*B. tabaci*) which retains the virus for less than 6 h. Therefore, individuals moving to nonhost plants may not remain viruliferous long enough to transmit the virus. *Aphis gossypii* and *M. persicae* are not vectors. Whether CVYV is seedborne has not been determined.

Control

CVYV management is mainly based on the use of virus-free stock plants as well as of *B. tabaci* populations as already outlined for CYSDV. Several detection methods based on molecular hybridization and polymerase chain reaction (PCR) have been developed and used for screening *Cucurbitaceae* germplasm that can show some degree of resistance to CVYV.

Graft Incompatibility in Grapevines

Geographical Distribution

Cases of graft union disorders have been documented from Europe ('Kober 5BB incompatibility', 'Syrah decline'), California, New Zealand, Italy, Australia, and Chile ('Young vine decline'), and again California ('Roostock stem lesions', 'Necrotic union', and 'Stem necrosis'), but are likely to occur also in other viticultural countries.

Disease Symptoms and Yield Losses

The increased use of grapevine clonal material is revealing unprecedented and widespread conditions of generalized decline that develop dramatically in certain scion–rootstock combinations. Newly planted vines grow weakly, shoots are short, leaves are small sized, with margins more or less extensively rolled downwards, and the vegetation is stunted. The canopy shows autumn colors off season so that leaves turn reddish in red-berried varieties or yellow in white-berried varieties much earlier than normal. A prominent swelling forms at the scion/rooststock junction ('Kober 5BB imcompatibility', 'Young vine decline') sometimes accompanied by necrosis at the graft union ('Necrotic union'), and variously extended necrotic lesions develop on the roostock stem ('Roostock stem lesion', 'Stem necrosis'). Severely affected vines decline and may die within 1 or 2 years. Syrah decline is a severe disease characterized by early reddening of the leaves and swellings with grooves and deep cracks at the graft union. Appearance of graft union disorders depends more on the rootstock than on the scion. For instance, European grape varieties grafted on tolerant rootstocks (e.g., Freedom, Harmony, Salt creek, 03916, 101-14) exhibit a green canopy and perform well, whereas varieties grafted on susceptible roostocks (e.g., Kober 5BB, 5C, 1103P, 3309) develop a discolored canopy, decline, and may die.

Causal Agents and Classification

An ordinary strain of grapevine leafroll-associated virus 2 (GLRaV-2) is consistently associated with Kober 5BB incompatibility in Europe, appears to be involved in California's young vine decline, and was detected in diseased Chilean and Argentinian grapes. GLRaV-2, a definitive member of the genus *Closterovirus* (family *Closteroviridae*), has flexuous filamentous particles *c.* 1600 nm long an RNA genome 15 528 nt in size made up of nine ORFs. A virus originally detected in cv. Redglobe in California called grapevine rootstock stem lesion-associated virus (GRSLaV) proved to be a molecular and biological variant of GLRaV-2 (GLRaV-2 RG). Other molecular variants of GLRaV-2 were reported from New Zealand, Chile, and Australia in association with young vine decline conditions. Based on the differential responses of a panel of 18 rootstocks, up to five different graft-transmissible agents inducing incompatibility were detected in California. Of these, only GLRaV-2 RG, the putative agent of roostock stem lesion, was identified. The agents of necrotic union and stem necrosis are unknown. Equally unkown is the agent of Syrah decline, although there is circumstantial evidence that grapevine rupestris stem pitting-associated virus (GRSPaV) may have a bearing on its aetiology. GRSPaV, a definitive member of the genus *Foveavirus* (family *Flexiviridae*), has filamentous particles *c.* 730 nm in length, a genome 8726 nt in size comprising five or six ORFs, and occurs in nature as a family of molecular variants.

Transmission

GLRaV-2 and GRSPaV have no known vectors, but GRSPaV is pollen- and seed-borne. Infected propagative material is the major means for dissemination of both viruses.

Control

Use of certified virus-free scionwood and rootstocks is recommended. Currently known graft incompatibility agents can be eliminated with reasonable efficiency by heat therapy, meristem tip culture, or a combination of the two. If scionwood is infected, the use of sensitive rootstocks is to be avoided.

Sudden Death of Citrus

Geographical Distribution

Citrus sudden death (CSD) has only been reported from the State of Saõ Paulo in Brazil, where it has already killed about 1 million trees. It has the potentiality for spreading to other Brazilian States and neighboring countries.

Disease Symptoms and Yield Losses

CSD is a destructive disease first observed in 1999 in Brazil on sweet orange and mandarin trees grafted on Rangpur lime (*Citrus limonia*) or Volkamer lemon (*Citrus volkameriana*). Outward symptoms of infected trees and modifications of the bark anatomy at the bud union resemble very much those elicited by citrus tristeza, the major difference being that CSD develops on trees grafted on tristeza-resistant rootstocks. Symptoms of CSD are characterized by a generalized discoloration of the leaves which are pale green initially, then turn yellowish and abscise. With time, defoliation becomes more intense, the trees do not push new vegetation, and the root system decays. A rapid decline and death of the plant ensues, due also to phloem degeneration in the graft union region. The phloem of the susceptible rootstocks Rangpur lime and Volkamer lemon shows a characteristic yellow strain. Until their sudden collapse, infected trees bear a normal crop.

Causal Agent and Classification

All trees affected by CSD host a strain of CTV and, with 99.7% association, a spherical virus denoted citrus sudden death-associated virus (CSDaV). This virus is a tentative member of the genus *Marafivirus* (family *Tymoviridae*), has isometric particles about 30 mn in diameter, a ssRNA genome 6805 nt in size with a high cytosine content (37.4%), encompassing two ORFs. ORF1 codes for a large polyprotein with a predicted M_r of 240 kDa which is processed to yield the replication-associated proteins (methyltransferase, helicase, and RNA-dependent RNA polymerase), a papain-like protease, and two CP subunits 21 and 22 kDa in size, respectively. One of the CP subunits is produced from the cleavage of the C-terminus of the polyprotein, the other is translated from a subgenomic RNA. ORF2 codes for a putative protein 16 kDa in size, with some relationship with a movement protein of viruses belonging to the sister genus *Maculavirus* (family *Tymoviridae*). It has not been ultimately established whether CTV or CSDaV are the causal agents of CSD, but their consistent association with the disease suggests that both may have a bearing on its etiology.

Epidemiology

CSD is transmitted by grafting and can be disseminated with propagation material. Natural spreading is by aphids (*Toxoptera citricida*) with a temporal and spatial pattern similar to that of citrus tristeza. CSDaV was detected in *T. citricida* that had fed on infected trees and was transmitted experimentally to healthy plants. Since marafiviruses are not aphid-borne, it was hypothesized that CSDaV may use CTV as a helper virus.

Control

Production and distribution of healthy scion material to be grafted onto tolerant rootstocks (Cleopatra mandarin, Swingle citrumelo) can help restraining the spread of CSD in newly established groves. Grafting the affected trees above the graft union with seedlings of tolerant roostocks allows their recovery.

Glossary

Amplicon The product nucleic acid obtained from a polymerase chain reaction.
Bocavirus A genus of the family *Parvoviridae* containing bovine, canine, and human species.
Kaposi's sarcoma A skin tumor which frequently develops in young males infected with HIV.
Kawasaki disease A mucocutaneous lymph node syndrome that has features of a virus infection but so far no causative agent has been discovered. There are about 120 cases per 100 000 population in Japan, a sixfold higher incidence than in the USA.
picobirnavirus A virus containing a genome consisting of two segments of double-stranded RNA, 2.6 and 1.5 kb in length.
Sigmodontinae A subfamily of rodents in the family Muridae that contains over 500 species, confined to the American continent.
Vero cells A heteroploid cell line derived from the kidney of a normal African green monkey (*Cercopithecus aethiops*).

Introduction

It became apparent during the last two decades of the twentieth century that new infectious diseases were increasingly being recognized in the human and animal populations. This led to the establishment of a formal committee of the Institute of Medicine of the National Academy of Sciences, USA, who reported on their deliberations in 1992, in a report edited by Joshua Lederberg and Richard Shope. This was followed 10 years later by a second report, edited by Mark Smolinski, Margaret Hamburg, and Joshua Lederberg, which appeared in 2003. Among the factors they cited as contributing to emergence were microbial adaptation and change, human susceptibility to infection, climate and weather, changing ecosystems, economic development and land use, human demographics and behavior, technology and industry, international travel and commerce, breakdown of public health measures, poverty and social inequality, war and famine, lack of political will, and finally intent to harm.

Recognition of Emerging and Reemerging Virus Diseases

The advent of highly specific molecular techniques such as the polymerase chain reaction (PCR) in the early 1980s permitted the detection and grouping of viruses on the basis of genome nucleotide sequence analysis, and in several respects these techniques have replaced serological analyses for the characterization of viruses. Although it is still important to isolate viruses in cell culture for their complete characterization, it is now possible directly to detect viruses in diseased tissues by PCR, then, by sequencing the amplicon, to determine whether a new virus has emerged to cause the disease. In fact, many viruses which do not readily grow in cell culture can only be differentiated by sequence analysis. The papillomaviruses are an example. Their study was very difficult until the advent of sequence analysis, which now has revealed more than 100 types in humans, and many more in animals and birds. For differentiation, three virus genes (E6, E7, and L1) are sequenced, and if the combined sequence of these three genes differs by more than 10% from known papillomaviruses, the virus is considered to be a new type. Other viruses which have not been grown in cell culture include many caliciviruses, and the ubiquitous anelloviruses, such as torqueteno (TT) virus, which can be detected and sequenced in the blood of most humans and many other vertebrate species.

Hepatitis C virus was originally described as non-A, non-B hepatitis virus because of the severe disease it caused but the virus would not grow in cell culture, and eventually was detected in blood known to be infected with the virus by reverse transcription of the RNA present using random primers then expressing the resultant DNA in the bacteriophage lambda gt 11. Thousands of clones were screened using patient blood as a source of antibody before positive clones were detected, which then allowed the development of enzyme immunoassays that could detect the virus in blood and so were used to screen blood destined for transfusion, saving millions of lives worldwide. Once the complete genome of hepatitis C virus was sequenced, it became apparent that there are many different genotypes circulating in the world, with different pathogenic properties.

Nucleotide sequence analysis has also been extremely useful in tracing the origins of viruses. For example, when hantavirus pulmonary syndrome, caused by a bunyavirus

of rodents, Sin Nombre virus, was initially detected in 1993 in the Four Corners region of Western USA, it was found that rodents inside a house where people had been infected carried a virus identical in sequence to virus isolated from human cases. However, rodents caught at various distances from the house had increasingly variable genome RNA sequences, providing strong evidence that these rodents, deer mice (*Peromyscus maniculatus)*, were the source of the infection. Subsequently more than 30 other hantaviruses, some of which also cause hantavirus pulmonary syndrome in humans, were isolated from rodents throughout North and South America. Each new virus seems to be associated with a different genetic variant of rodent host, and all rodents that carry the virus belong to the subfamily Sigmodontinae, unique to the American continent.

A particularly powerful tool for the initial recognition of an emerging virus is the application of immunohistochemistry to diseased tissues. Provided a comprehensive collection of antibodies is available, the particular virus or related group of viruses can often be detected. For example, when Hendra virus first appeared in 1995 in Australia, causing the death of a horse trainer and 14 of his horses, antibody against the virus was sent to the Centers for Disease Control and Prevention (CDC). Then, in 1999, CDC was asked to investigate a newly emerged epidemic that had appeared in Malaysia, killing more the 100 people and causing disease in many pigs. Initially, it was suspected to be caused by a virus related to Japanese encephalitis virus, but a virus was isolated from the pigs that replicated in Vero cells, and reacted in an immunofluorescence test against the Hendra virus antiserum. This could subsequently be used on patient tissues to study the pathogenesis of the disease, and after comparison of the genome sequences of Hendra virus and Nipah virus they were found to be closely related and are now classified in the genus *Henipavirus* of the *Paramyxoviridae*.

Finally, molecular methods can be used to detect new, emerging viruses in the absence of disease in the host. In 2001, Allander and colleagues searched for RNA viruses in human respiratory secretions using random primer PCR, and discovered a hitherto unknown parvovirus with a sequence related to the bovine and canine parvoviruses, which are grouped together in the genus *Bocavirus*. The new virus was called human bocavirus, and many research groups worldwide have now confirmed the presence of the virus, particularly in pediatric samples, although it is still not certain how important this virus is in causing morbidity and mortality. Their method also amplified a human coronavirus from the respiratory samples, and when sequenced this turned out to be HKU1, a recently emerged coronavirus detected by scientists at Hong Kong University. It is possible that a systematic search of human samples using such molecular techniques might reveal more hitherto unknown human viruses.

Human Demographics and Behavior

In some cases, the emerging viruses themselves have contributed to other viruses emerging and reemerging in the population. This is especially true of human immunodeficiency virus (HIV), the cause of acquired immune deficiency syndrome (AIDS), which rapidly spread following its emergence in the early 1980s to infect more than 40 million people worldwide by the end of the twentieth century. Because of its severe effects on the immune system, the virus leads to numerous other infections in the HIV-infected population. For example, picobirnaviruses, that had been detected in fecal samples from chickens and rabbits, were difficult to detect in human fecal samples until a cohort of men with AIDS was examined, and in these humans picobirnavirus was detected for the first time. Some rare diseases have become common in persons with AIDS. For example, the human polyomavirus known as JC virus can cause the rare brain disorder known as progressive multifocal leukoencephalopathy (PML). Normally, the virus remains dormant in the kidney, but in HIV-infected individuals the HIV-encoded transactivator Tat acts as a transactivator of JCV leading to PML which progresses to death within 4 months after infection. Other important virus infections which emerge in AIDS patients are human herpesviruses (cytomegalovirus, herpes simplex viruses 1 and 2, varicella-zoster virus, and human herspesvirus 8, which causes Kaposi's sarcoma).

HIV is mainly spread through sexual activity between an infected and a noninfected person, and is most common in those who indulge in high-risk sexual behavior with multiple partners. It can also be transmitted by direct contact with infected blood, and is common in persons who indulge in intravenous drug use, particularly when needles, syringes, or equipment used to prepare drugs for injection are shared. It is therefore an example of a virus disease which is dependent on risky human behavior for its maintenance in the human population.

The ability of such new infections to spread in the population has been greatly enhanced by population growth and ease of movement as a result of rapid air travel. A dramatic recent example of this was the appearance of the coronavirus causing severe acute respiratory syndrome (SARS) in late 2002 which spread by air travel from a single infected Chinese physician who infected 12 persons in a Hong Kong hotel. These infected persons then traveled by air and spread the infection to more than 8000 individuals worldwide, 10% of whom died. The virus then apparently receded from the human population in July 2003. Only recently was it discovered that the SARS coronavirus has a natural reservoir in Chinese horseshoe bats (*Rhinolophus sinicus*). Some other species such as Himalayan palm civets and raccoon dogs from which the virus has been isolated may serve as amplification hosts.

Following the recognition of the human coronavirus SARS, research on coronaviruses intensified, and this led to the discovery in 2004 of two previously unrecognized human viruses, one found by Hong Kong University, called HKU1 virus, and another reported almost simultaneously from the Netherlands, called NL63, and from Yale University, called New Haven coronavirus. The latter viruses probably represent two isolates of the same virus species. They are clearly associated with lower respiratory tract infection in children, but initially it was claimed that New Haven coronavirus was also associated with Kawasaki disease in children. This intriguing claim was rapidly investigated and refuted by several different groups in Japan, Taiwan, and elsewhere, and the cause of Kawasaki disease, which has features resembling a virus infection, remains unknown.

Zoonotic Diseases

A majority of recent emerging virus diseases have been zoonoses (i.e., diseases transmitted from animals to humans under natural conditions). Some of the more important of these include HIV-1, which was transmitted to humans from chimpanzees in Central Africa around 1931, and HIV-2, transmitted from sooty mangabeys to humans in West Africa around 1940.

Other important recent examples are the viruses of the genus *Henipavirus*. Hendra virus was first recognized through a disease outbreak in some horse stables in Hendra, Queensland, Australia, when 14 horses and their trainer died from pulmonary disease with hemorrhagic manifestations in 1994. The reservoir of the virus was found to be in large fruit-eating bats (*Pteropus* spp.), and one year later a horse farmer 600 miles away in Mackay, Queensland, died of encephalitis from the same virus. Then, in 1999, a related virus was discovered in Malaysia following a major outbreak of respiratory disease in pigs and neurological disease in humans in their close contact. More than 100 humans died, and in a successful effort to control the disease 1.1 million pigs were slaughtered. The causative virus was isolated from a fatal human case that had lived in Nipah River Village, and so was named Nipah virus. Hendra and Nipah viruses are clearly members of the family *Paramyxoviridae*, but have been placed in a separate genus as their RNA genome is about 19 kb in length, larger than that of any other paramyxovirus.

Nipah virus, like Hendra virus, was found to have a reservoir in *Pteropus* bats, and has since been identified in fatal human disease outbreaks in India in 2003 and Bangladesh in 2004.

Other new viruses which apparently have a reservoir in fruit bats include Menangle virus, a new paramyxovirus which emerged in a commercial piggery near Sydney, Australia, to cause stillbirths and abortion in pigs. Menangle virus also caused disease in two workers in the piggery. A new virus related to Menangle virus emerged during an investigation of urine samples from *Pteropid* bats collected on Tioman island, off the coast of Malaysia, in 2001, and was named Tioman virus. During the same investigation, a new orthoreovirus was isolated from *Pteropus hypomelanus* in 1999 and called Pulau virus, and more recently a related orthoreovirus called Melaka virus was isolated from a human case of acute respiratory disease in Melaka, Malaysia. Serological studies of sera collected from human volunteers on Tioman island showed that 13% had antibodies against both Pulau and Malaka viruses.

Another important group of zoonotic diseases are rodent-borne, and caused by members of the genus *Hantavirus* of the family *Bunyaviridae*. These viruses first emerged during the Korean War of 1950–52, when thousands of UN troops developed a mysterious disease with fever, headache, hemorrhage, and renal failure with a fatality rate of 5–10%. It was more than a quarter of a century before the causative virus was isolated from field mice in Korea, and named Hantaan virus, the cause of hemorrhagic fever with renal syndrome (HFRS) in humans.

Then, in 1993, a new hantavirus emerged in the Four Corners region of Southwestern USA as the cause of a severe acute respiratory disease syndrome, with a fatality rate close to 40%, and named Sin Nombre virus. This virus was shown to be transmitted to humans by inhalation of virus present in the urine, feces, or saliva of deer mice (*Peromyscus maniculatus*). It seems likely that this disease had existed for many years, and was only recognized in 1993 because of a clustering of human cases as a result of a regional upsurge in the rodent population resulting from climatic conditions causing increased availability of rodent food. Fortunately, in most of these infections, humans appear to be a dead-end host, and transmission between humans does not occur except with the Andes virus in South America.

Rodent-borne viruses of the family *Arenaviridae* also cause a number of serious zoonotic diseases in humans. The 'Old World' arenaviruses such as Lassa fever virus have been known for some time, but still cause thousands of fatal hemorrhagic fever cases every year in West Africa. However, 'New World' arenaviruses such as Junin virus causing Argentinian hemorrhagic fever and Machupo virus causing Bolivian hemorrhagic fever have long been recognized in South America. Recently, new arenaviruses have emerged, probably as a result of deforestation, which results in rodents seeking shelter in human habitation, and brings them into closer contact with people. These viruses include Guanarito virus that causes Venezuelan hemorrhagic fever with 36% mortality rate from confirmed cases, and Sabia virus isolated in 1990 that causes Brazilian hemorrhagic fever with a high fatality rate, including two laboratory acquired cases.

Rabies is a zoonotic disease of great antiquity that has mainly been associated with carnivores, such as dogs. The virus is excreted in the saliva of infected animals, and following infection it moves through the nervous system to attack the brain, causing aggressive behavior which results in the animal biting humans and animals with which it comes into contact and thereby spreading the virus infection. Fortunately, due to early work by Louis Pasteur, a vaccine was developed that protects humans or other animals from infection, and can also be given immediately post exposure, and the domestic dog population in the developed world is vaccinated and does not pose a risk to humans. However, in some developing countries, it is not uncommon for a rabid dog to bite and infect more than 25 people before it can be put down, and worldwide there are still some 30 000 human rabies deaths per year. Using molecular sequencing techniques, it is now possible to distinguish the genotypes of rabies viruses associated with different species of host, as the virus has become adapted through frequent transmission between members of the same host species. In the USA, there are six recognized terrestrial animal genotypes, in raccoons in eastern states, skunks in north-central states, skunks in south-central states, coyotes in southern Texas, red foxes in Alaska, gray foxes in Arizona, and several genotypes associated with particular species of bat. In fact, most fatal cases of human rabies in the USA can now be traced to bats, which are often not detected when the person is bitten; so rabies is not suspected and vaccination is not undertaken until the disease has taken hold.

Ecological Factors Favoring Virus Emergence

Many important virus diseases are spread by arthropods, and exposure to new arthropods and the viruses they carry is critical to the emergence of new virus diseases. Dengue hemorrhagic fever is caused by dengue virus which is transmitted mainly by the Asian mosquito (*Aedes albopictus*), and dengue fever is one of the most rapidly emerging diseases in tropical regions of the world. There are four serotypes of dengue virus, and it seems that consecutive infections with two antigenic types can lead to the more serious disease of dengue hemorrhagic fever with shock syndrome, which, if untreated, can result in up to 50% mortality. Unfortunately, through the importation of vehicle tires containing water from Korea, the Asian mosquito was introduced into the USA, and is now present in several regions of the Southern states. It can act as a vector not only for dengue virus, but also for California encephalitis virus.

In Europe, the emergence of two important animal diseases has occurred through the movement of arthropod vectors into the Iberian Peninsula. African horse sickness virus causes a disease that can be fatal to horses, mules, and donkeys, and is transmitted by nocturnal biting flies of the genus *Culicoides*. These were introduced inadvertently into Spain, and the disease is now endemic around Madrid and regions to the south. African swine fever virus is transmitted by ticks of the genus *Ornithodorus* and it causes a fatal disease resembling classical swine fever in domestic pigs. It first emerged in Portugal and Spain in 1957, France in 1964, Italy in 1967, and Cuba in 1971. Through slaughter of infected animals, the disease was eradicated from Europe, except Sardinia, by 1995.

The most recent dramatic example of the movement of a virus vector is provided by West Nile virus, a flavivirus first isolated in Uganda in 1937. This virus uses birds as a reservoir host, and is transmitted from birds to humans and other vertebrates by mosquitoes. In 1999, cases of encephalitis in New York were found to have been caused by a strain of West Nile virus that was phylogenetically similar to a virus isolated from geese in Israel.

At the same time, many birds, especially corvids, began dying in New York State. Since the introduction in 1999, West Nile virus has become well established throughout the USA and moved north into Canada and south into the Caribbean and into Mexico. It is not known how the virus moved from Israel to the USA, but the most reasonable explanation is that it was carried in an infected mosquito or possibly an infected bird in the hold of an aircraft. Transmission by an infected human seems less likely since the titer of virus in human blood is usually too low for efficient mosquito transmission.

It is clear, nevertheless, that once it arrived in North America, West Nile virus found an extremely favorable environment with abundant avian and arthropod hosts that facilitated its spread throughout the American continent.

Prospects

The emergence of new viruses is likely to continue as viruses evolve and find new ecological niches in the human and animal population. It is noticeable that most newly recognized viruses have been RNA viruses, perhaps since RNA evolves at a faster rate than DNA, for which host cells have developed efficient proofreading enzymes. It will be important in the future to detect new viruses before they can emerge to cause disease in the population. The SARS epidemic provides an excellent example. Before the epidemic, only two human coronaviruses were known, human coronaviruses 229E and OC43. Despite the fact that serious coronavirus diseases were well known in other vertebrates, such as feline infectious peritonitis and avian infectious bronchitis virus, it was not until the SARS epidemic that research on human coronaviruses led to the discovery of three new human coronaviruses – SARS, HKU1, and NL63/New Haven.

There are other genera of viruses that cause serious disease in animals but have not been adequately investigated in humans. An example is the genus *Arterivirus*, which has members causing serious disease in horses and pigs, but has not been reported at all in humans. This could be a worthwhile area for future investigation.

Another critical factor in the future control of emerging viruses is better vector control. When mosquito control was conducted using DDT, dengue fever virus was virtually eliminated from the Americas in the 1970s, but environmental concerns led to the widespread banning of the use of DDT, so that since the 1980s there has been a considerable expansion of dengue fever in South America, with the appearance of dengue hemorrhagic fever there for the first time. There is a real need to improve mosquito control measures to control this disease. Although there are prospects for a dengue virus vaccine, this is so far not available.

Finally, one of the most important viruses that continue to emerge in different antigenic forms is influenza virus. The main reservoir of influenza viruses is in birds, and over the past century several pandemics of influenza have emerged, the most serious of which was in 1918. Pandemic strains usually arise by a process of antigenic shift, where one of the genes encoding the hemagglutinin and/or the neuraminidase of influenza virus is replaced by one from birds. New pandemics occurred in 1918 (H1N1 subtype), 1957 (H2N2 subtype), and 1968 (H3N2 subtype). Since 1968, there have been no new pandemics, but it is widely expected that another will occur. At the time of writing, there is worldwide concern that a highly pathogenic avian influenza virus (H5N1 subtype), which has caused some human infections and deaths in persons in close contact with infected birds, might mutate or recombine to generate a virus which would be highly transmissible in the human population. Plans are being developed in many countries and by the WHO to try to prepare for such an event by generating possible vaccines against such a virus and stockpiling antiviral drugs.

Emerging Geminiviruses

C M Fauquet and M S Nawaz-ul-Rehman, Danforth Plant Science Center, St. Louis, MO, USA

© 2008 Published by Elsevier Ltd.

Glossary

Geminivirus A class of plant viruses with a genome composed of single-stranded DNA encapsidated in geminate particles.

Pandemic An epidemic at the regional or worldwide level.

Satellite An infectious molecule that depends on a helper virus for crucial functions.

Introduction

Geminiviruses, which are circular single-stranded DNA (ssDNA) plant viruses, are divided into four different genera (*Curtovirus*, *Mastrevirus*, *Topocuvirus*, and *Begomovirus*). All geminiviruses are transmitted by insects; the most devastating begomoviruses are transmitted by whiteflies (*Bemisia tabaci*). In the last 20 years, we have witnessed in many parts of the world the emergence of newly discovered or previously recorded geminivirus diseases. These emergences are attributable to several factors, including an explosion of whitefly populations in many parts of the world, an increase in human activities, and a large development of global trade introducing new plant hosts, vectors, and viruses in different ecosystems. As there are too many geminivirus emerging diseases to be discussed here, we will restrict our description to the three most important diseases caused by begomoviruses that will illustrate the impact of the various factors influencing geminivirus emergences in the world.

The Tomato Yellow Leaf Curl Disease

Geographical Distribution

The tomato yellow leaf curl virus (TYLCV) was originally reported/isolated from Israel and was described in the 1960s, mostly infecting tomatoes and causing very severe symptoms and huge losses. In Spain and Italy, tomato production increased considerably in the 1980s, and closely related viruses were identified in these countries which were first mistakenly identified as new strains of TYLCVs, although the Israeli virus was subsequently identified in these countries. Furthermore, recombinants between local viruses and TYLCV were found and are now prevalent in several regions of both countries. TYLCV was later exported to several countries around the Mediterranean region and worldwide. In 1994, TYLCV was identified in the Caribbean islands and in 1997 was identified for the first time in the USA. Since then, the virus has been exported worldwide (**Figure 1**) and is present in the following countries: USA (California, Georgia, New Mexico, Arizona), Mexico, Puerto Rico, Dominican Republic, Cuba, Tunisia, Morocco, Egypt, Spain, Italy, France, Greece, Turkey, Sudan, India, China, Japan, and Australia.

Symptoms and Yield Losses

The symptoms induced by TYLCV are typically a leaf curling of the leaves with different levels of yellowing (**Figure 2**). However in a single field of infected tomato plants a variety of symptoms can be observed from green to purple leaf curling, thickening of the veins and the stems, and various levels of stunting. In some instances, the leaf surface is reduced a minimum, with large veins and thick lamina. When plants are infected at an early stage, the plant fail to produce fruits and will stay stunted. Losses are in general very high, and depending on the earliness of the infection and on the level of resistance of the variety can reach 100%. TYLCV is considered a major threat for farmers growing tomatoes, both for commercial or subsistence purposes.

Causal Agent with Classification

TYLCV belongs to the genus *Begomovirus*, in the family *Geminiviridae*. Begomoviruses are either monopartite and bipartite, meaning that their genome is composed of a single or two molecules of circular ssDNA and TYLCV is a monopartite virus. This feature does not explain the prevalence of TYLCV in the world, as there are many monopartite geminiviruses in the Old World that do not show the characteristics of a new virus emergence. Regarding the genome organization, TYLCV is a typical monopartite begomovirus coding for six open reading frames (ORFs). A total of five strains of TYLCV, called TYLCV-Iran, -Gezira, -mild, -Oman, and -Israel, have been identified, but it is mostly the Israeli strain that has, so far, spread all over the world.

Epidemiology

Begomoviruses are not seed transmitted, nor mechanically transmitted (with a few exception in lab conditions); they are only transmitted by the whitefly *Bemisia tabaci*. In the 1960s, TYLCV was found in local weeds in Israel, serving as virus reservoir, when tomatoes were planted in the field. In the 1980s in Spain, the year-round cultivation of tomatoes under plastic screen houses promoted the spread of the disease, but beans were also found as a host of the virus. Over the years, it was found that the privileged mode of spreading of the disease in the world was via international trade of tomato plantlets, but it was demonstrated that the green tissue attached to the fruits (sepals, stems) was a very efficient virus reservoir for local whiteflies. In several instances (Dominican Republic and Florida), it was observed that TYLCV became the prevalent virus, displacing the local geminiviruses previously infecting tomatoes. This could be due to the fact that TYLCV is very aggressive and could become prevalent because of a better fitness to the host. In addition to the trade impact, the explosion of the B-type population of whiteflies can explain the worldwide spread of TYLCV. This particular B-type population of whiteflies is very ubiquitous and infects more than 1000 different plant hosts, providing the insect with enormous resources for winter survival and local adaptation.

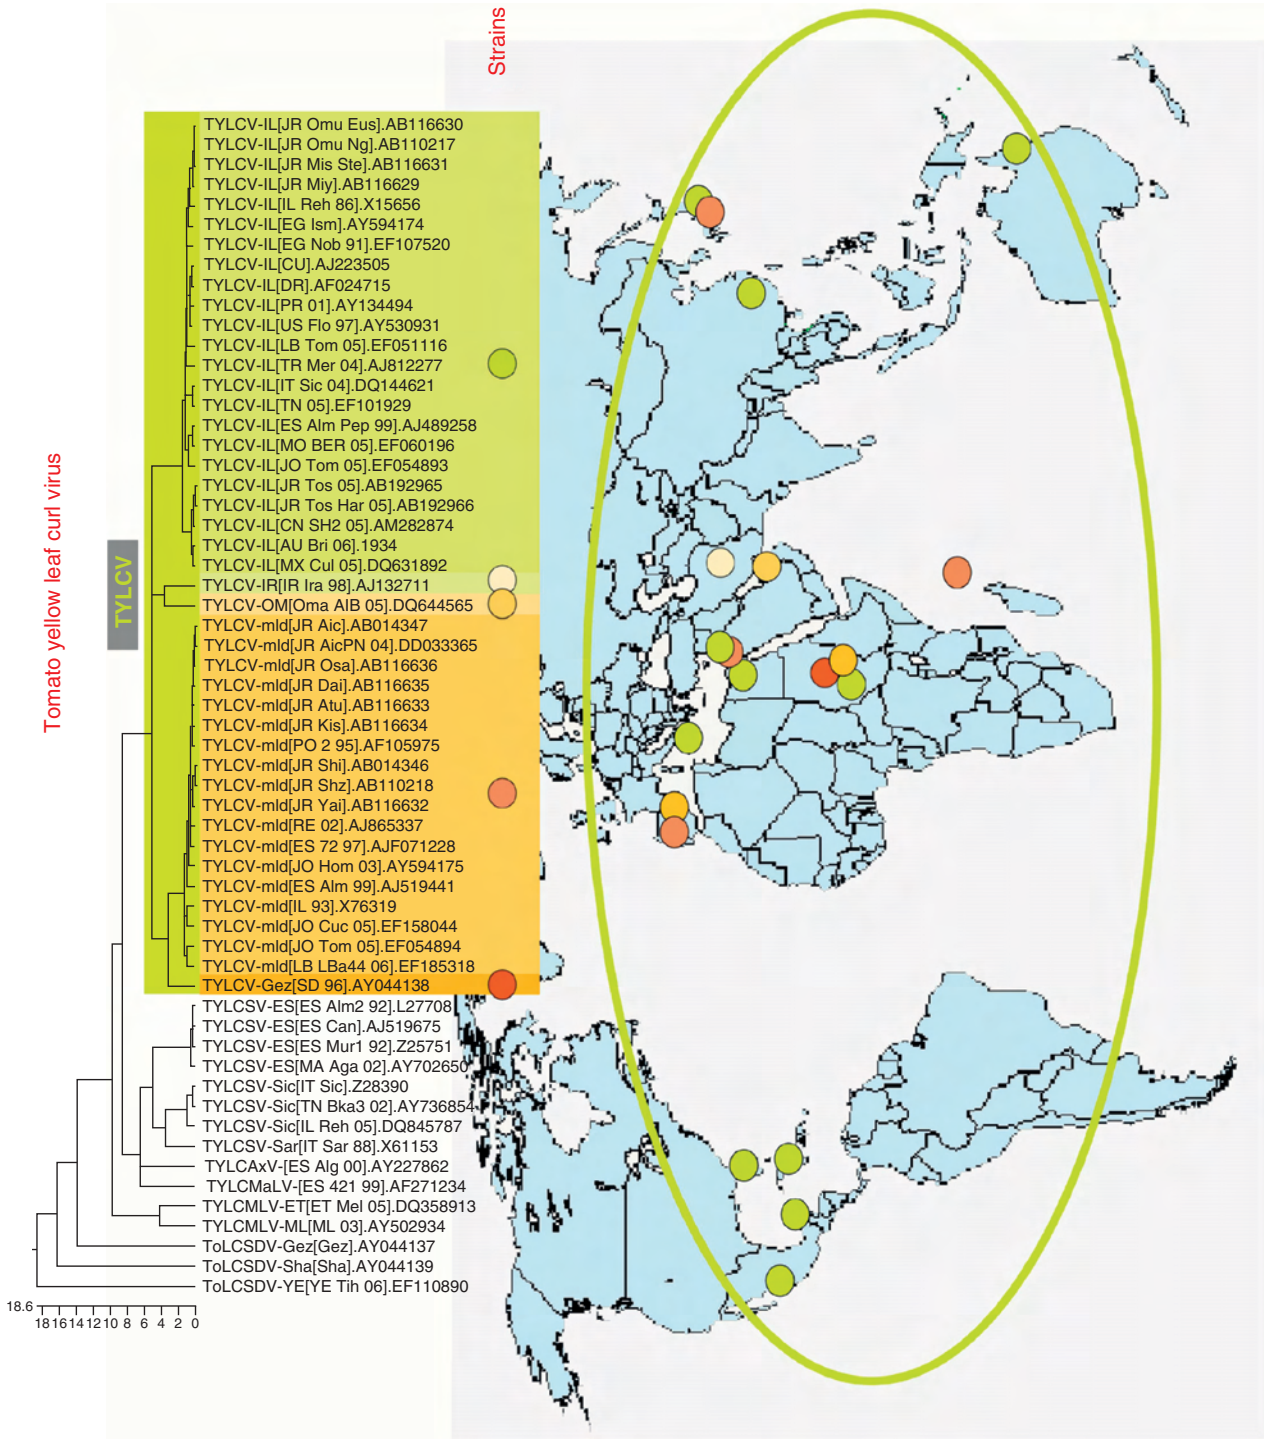

Figure 1 World map on which each of the 44 members representing five begomovirus strains of the TYLCV species have been indicated. The abbreviated name and accession numbers of the isolates are listed in phylogenetic tree in the upper part of the diagram. The phylogenetic tree has been built using their complete A component sequence. The Clustal V algorithm of the program MegAlign from DNAStar has been used and distances in percentage difference are indicated on the left. The tree shows a partition in six major clusters, one for each of the six designated viruses, TYLCV, tomato yellow leaf curl Sardinia virus (TYLCSV), tomato yellow leaf curl Axarquia virus (TYLCAxV), tomato yellow leaf curl Malaga virus (TYLCMalV), tomato yellow leaf curl Mali virus (TYLCMLV), and tomato leaf curl Sudan virus (ToLCSDV). These six species constitute the so-called TYLCV cluster of the Old World begomoviruses. The individual viruses composing the TYLCV cluster are positioned on the world map, as filled circles of various colors representing their pertaining to one of the six specific TYLCV strains, as indicated in the colored boxes at the bottom of the tree. On the world map, the individuals pertaining to the TYLCV species are shown with filled circles.

Control

Geminiviruses are in general very difficult to control. The most efficient way is the use of virus-resistant varieties when they are available, acceptable, and affordable. The cost of such varieties is limiting their use to industrial tomato plantations and therefore most of the tomato fields in poor farmers fields are extremely susceptible. Another limiting factor is the taste and shape of virus-resistant tomatoes that do not match local requirements and encourage the use of susceptible varieties. Controlling the insect, by chemical means, is practically impossible and very expensive. Agricultural practices, although efficient in certain conditions, have been of little help to control TYLCV in a practical manner.

The African Cassava Pandemic

Geographical Distribution

The cassava geminivirus pandemic in Africa started in the early 1990s and is still going on today. It started in Uganda in 1994, invaded several countries in East Africa around Lake Victoria, before crossing the mountains in Rwanda-Burundi, to infect the entire Congo Basin and invade up to Gabon and the south of Cameroon (**Figure 3**). Cassava plants were already infected with African cassava mosaic

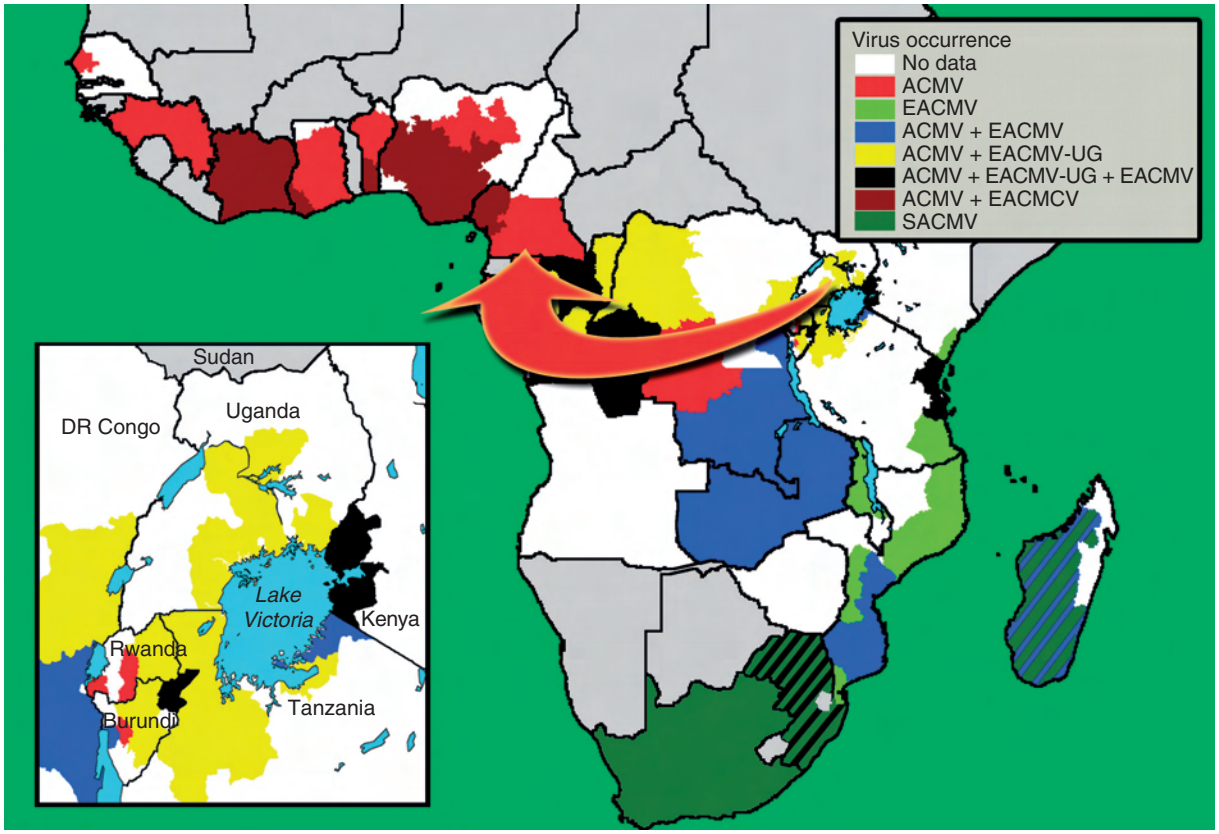

Figure 3 Distribution of cassava mosaic geminiviruses in Africa obtained from CMD surveys in Africa, 1998–2004. ACMV, African cassava mosaic virus; EACMV, East African cassava mosaic virus; EACMV-UG, East African cassava mosaic virus – Uganda; EACMCV, East African cassava mosaic Cameroon virus; SACMV, South African cassava mosaic virus.

virus (ACMV) and other viruses, but became superinfected with an Ugandan strain of East African cassava mosaic virus (EACMV-UG), which displaced other viruses.

Symptoms and Yield Losses

Symptoms due to the EACMV-UG are extreme reduction of the surface leaf, yellowing of the lamina, and downcurling of the leaves. The entire infected plants look yellow compared to healthy plants, with reduced size and extremely limited foliage. Furthermore, in many instances, plants are infected with both EACMV-UG and ACMV, and these two viruses synergize to cause a very dramatic syndrome, called 'candlestick syndrome'. In this instance, the stem is thick and turns purple, the leaves are even more reduced in size, with very thick veins and almost no lamina (**Figure 4**(**d**)). Cassava is normally propagated using the stem, but if the plants have been co-infected with ACMV and EACMV-UG, the stems cannot be used anymore and cassava cannot be propagated to the next season. This caused dramatic cassava shortages in Uganda between 1994 and 2000, estimated to losses amounting to 6 million tons per year, and famine and death for thousands of people.

Causal Agent with Classification

ACMV and EACMV-UG are both members of the genus *Begomovirus*, in the family *Geminiviridae*, similarly to TYLCV above. These viruses however are bipartite viruses, with a second DNA molecule coding for two movement proteins. Furthermore, EACMV-UG is a recombinant between ACMV and EACMV, with a fragment of 550 nt from the core part of the coat protein of ACMV integrated into the EACMV genome. Although there is no direct proof that this recombinant has any specific advantage over the nonrecombinant EACMV, it is a fact that the EACMV-UG strain is present in all the plants that show severe symptoms and is strictly correlated with the development of the pandemic across the African continent. In addition, these two viruses do synergize to cause a dramatic 'candlestick' symptom, preventing the cuttings from these infected plants to grow for the next generation. The explanation for this phenomenon resides in the fact that each virus codes for a very strong and differential gene silencing suppressor, and when both suppressors are present, the infected plant collapses from the resulting dual virus infection. This is the first time that such synergism between two geminiviruses has been found.

Epidemiology

ACMV and EACMV-UG are spread by the whitefly *Bemisia tabaci* and through the cassava cuttings, as there is no virus-clean material propagation system in place in Africa. The explosion of the cassava mosaic pandemic in Africa is currently explained by a conjunction of several mechanisms. (1) The synergism between the two viruses certainly played a key role, as it translates into a huge increase in viral DNA in the tip of the plants by 30–100 times, thereby enhancing the whitefly transmission capacity. (2) The recombinant fragment could provide an advantage to EACMV-UG, as it has been shown that the whitefly transmission epitopes are coded by this fragment and that there has been co-adaptation as far as the rate of transmission is concerned, between the local whitefly and viruses. (3) Finally, there has been a tremendous increase in whitefly populations adapted to cassava in Uganda, where the epidemic started. The conjunction of these three elements is believed to be at the triggering and maintenance of the cassava mosaic disease pandemic in Africa.

Control

Similar to the TYLCV, the only available method of control of the cassava mosaic disease is the use of virus-resistant cassava cultivars. Fortunately, such plants were made available to farmers in Uganda by the end of the 1990s, and the use of these plants allowed to restore the cassava production in Uganda. This however did not stop

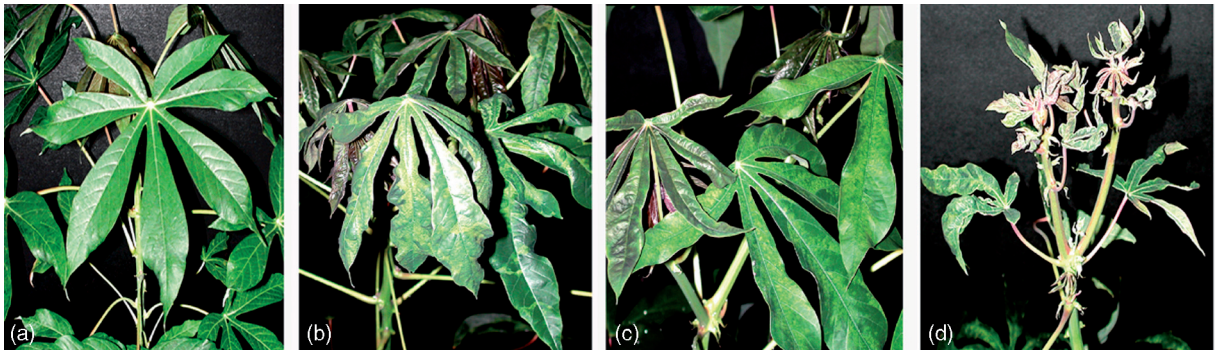

Figure 4 Typical symptoms of cassava infected with ACMV (b) and EACMCV from Cameroon (c), and synergism between the two viruses expressing the 'candlestick' symptoms (d), compared to the control healthy cassava leaves (a).

the pandemic that is still going on in West Africa. Furthermore, many of the farmers in Uganda, and elsewhere, are now going back to their preferred cassava plant material that is not virus resistant, but highly appreciated for their organoleptic and processing qualities. Consequently, more virus-resistant cassava cultivars, acceptable to farmers, are needed.

The Cotton Leaf Curl Disease in the Indian Subcontinent

Geographical Distribution

The leaf curl disease of cotton (*Gossypium hirsutum* L.) was first observed in Multan, Pakistan, in 1967. The disease reappeared in 1987 in its epidemic form in most of the cotton-growing areas of Pakistan. In 1992, the disease was observed throughout the central and southern parts of Punjab in Pakistan. During 1997–98, the disease was established in the border areas of India (Rajasthan, Haryana, and Punjab), joining the southern Punjab of Pakistan. The most devastating virus known as cotton leaf curl Multan virus (CLCuMV) is attributed to huge losses throughout the Indian subcontinent. The estimated direction of movement for the disease is from the center of Pakistan to northern and southern districts of India. Nowadays, the disease can be observed in all primary or secondary cotton-growing areas of the Indian subcontinent (**Figure 5**).

Symptoms and Losses

Cotton leaf curl disease (CLCuD) is not a seed-borne disease, but is only transmitted through whiteflies. After 2–3 weeks of virus inoculation by the insects, vein thickening on young leaves can be observed. Later, upward or downward curling of leaves starts and a cup-shaped leaf enation appears at the underside of the leave (**Figure 6**). The infected plants remain stunted throughout their life cycle and may lose 100% of the total yield. Disease spread can be observed with the wind direction. During the last two decades, the disease caused heavy cotton yield losses which reached up to US$ 5 billion in Pakistan in 1992–97. Recently, the introduction of relatively resistant varieties has selected a more aggressive virus in 2002 in central Pakistan, called cotton leaf curl Burawalia virus (CLCuBuV), and this strain is now prevailing in all cotton-growing areas of Pakistan.

Causal Agent and Classification of Cotton Leaf Curl Disease

The begomoviruses associated with CLCuD are monopartite begomoviruses with an associated ssDNA satellite molecule known as DNA-β (beta satellite).

According to sequence analysis of the available sequences in gene bank, there are viruses belonging to seven different species involved in the etiology of CLCuD named as, CLCuMV, cotton leaf curl Kokhran virus (CLCuKV), cotton leaf curl Rajasthan virus (CLCuRV), cotton leaf curl Allahabad virus (CLCuAV), cotton leaf curl Burawalia virus (CLCuBuV), cotton leaf curl Bangalore virus (CLCuBV), and papaya leaf curl virus (PaLCuV). Cotton leaf curl Bangalore virus is only present in the Bangalore district of southern India, while viruses belonging to the other six species are widespread throughout the cotton-growing areas of the north of the Indian subcontinent.

The area of maximum diversity for CLCuD is in central parts of Pakistan, hosting viruses belonging to five species of cotton leaf curl viruses (CLCuVs) and one of PaLCuV.

CLCuD is in reality caused by a complex of viruses associated with virus satellites. A monopartite geminivirus, belonging to different species of viruses, is typically associated with a beta satellite (DNA-β) or a DNA-1 satellite. If DNA-β's have only been found associated with geminiviruses, DNA-1 satellites have originally been found associated to nanoviruses. Both satellite genomes are encapsidated by the geminivirus capsid protein, and thereby both are transmitted by whiteflies. Full-length clones of several CLCuVs DNA-A were unable to reproduce the symptoms in cotton and other different hosts such as tobacco. Infectious clones of DNA-1 were also not capable of inducing symptom development of CLCuVs in the inoculated plants.

With the discovery of DNA-β, it was proved that both DNA-A and DNA-β are necessary to induce typical symptoms of CLCuD, while DNA-1 is not necessary to induce the symptoms and is seldom found in association with the disease complex. At present, the origin of DNA-β is unknown but it can be transreplicated by diverse geminiviruses associated with the CLCuD complex. The DNA-β is only ±1300 nt long and codes only for one ORF called βC1. The gene βC1 codes for a strong suppressor of gene silencing, thereby providing a tremendous advantage to the cognate helper virus. DNA-1 satellite codes for a Rep protein that allows this satellite to be replicated on its own, but the satellite depends on the helper virus for all the other functions, such as gene-silencing suppression, movement, and transmission. DNA-β is dependent on DNA-A for replication, movement, and transmission. The genome organization of DNA-A is typical of any other begomovirus and has no similarity with its associated satellite molecules. Both DNA-β and DNA-1 are approximately half the size of DNA-A, that is, 1350 nt.

Epidemiology

Cultivated cotton or upland cotton (*G. hirsutum*) was introduced into the Indian subcontinent from southern

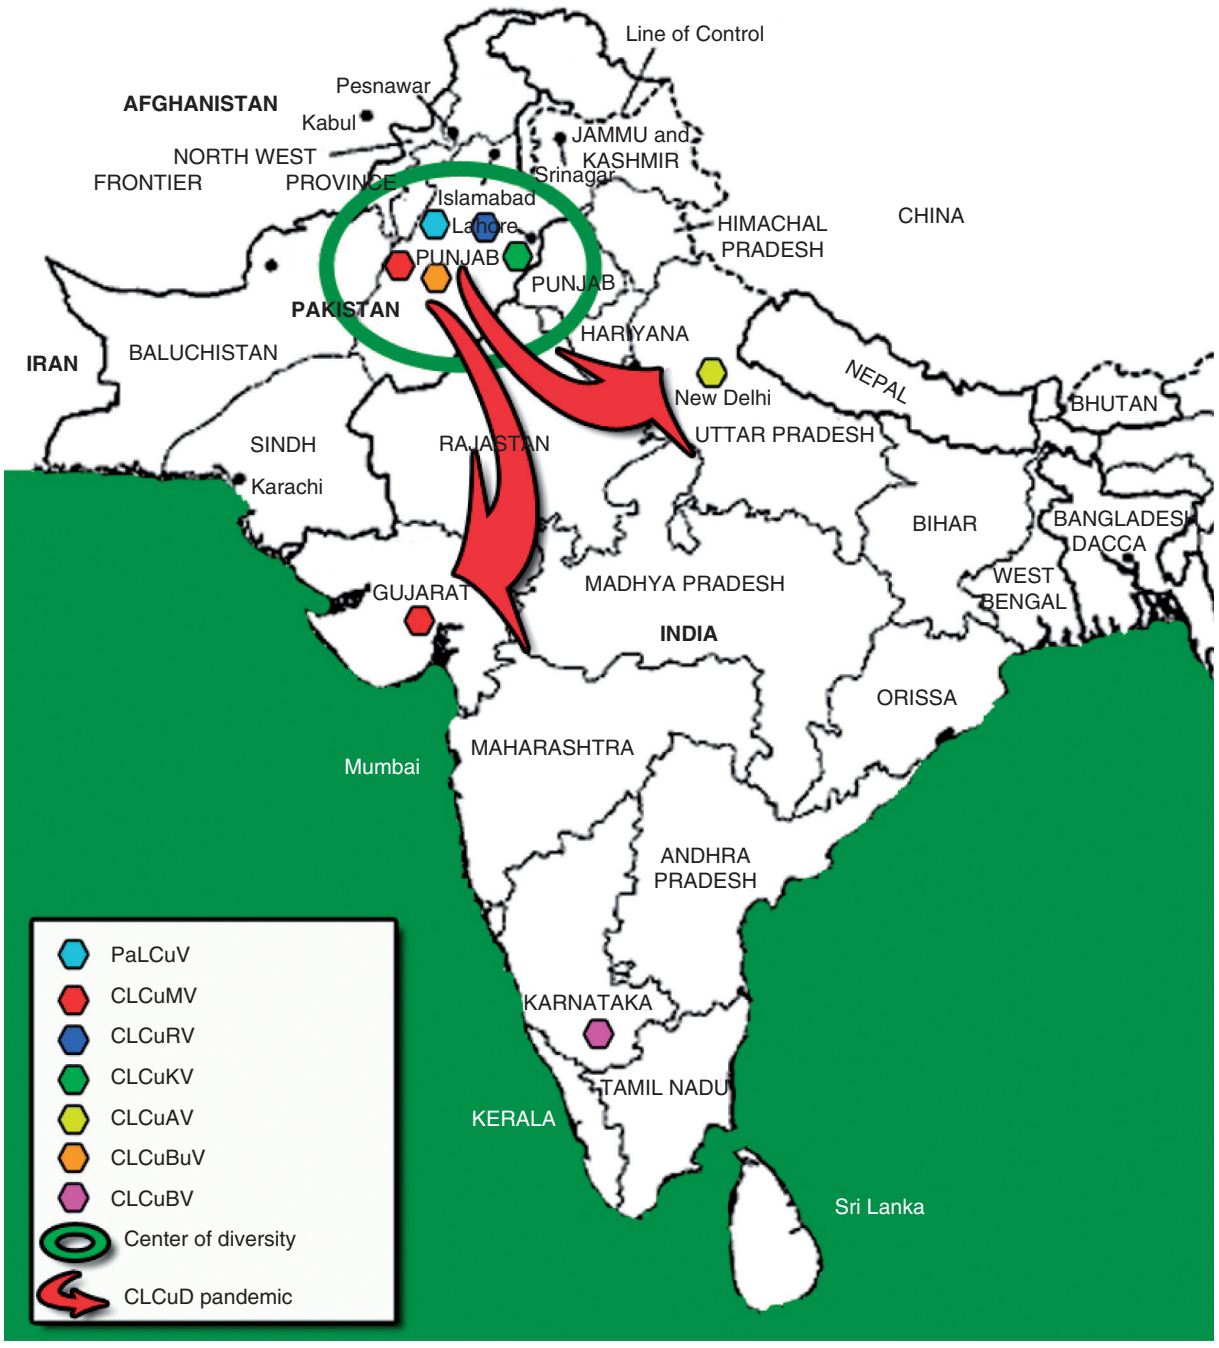

Figure 5 Localization of cotton leaf curl geminiviruses in the Indian subcontinent. Mexico during the nineteenth century. In its native place, cotton is not associated with virus diseases as in the Indian subcontinent. CLCuD complex most probably evolved from some wild species of cotton growing over a long period of time or from other weed hosts present before the cultivation of upland cotton in this part of the world. In 1991, a new variety of cotton (S12) was introduced from Texas, because of its excellent fiber qualities; unfortunately, this new variety was hypersensitive to CLCuD and the disease propagated very quickly after this introduction. The CLCuD threat was greatly increased due to intensive cotton cultivation, monocropping pattern of agriculture, and overlapping seasons of other crop plants. CLCuVs can infect a number of diverse hosts in the

Figure 6 Downward leaf curl symptoms of cotton induced by the CLCuMV in association with the cotton leaf curl Multan beta satellite.

families Malvaceae and Solanaceae. The virus infection was not highly noticed at the early beginning of the epidemic, when perhaps it could have been possible to eradicate the disease. The disease is transmitted through whitefly in a persistent manner. The disease spread is directly correlated with the spread of the whitefly population, along the prevailing wind direction.

Control

Controlling the whitefly vector population is an important aspect to control CLCuD. Insecticides used to control whitefly play a vital role in the control of disease, but still cannot completely eliminate the disease. Over the years, breeders have selected several varieties of cotton with various levels of resistance, but either this level of resistance was unsatisfactory or has been broken by the appearance of new strains of the virus, such as the CLCuBuV from Burawalia. Recently RNA interference (RNAi) has been used and shown to be efficient, in model plants, to control the disease. However, there is still a need to do more work to control the disease in crop plants. In order to create a broad-spectrum resistance to control the disease complex, there is a need of integrated efforts of conventional and genetic engineering approaches.

Conclusion

The three examples of geminivirus emergence presented here provide examples of the importance of different factors that favor the emergence of geminiviruses under very different conditions and environments. In the case of TYLCV, it is a relatively simple case with a single monopartite geminivirus that is transported, through human-based international trade, to various places in the world, and where this very effective virus overcomes existing local viruses and prevails. Although we do not know the molecular and biological basis for the prevalence of TYLCV, it is clear that this virus has a better fitness in tomato and other hosts, compared to local geminiviruses, whether they be bipartite New World geminiviruses or monopartite Old World geminiviruses.

In the case of cassava mosaic geminiviruses, the situation is more complex as it involves at least two different geminiviruses, a new whitefly population, better adapted to cassava, as well as human participation to move the viruses, and probably the whiteflies, in new environments over chains of mountains, where the disease can again explode. It is therefore the apparent conjunction of various biological and human-based activities that promoted the pandemic in Africa. On the biological side, at least three elements can be related to the emergence: (1) the encountering of two geminiviruses with differential and combinatorial gene silencing suppressors that promoted synergism; (2) the occurrence of an apparent successful recombination between these two viruses; and (3) the adaptation of a new population of whiteflies to cassava. The pandemic has been able to travel eastward more than 3500 km in 12 years, and this would not have happened without human intervention. It remains to be seen if the pandemic will continue in West Africa or if it will fade away in this new ecological zone.

The CLCuD case is even a more complex situation where human intervention by introducing new cotton varieties, highly susceptible to local unknown viruses and satellites, as well as the absence of human intervention to stop the disease, triggered the CLCuD pandemic in the Indian subcontinent, costing billions of dollars to poor farmers and impacting Pakistan economy to about 30% for years. On the virological side, this pandemic revealed a new concept, that is, the crucial role of satellites like the DNA-β for inducing symptoms and finally for allowing the whole pandemic. It is the association of a single DNA-β to a variety of helper geminiviruses that is causing the disease and not a single monopartite geminivirus. It is now obvious that recombination of both DNA-β and its geminivirus helpers is an important evolutionary mechanism to create new diversity to overcome virus resistance, revealing the power of geminiviruses and their satellites to adapt to new ecological situations.

The common factor among these three examples is that human intervention, or lack of intervention, is providing viruses and their satellites opportunities to promote

new disease emergences in combination with ecological changes, which are also linked to human impact. These dramatic pandemics, costing billions of dollars in losses and thousands of lives, offer however opportunities to the scientists to better understand the biological causes of these emerging diseases. Taking advantage of these global scale 'experiments', it may be possible to identify the relevant biological factors that could in future allow such diseases to be controlled.

Endogenous Retroviruses

W E Johnson, New England Primate Research Center, Southborough, MA, USA

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Metazoan A multicellular animal.
Monophyletic A taxonomic grouping comprised exclusively of an ancestor and its descendants.
Phylogenetic tree A diagram of the evolutionary relationships between entities descended from a common ancestor.
Proto-oncogene A gene whose normal function is to control cell growth or differentiation, but which can be converted into a cancer-causing gene (oncogene) by mutation or disregulation.

Introduction

At the heart of the retrovirus replication cycle is a stage in which the viral genome, having been converted from single-stranded RNA into double-stranded DNA by the viral reverse transcriptase, is inserted at random into a chromosome of the infected cell. The resulting DNA 'provirus' directs expression and assembly of progeny virions. The integrated provirus itself is contiguous with the rest of the host-cell chromosome, just like any other stretch of genomic DNA sequence. Consequently, if a cell harboring a provirus continues to divide and multiply, the provirus will be inherited by daughter cells during subsequent rounds of cell division like any other cellular gene. If retroviral integration occurs in a cell belonging to germline tissue of a host organism (e.g., in an oocyte or in an embryonic cell destined to develop into germline tissue), the resulting provirus constitutes an insertional mutation, and the new allele can potentially be passed on to the next generation like any other chromosomal locus. As a new allele, the proviral locus will be subject to the processes of random genetic drift and selection and, as a result, many such events may quickly be lost. But some will spread in the population and, given enough time, may eventually become fixed. In fact, this scenario has played out many millions of times over the course of metazoan evolution, such that the genomes of almost all animal species contain numerous sequences resembling proviruses. These elements are referred to as endogenous retroviruses (ERVs). While exogenous retroviruses spread from individual to individual by infection (horizontal transmission), endogenous retroviruses, as components of the germline, are inherited in the same fashion as other genes. The two modes are not mutually exclusive, and virions expressed from ERVs can give rise to spreading infections within the host and may also be transmitted to other individuals.

Structure

The typical retroviral provirus consists of *gag*, *pro*, *pol*, and *env* open reading frames, which encode the viral structural and nonstructural proteins, bookended by two identical regulatory regions called long terminal repeats (LTRs).

No chromosomal DNA is lost as a consequence of integration; however, a short stretch of host-cell DNA (typically around 4–6 bp) is duplicated, resulting in direct repeats (DRs) of cellular sequence flanking the provirus. Important *cis*-acting sequences for replication are located within the LTRs, and primer recognition sequences for reverse transcription are located at the junctions between the 5′ LTR and *gag* (first-strand synthesis), and between *env* and the 3′ LTR (second-strand synthesis). Retroviruses use a cellular transfer RNA molecule (tRNA) as the primer for the first step in reverse transcription; thus, the primer binding site (PBS) is complementary to the 3′ end of a cellular tRNA. The second primer is derived from a purine-rich stretch of the viral RNA itself (polypurine tract or PPT). The generic structure of a provirus is therefore:

DR-5′LTR-PBS-gag-pro-pol-env-PPT-3′LTR-DR

In general, ERVs can be recognized as genomic loci conforming to this basic arrangement, even though in many cases significant portions of the original provirus may be missing (**Figure 1**). There are no viral or cellular mechanisms for precise deletion of integrated proviruses, but ERV sequences can be lost or rearranged, in whole or in part, by the same general processes affecting all chromosomal DNA. For example, homologous recombination can occur between the two LTRs of an ERV, resulting in deletion of the intervening proviral sequences and leaving behind a single LTR (or solo-LTR). Solo-LTRs are abundant in animal genomes, and in many cases may significantly outnumber intact proviruses.

Discovery and Distribution

Even prior to the discovery of reverse transcriptase in 1970 (and confirmation that retroviruses replicate through a proviral intermediate), there was some phenotypic evidence for the existence of ERV loci. Then beginning in the early 1970s, the widespread existence of ERVs was quickly revealed using genomic DNA samples and nucleic acid hybridization techniques. Novel ERV sequences were cloned initially using probes derived from existing retroviruses, by accident during the cloning and characterization of unrelated genes, and later by using a variety of polymerase chain reaction (PCR)-based approaches. By far the richest vein of new ERV sequences has come from mining the human genome databases and subsequent whole-genome sequences of other organisms.

The distribution of ERV among modern species speaks of their age. ERV families or specific ERV loci are often shared among the genomes of related species, indicating that the integration events occurred in the genomes of ancestors shared by those species. For example, a large number of ERVs are located in identical positions in humans and closely related primates, such as chimpanzees, bonobos, and gorillas. Thus, these loci must have originated in a common ancestor of these species. This also provides a lower bound to the estimated time of integration based on the approximate time of divergence of these lineages. In the case of an ERV locus shared exclusively by humans and chimpanzees, for example, the provirus will be no less than about 5 million years old, whereas a locus shared by humans, apes, and Old World monkeys will be greater than 25 million years old.

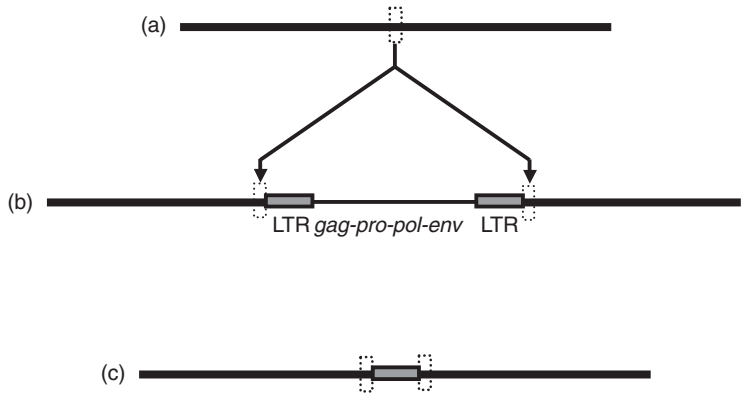

Figure 1 Structure of an ERV. Thick black line represents a segment of a host-cell chromosome. Thin line (labeled *gag-pro-pol-env*) and gray boxes (LTR) represent integrated viral sequences. Small boxes (dashed line) indicate short segment of chromosomal DNA duplicated (arrowheads) at the time of proviral integration. (a) Chromosomal segment prior to integration of a provirus. (b) Same chromosomal locus, but containing an integrated provirus. No chromosomal DNA is lost due to integration, and a short segment (~4–6 bp) is duplicated. When this structure occurs in the germline, it constitutes an ERV. At the time of integration, the LTRs of the ERV are identical, but these sequences will thereafter diverge due to the accumulation of random mutations; thus, the degree of divergence between the LTRs of an ancient ERV are a reflection of the age of the provirus. (c) Same locus, after recombination between the two LTRs, has resulted in loss of the intervening proviral sequence. Only a single copy of the LTR sequence remains, along with the flanking repeats.

In general, the wider spread an ERV-sequence family is among extant species, the more ancient that family is. More modern ERVs are found among a smaller subset of species or are even confined to a single species. (This is a generalization because viruses have the potential for horizontal, cross-species transmission; ERV sequences derived from a modern retrovirus could appear in the genomes of more than one lineage.) Modern ERVs are also more likely to be intact (and capable of expressing virus), and are often closely related to known exogenous retroviruses.

Origins

There are at least four possible scenarios to explain the presence of multicopy ERV families in the germline: (1) repeated, *de novo* infection of germline tissue by an exogenous retrovirus; (2) expression of an existing endogenous provirus with subsequent reinfections of germline tissue; (3) intracellular retro-transposition from an existing ERV; and (4) duplication of genomic DNA fragments already containing an integrated ERV (however, even in this case, the original ERV sequence must have arisen via one of the first three mechanisms). Although there is experimental proof-in-principle for all four processes, it is generally believed that scenarios involving extracellular replication and infection (i.e., the first two mechanisms) predominate in nature.

Whatever the mechanism, presence in the germline requires that integration, takes place either in cells of germline tissue or, because the provirus is maintained during cell division, in a cell lineage destined to develop into germline tissue. Once integrated, the selective forces that work on the proviral sequences will depend on a number of factors, including the state of the provirus at the time of integration. For example, did the viral genome suffer attenuating or debilitating mutations during reverse transcription? Was it intact and capable of expression at the time of provirus formation? Did integration occur in junk DNA, close to a gene, or in a gene? Was the provirus silenced after integration (e.g., by methylation), and in what developmental stages and in which tissues was the provirus expressed? In other words, whether or not a newly formed provirus will persist as an endogenous retrovirus is determined in part by its immediate effect on the survival of the infected cell and its ultimate effect on reproductive fitness of the host organism. ERVs that are strongly counterselected due to pathogenic or detrimental effects on the host are likely to be lost from the gene pool.

Although the bulk of integrations may occur in junk DNA, experimental evidence suggests that integration may occur preferentially into transcriptionally active areas, which increases the likelihood of insertion in and near genes. Insertional inactivation of critical genes can be immediately deleterious to the host, or may only be lethal in the homozygous state (in the latter case, an ERV-containing locus could persist for many generations as a minor allele). Integration can also lead to activation or aberrant regulation of genes near the site of integration. For example, activation of proto-oncogenes in the vicinity of integrated proviruses has been detected many times in experimental animal models of retroviral pathogenesis; it is possible that similar scenarios could also occur during formation of an ERV. Expression of the ERV can potentially be a source of pathogenic virus or can contribute to pathogenecity by recombination with other retroviruses.

ERV sequences may also have beneficial consequences for the host. Laboratory studies with both chickens and inbred mice have identified several ERV-derived genes that now function to reduce or prevent exogenous retroviral infection. ERV sequences also have the potential to provide new cellular functions during the course of evolution. The human Syncytin protein may be a striking example of the latter; this protein is in fact the envelope protein of an ancient endogenous provirus that appears to have been co-opted during evolution to function in human placental morphogenesis.

Stochastic factors will also influence the persistence of an ERV locus in the genome. Proviruses in the germline are subject to the same processes that affect all genomic sequences, including substitutions, deletions, insertions, recombination, gene conversion, random assortment, and genetic drift. Even in the absence of selective pressures, a newly formed ERV represents a minor allele and stands a good chance of being lost by chance. In the absence of positive selection, random accumulation of mutations over time will eventually degrade the viral open reading frames and the *cis*-acting elements required for expression. Thus, the interplay between random processes, as well as the nature and extent of selective forces acting on the ERV, will affect the way in which these sequences evolve during their residence in the germline.

Taxonomy and Classification

The term 'endogenous retrovirus' does not refer to a biological entity distinct from other retroviruses, but simply describes any DNA provirus, retroviral in origin, that has found its way into an organismal germline. This is true regardless of whether the provirus is still capable of expressing infectious virions. In fact, even highly degraded proviruses containing large deletions, insertions, and substitutions are often referred to as ERVs, as long as they are still clearly derived from a retrovirus.

Phylogenetic trees incorporating multiple genera of retroviruses are typically constructed using amino acid alignments corresponding to conserved domains in the reverse transcriptase gene. When representatives of multiple ERV families are included in such analyses, they do

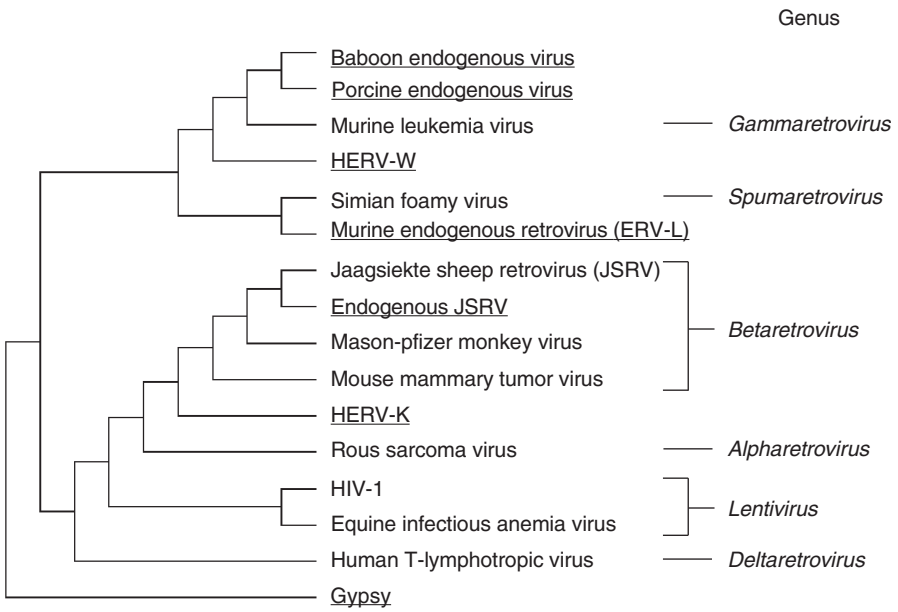

Figure 2 Phylogenetic tree based on amino acid alignment of reverse transcriptase from a variety of retroviruses. ERVs are underlined. Viruses representing genera in the family *Retroviridae* are indicated. Gypsy is an endogenous retroviral element from the invertebrate species *Drosophila melanogaster*. Tree was generated by maximum parsimony and represents one of five equally parsimonious trees. Note that ERV sequences are interleaved with exogenous sequences and do not represent a separate lineage.

not form a monophyletic cluster, but rather are scattered within and between the various genera of exogenous retroviruses (**Figure 2**). Moreover, modern ERVs may have very closely related, exogenous counterparts. Thus, ERVs do not constitute a separate taxonomic division from exogenous retroviruses (this refers to ERVs as a whole; any individual ERV locus or family may still represent a novel (and possibly extinct) retroviral genus).

Although there are exceptions, the vast majority of ERVs (particularly the ancient ERVs) is not closely related to known exogenous retroviruses, is no longer capable of expressing virus, and has no other associated biological or phenotypic properties to facilitate classification. The interleaving of ancient ERV sequences with extant retroviruses in phylogenetic trees, along with similarities to modern viruses in provirus organization, indicates that ancient ERVs are not ancestral stages in the evolutionary pathway leading to retroviruses (i.e., they are not protoretroviruses), but rather represent fully evolved (albeit extinct) sibling species to modern retroviruses.

There is as yet no officially recognized nomenclature for endogenous retroviruses, and a variety of naming conventions exist. In general, these represent myriad naming practices coined by various investigators at the time each novel ERV was discovered. For ERVs originally identified in the human genome, the practice has been adopted of using the acronym HERV (for human endogenous retrovirus) followed by a single letter that specifies the most likely tRNA primer (based on complementarity to the putative PBS sequence). Thus, HERV-K refers to endogenous proviruses with a PBS sequence complementary to a lysine tRNA. This convention has made the HERV literature much more accessible, but in practice it still leads to some ambiguity, because: (1) otherwise unrelated retroviruses may share the same or similar tRNAs; (2) many ERV loci may not contain a recognizable PBS element; and (3) in some cases, the PBS will be sufficiently degraded by substitutions that unambiguous prediction of tRNA specificity is not possible. Despite the name, the vast majority of HERV loci is not unique to humans but is shared with other, closely related primates (having first appeared in a common ancestor); thus, HERV loci should not be thought of as human specific, but rather as human orthologs of loci found in other primate species. Because some HERV families have hundreds or thousands of members, when a specific HERV locus is being described in reference to the chromosomal location, database accession number or cosmid clone is sometimes used for clarity (e.g., HERV-K6p22 refers to a provirus of the HERV-K family found at band 22 on the short arm of chromosome 6). However, this practice is recent and many of the original clone names are still in use.

Conclusion

Given the sheer number and ubiquity of ERVs among extant species, it is likely that retroviruses have made major contributions to both the content and structure of animal genomes for hundreds of millions of years. Retroviruses can give rise to new DNA content via

proviral integration as well as by retro-transposition or transduction of nonviral sequences. Because many ERVs constitute multilocus families of closely related sequences, they can mediate intergenic recombination events leading to large-scale deletions, duplications, interchromosomal translocations, and inversions of chromosomal sequence. All of these processes are also mutagenic, and therefore provide sources of variation upon which selective forces may operate. ERVs can also recombine with exogenous retroviruses during infection, providing additional sources of viral variation and giving rise to retroviruses with altered or novel properties. In modern times, the advent of xenotransplantation (using appropriate animals as organ donors for human transplantation) has raised concerns that ERVs expressed in the donor organs could introduce new retroviruses into the human population. Finally, because of the vast archive of retroviral sequences present in animal genomes in the form of ERVs, the deep evolutionary past of the *Retroviridae* is amenable to scientific exploration in a way that other viral families are not.

Glossary

Cytoplasmic male sterility (CMS) Male sterility caused by a cytoplasmic factor.
Isogenic line Genetically identical pure-breeding group of individuals.
Mycovirus A virus that infects fungal species.
Replicon A genetic unit of replication.

Introduction

Double-stranded RNAs (dsRNAs) have frequently been identified in various healthy plants, from algae through to higher plants. These dsRNAs are not transcribed from the host genome DNAs, and they have important properties in common that differ from those of conventional viruses: (1) most of these dsRNAs have no obvious effect on the phenotype of their host plants; (2) they are present at a constant low concentration in the host plant; (3) they are efficiently transmitted to the next generation via seeds, but their horizontal transfer (infection) to other plants has never been proved. The size of these dsRNAs varies from 1.5 to 20 kbp. Smaller dsRNAs (~2.0 kbp) are often found with virus-like particles and some of these dsRNAs have already been classified as viruses in the genera *Alphacryptovirus* and *Betacryptovirus* of the family *Partitiviridae*. Partitiviruses have two unrelated linear dsRNA segments, each about 2.0 kbp in size. Larger

dsRNA segments (more than 10 kbp) are unlikely to be associated with distinct virus-like particles, because no distinct virus-like particles have been detected in preparations obtained with various purification procedures. Thus, these large dsRNAs were previously referred to as RNA plasmids, enigmatic dsRNAs, or endogenous dsRNAs.

Large dsRNAs (Endornaviruses) in Plants

In 1966, a cytoplasmic male sterility (CMS) trait, termed '447', in broad bean (*Vicia faba*) was described, and in 1976, electron microscopy observations revealed that the cytoplasm of 447 male-sterile plants contained cytoplasmic spherical bodies (CSBs) that resembled vesicles of about 70 nm in diameter. These CSBs were found in all tissues of the 447 plants, and contained a high-molecular-weight dsRNA. An absolute correlation between the CMS trait and the presence of the CSB containing the dsRNA has been established.

In the 1990s, large dsRNAs of about 14 kbp in length were found in many strains of cultivated rice (*Oryza sativa* L.) in Japan (temperate *japonica* rice) and the Philippines (tropical *japonica* rice), but not in the *indica* subspecies of *O. sativa*. A similar dsRNA was also detected in one strain (W-1714) of wild rice (*O. rufipogon*), which is considered an ancestor of *O. sativa*. dsRNA-carrying plants and dsRNA-free plants were found for the Nipponbare cultivar of temperate *japonica* rice, but these two isogenic lines were indistinguishable in their phenotypes. Even rice breeders and farmers could not distinguish these two lines; in fact, dsRNA-carrying and dsRNA-free rice plants were found in the same rice paddy field at our university farm. If the dsRNA-carrying line had a lower harvest yield than the dsRNA-free line, rice breeders and/or farmers would have recognized this phenotype and discarded the lower-yielding line. Given that this did not occur, these two lines can be considered identical with respect to all phenotypes, including harvest yield. Electron microscopy observations revealed that all dsRNA molecules from rice plants are linear. Differential centrifugation and sucrose density-gradient centrifugation revealed that the dsRNA in rice is localized in the cytoplasm.

Large dsRNAs of about 14 kbp in length have also been found in other crops, but only three of these dsRNAs, from the 447 male-sterile strain of broad bean (*V. faba*), the Nipponbare cultivar of cultivated rice (*O. sativa*), and the W-1714 strain of wild rice (*O. rufipogon*), have been sequenced completely. All three dsRNAs encode a single long open reading frame (ORF), in which conserved motifs for RNA-dependent RNA polymerase (RdRp) and RNA helicase (Hel) are found (**Figure 1**). The large dsRNAs are RNA replicons that can

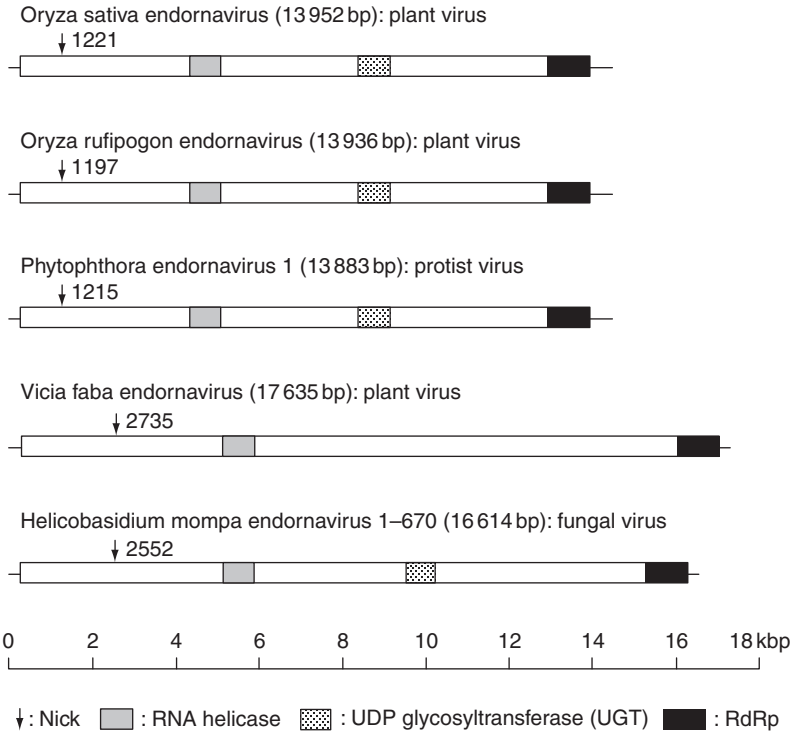

Figure 1 Comparison of the genome organizations of five endornaviruses: oryza sativa endornavirus (OsEV), oryza rufipogon endornavirus (OrEV), phytophthora endornavirus 1 (PEV1), vicia faba endornavirus (VfEV), and helicobasidium mompa endornavirus 1–670 (HmEV1–670).

replicate independently of their host genome by using their own RdRps, as will be discussed later. Phylogenetic analyses of the amino acid (aa) sequences of the RdRp and Hel motifs indicate that the three large dsRNAs that have been sequenced share a common ancestor with the alpha-like supergroup of positive-sense, single-stranded RNA (ssRNA) viruses, which includes many plant viruses, such as those of the genera *Tobamovirus* and *Cucumovirus*. Based on this information, in its eighth report, the International Committee on Taxonomy of Viruses (ICTV) accepted that these large plasmid-like dsRNA replicons are members of a new virus genus, *Endornavirus*. The dsRNAs found in cultivated rice, wild rice, and broad bean have been named oryza sativa endornavirus (OsEV), oryza rufipogon endornavirus (OrEV), and vicia faba endornavirus (VfEV), respectively (**Figure 1**).

Nonplant Endornaviruses

dsRNAs are found not only in plants, but also frequently in a variety of fungi; in fact, they have been recorded in all major fungal taxonomic groups, including various plant pathogens. The genomes of most mycoviruses consist of dsRNAs, and these fungal dsRNA viruses have so far been classified into five families: *Reoviridae, Totiviridae, Partitiviridae, Chrysoviridae,* and *Hypoviridae*. Members of only one of these families, the *Hypoviridae*, contain a single large dsRNA genome about 10–12 kbp in length, in contrast to members of the other families that contain one or multiple small dsRNA genomes about 2–6 kbp in length. However, many unclassified dsRNAs are still found in various fungi, some of which are larger than 10 kbp in length.

The AG3 isolate of the fungus *Rhizoctonia solani* is the major cause of rhizoctonia disease in potato, and contains two large dsRNAs, L1 (25 kbp) and L2 (23 kbp), in some strains of the fungus. The nucleotide sequence of the L2 dsRNA has been partially determined, and was found to be similar to the RdRp regions of the ORFs encoded by plant endornaviruses.

The violet root rot fungus, *Helicobasidium mompa*, occurs on various plants, and contains various-sized dsRNAs. A large dsRNA (L1 dsRNA) in the V670 strain of *H. mompa* has been identified as a hypovirulence factor, and has been sequenced completely. It encodes a single long ORF (5373 aa), in which conserved RdRp and Hel motifs are found (**Figure 1**). A BLAST search using the aa sequence of this ORF revealed significant sequence similarities to the dsRNAs of members of the genus *Endornavirus*. These results indicated that the large dsRNA in *H. mompa* belongs to the genus *Endornavirus*, and it was thus named helicobasidium mompa endornavirus 1–670 (HmEV1–670).

Plant pathogens of the genus *Phytophthora* have many of the same biological properties as fungi. However, on the basis of sequence similarities they have been classified together with diatoms and brown algae in a protist group known as the stramenopiles or chromista. The complete nucleotide sequence of the 13.9 kbp dsRNA isolated from a *Phytophthora* isolate from Douglas fir has also been published recently. The dsRNA encodes a single long ORF (4548 aa), whose genome organization is very similar to that of known endornaviruses (**Figure 1**). Phylogenetic analyses support the classification of this dsRNA (named *Phytophthora endornavirus* 1 (PEV1)) as a member of the genus *Endornavirus*.

Therefore, entire nucleotide sequences have been published for a total of five endornaviruses, three from plants (OsEV, OrEV, and VfEV), one from a fungus (HmEV1-670) and one from a protist (PEV1). Despite the diversity of their hosts, a comparison of the genome organizations of the five endornaviruses indicates that they share a unique structure (**Figure 1**): all five endornaviruses encode a single unusually long ORF, in which conserved motifs for RdRp and Hel are found in the same regions, and they contain a site-specific nick in the 5′ region of the coding strand.

Tentative Members of the Genus *Endornavirus*

In the 1990s, dsRNAs of about 14 kbp in size were found in many cultivars of barley (*Hordeum vulgare*), kidney bean (*Phaseolus vulgaris*), and bell pepper (*Capsicum annuum*). Barley and bell pepper plants hosting the dsRNAs are available commercially, so these plants must be healthy and common (not special) cultivars. These dsRNAs have been reported to be efficiently transmitted to the next generation. Therefore, these large dsRNAs with plasmid-like properties may be members of the genus *Endornavirus*. Unfortunately, only limited sequence information for these dsRNAs is available (except for an approximately 630-nt sequence of the dsRNA from kidney bean), so it is currently unclear whether they do in fact belong to the genus *Endornavirus*.

Partial sequences of the large dsRNAs from kidney bean (*P. vulgaris,* cv. Black Turtle) and bottle gourd (*Lagenaria siceraria*) have been reported recently, and a single ORF was found in dsRNAs from both species. Homologous sequence searches for these ORFs indicate that both ORFs contain sequences similar to the entire RdRp regions of endornaviruses, and that, in turn, the RdRp domains of endornaviruses are similar to the pfam00978 (RNA_dep_RNApol2) domain in the Conserved Domain Database. RdRps of ssRNA viruses of the alpha-like superfamily are classified as the pfam00978 domain. Molecular phylogenetic analyses using the aa sequences encoded by the RdRp regions (about 470 aa residues) of the kidney bean and bottle gourd dsRNAs as well as of the five endornaviruses and the 10 most diverse

members of pfam00978 were carried out. The resulting phylogenetic tree shows that the kidney bean and bottle gourd dsRNAs form a monophyletic group with the known endornaviruses, a grouping that was supported by a high bootstrap probability (100%; **Figure 2**(**a**)), indicating that these two dsRNAs are members of the genus *Endornavirus*.

Furthermore, partial sequences of dsRNAs from barley (*H. vulgare*, cv. Kashima), melon (*Cucumis melo*), Malabar spinach (*Basella alba*), seagrass (*Zostera marina*), and strain V1369 of the violet root rot fungus (*H. mompa*) have also been recently reported. The sequences are short, but commonly contain core RdRp regions of about 80 aa residues. Phylogenetic analyses were carried out for these five dsRNA sequences, seven known endornaviruses (including kidney bean and bottle gourd dsRNAs), and 10 ssRNA viruses. Although the analyzed RdRp regions of the dsRNAs and viruses were short (~80 aa), the phylogenetic tree was essentially the same as the tree in **Figure 2**(**a**), in which the five dsRNAs mentioned above formed a monophyletic group with the seven endornaviruses (**Figure 2**(**b**)). These results suggest that these five dsRNAs from four plants and one fungus are members of the genus *Endornavirus*. Therefore, there is a growing list of new dsRNA viruses that belong or very probably belong to the genus *Endornavirus*, distributed over the plant, protist, and fungal kingdoms (**Table 1**).

Proteins Encoded by Endornaviruses

All five endornaviruses that have been completely sequenced encode a single unusually long ORF, from 4500 to 5500 aa residues in length, which is one of the unique molecular features of endornaviruses (**Figure 1**). Conserved motifs encoding RdRp and Hel are found in the same regions of these long ORFs. The genes encoding RdRp and Hel are structurally similar to those encoded by the ssRNA genome of members of the alpha-like supergroup of RNA viruses. Thus, the endornavirus RdRp and Hel probably function in the replication of the dsRNA genome, just as their homologs encoded by ssRNA viruses function in the replication of the ssRNA genome. Indeed, viral RdRp activity has been detected in plants containing OsEV or VfEV (to be discussed later).

The enzyme uridine diphosphate (UDP) glycosyltransferase (UGT) is commonly found in eukaryotes. This enzyme catalyzes the addition of the glycosyl

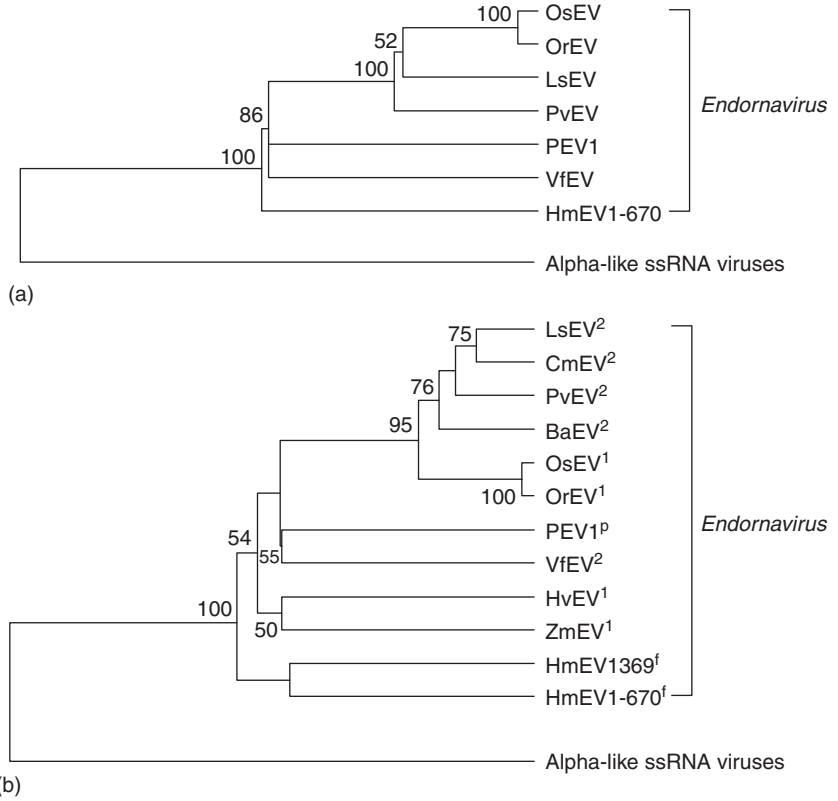

Figure 2 Phylogenetic positions of endornaviruses. (a) About 470 aa of the RdRp regions of seven endornaviruses and 10 alpha-like ssRNA viruses and (b) about 80 aa of the RdRp regions of 12 endornaviruses and 10 alpha-like ssRNA viruses were analyzed by using the ClustalX and MEGA2 (Molecular Evolutionary Genetics Analysis) programs, and the resulting neighbor-joining (NJ) trees are shown. A bootstrap test was performed with 100 resamplings. The hosts of endornaviruses are monocotyledonous plants (1), dicotyledonous plants (2), fungi (f), and a protist (p).

Table 1 Members in the genus *Endornavirus*

	Host	*Virus*	*Abbreviation*
Plant	Rice	Oryza sativa endornavirus	OsEV
	Wild rice	Oryza rufipogon endornavirus	OrEV
	Broad bean	Vicia faba endornavirus	VfEV
	Kidney bean	Phaseolus vulgaris endornavirus	PvEV
	Bottle gourd	Lagenaria siceraria endornavirus[a]	LaEV
	Barley	Hordeum vulgare endornavirus[a]	HvEV
	Malabar spinach	Basella alba endornavirus[a]	BaEV
	Melon	Cucumis melo endornavirus[a]	CmEV
	Seagrass	Zostera marina endornavirus[a]	ZmEV
Fungus	Violet root rot fungus	Helicobasidium mompa endornavirus 1–670	HmEV1–670
	Violet root rot fungus	Helicobasidium mompa endornavirus 1369[a]	HmEV1369
Protist	Phytophthora	Phytophthora endornavirus 1	PEV1

[a]Tentative member.

group from a UDP-sugar to a small hydrophobic molecule. UGTs have been identified in dsDNA viruses, including baculoviruses and nucleopolyhedroviruses from insects. In insect cells, the viral ecdysteroid UGT inactivates the molting hormones (ecdysteroids) of the host insect by sugar conjugation. Although a UGT gene has never been found in the genomes of the alpha-like supergroup of ssRNA viruses, it is found in strains of two hypoviruses (fungal dsRNA viruses), cryphonectria hypovirus 3 and 4 (CHV3 and CHV4). Amino acid sequences significantly similar to that of UGT are found in four of the five endornaviruses that have been sequenced in their entirety (**Figure 1**; they are not found in VfEV). Because the locations of the UGT motifs between the Hel and RdRp domains are conserved among the four endornaviruses, a common ancestor of the endornaviruses was likely to have also had a putative UGT gene. VfEV might have lost this gene during course of evolution, or a putative UGT gene encoded by VfEV might vary so much from other putative UGT genes that it was not identified as such. The functions of the putative UGT proteins in endornaviruses are unknown.

Because the single ORF of endornaviruses is very large (**Figure 1**), it very likely encodes several other proteins in addition to those already discussed. The ORF must encode a polyprotein, so it must also encode one or more proteinases to cleave the putative polyprotein into functional units (including RdRp, Hel, and UGT). A similar situation occurs in the potyviral genome, which contains a single large ORF encoding a polyprotein of more than 3000 aa residues; this also has proteinase activities which cleave the polyprotein into functional units. Furthermore, endornaviruses may encode an RNA-silencing suppressor, given that many other viruses contain this protein for protecting themselves against the host defense (RNA silencing) system.

Site-Specific Nick in the Coding Strand

All five endornaviruses that have been sequenced completely contain a site-specific nick in the 5′ region of the coding strand, which divides not only the coding strand but also the single long ORF (**Figure 1**). The biological implications of the nick remain unknown. However, it must affect at least two important steps in the life cycle of the endornavirus, because the divided coding strand can no longer be used as either a template for noncoding strand synthesis or an mRNA for translation of the putative polyprotein. The molecular mechanism that generates the nick is also unknown: an unknown endonuclease encoded by either the host genome or the endornavirus itself might cleave the coding strand site specifically. These two molecular features, the single long ORF and the site-specific nick, are unique, and have never been found in other known RNA viruses.

Inheritance (Vertical Transmission)

The transmission of endornaviruses relies essentially on cell division, and endornaviruses may survive in cooperation with their host cells. No horizontal spread has been observed in the field, and no potential vectors have been identified. OsEV-carrying plants and OsEV-free plants are found coexisting in the *japonica* rice cultivar Nipponbare, and these two isogenic lines cannot be distinguished on the basis of their appearance. Crossing experiments with OsEV-carrying and OsEV-free plants have indicated that the efficiency of OsEV transmission via pollen is more than 98%, and that of transmission via ova is 100%. Although OsEV is localized in the cytoplasm, it is transmissible to progeny plants via pollen as well as ova. Analyses of the F2 progeny plants of cv. Nipponbare indicated that the absence of OsEV is not associated with any particular gene(s) in the OsEV-free plants. The observed inheritance of OsEV is very different from that of other cytoplasmic genetic elements (e.g., chloroplasts and mitochondria), which are usually inherited only via egg cells. Thus, the propagation of OsEV, and probably other plant endornaviruses, may be entirely dependent

on seed-mediated transmission. The high efficiency of transmission of OsEV via both pollen and ova is likely to be responsible for the wide distribution of OsEV in cultivars of *japonica* rice.

OsEV has been found in many cultivars of *japonica* rice (*O. sativa*) but not in any cultivars of *indica* rice (a subspecies of *O. sativa*). *Japonica* and *indica* are distinguishable on the basis of their phenotype (e.g., grain shape) and genotype (e.g., the distribution of transposons in their genomes). To determine the reason why OsEV is not found in *indica* rice cultivars, reciprocal crosses between an OsEV-carrier *japonica* variety (cv. Nipponbare) and an OsEV-free *indica* variety (cv. IR 26 or Kasalath) were performed. When cvs. IR 26 and Nipponbare were used, efficient transmission of OsEV via ova (93%) and pollen (89%) was observed. However, when the Kasalath and Nipponbare cultivars were used, OsEV transmission efficiency to F1 progeny was 68% via ova and 20% via pollen, and transmission to F2 progeny plants also followed a complicated, non-Mendelian inheritance pattern. These results suggest that OsEV is unstable in *indica* rice plants, which may lack one or more genes that are involved in the maintenance (replication) of OsEV.

Because OsEV is efficiently transmitted to progeny plants via pollen, reciprocal crosses between cultivated rice (*O. sativa*, cv. Nipponbare) and wild rice (*O. rufipogon*, W-1714) were performed to introduce two evolutionarily related endornaviruses (OsEV and OrEV) into F1 progeny plants. Unusual cytoplasmic inheritance of these endornaviruses was observed in F1 hybrids: the evolutionarily related endornaviruses were incompatible, and in some F1 plants the resident OsEV of an egg cell from cultivated rice was excluded by the incoming OrEV from a pollen cell from wild rice. The two coexisting endornaviruses in some F1 hybrids segregated away from each other in the F2 plants. However, the total number of the two coexisting endornaviruses in the F1 hybrid cells remained constant relative to the number of endornaviruses in the parent cells (approximately 100 copies/cell). The stringent regulation of endornavirus copy number may be responsible for their unusual inheritance pattern. This phenomenon is similar to the plasmid incompatibility that occurs with two evolutionarily related DNA plasmids in *Escherichia coli*.

Copy Number Regulation of OsEV

OsEV is found in every tissue as well as at every developmental stage in its host plants. Regardless of the host rice cultivar, the relative concentration of OsEV in comparable cell types is approximately constant. A comparison of the relative amounts of OsEV and rice DNA (430 Mb per haploid genome) showed that there are approximately 100 copies of OsEV per cell. No significant difference in OsEV concentration was found between seedlings, roots, mature leaves, and stems. Crossing experiments indicated that a mechanism for stringent regulation of endornavirus copy number may exist in host rice cells.

A 14-kb dsRNA has also been found in another ecospecies of cultivated rice, the tropical *japonica* rice cultivars grown in the Philippines, which are also classified as *O. sativa*. A partial nucleotide sequence from the RdRp region of the dsRNA from cv. Gendjah Gempel (tropical *japonica* rice) has been determined, revealing that this sequence has already diverged from that of the dsRNA from cv. Nipponbare (temperate *japonica* rice from Japan). The dsRNAs from cv. Nipponbare (temperate *japonica* rice) and cv. Gendjah Gempel (tropical *japonica* rice) are hereafter referred to as OsEV-N and OsEV-G, respectively. Although the three dsRNAs (OsEV-N, OsEV-G, and OrEV) in the genus *Oryza* have already diverged from one another at the nucleotide sequence level, the copy number of each dsRNA genome in their respective host cells is almost identical (100 copies per cell).

In contrast, the number of endornavirus copies in cultured cells was found to be about 10 times that in the cells of seedlings; a similarly high level of OsEV has been observed in each culture established from an independent temperate *japonica* seed (cv. Nipponbare). Although no changes in the copy number of OsEV were found in suspension cultures over the course of 3 years, the copy number returned to the original low level in rice plants regenerated from the cultured cells. An approximately tenfold increase of OsEV-G and OrEV copy numbers also occurred in suspension cultures of cv. Gendjah Gempel (tropical *japonica* rice) and W-1714 (wild rice) seeds, respectively. Thus, the copy numbers of OsEV-N, OsEV-G, and OrEV are dependent on the physiological conditions of the host plant, and may be maintained by a similar regulatory system in each rice genotype.

The amount of OsEV-N, OsEV-G, and OrEV also increases about 50-fold in the pollen grains of the host plants relative to the rest of the plant. There is no evidence for the horizontal transmission of these endornaviruses, so their propagation seems to depend on steady replication before every host cell division (not only mitosis but also meiosis) and efficient transmission to the next generation via egg and pollen. An unregulated increase in the amount of endornaviruses in cells could result in disease or death of the host plant, as seen with conventional viruses. Conversely, a decrease in the number of endornaviruses could cause the virus to disappear from a host plant (germ cells). The mating of host plants must be an opportunity for endornavirus propagation. An increase in the endornavirus copy number only in pollen grains must be a strategy to ensure their transmission to host progeny, despite their cytoplasmic localization. Unlike almost all other viruses, endornaviruses are not able to transmit horizontally, but they are capable of vertical transmission, which the majority of viruses cannot do.

Replication (RdRp Activity)

In 1990, the RdRp activity of endornaviruses was reported from a study of dsRNA in the 447 male sterile strain of broad bean (VfEV). Purified cytoplasmic membranous vesicles containing the dsRNA (VfEV) had RdRp activity, which required Mg^{2+} ions and the four nucleotide triphosphates, and was unaffected by inhibitors of cellular DNA-dependent RNA polymerases (e.g., alpha-amanitin and actinomycin D). Treatment of the vesicles with a nonionic detergent released the VfEV dsRNA together with the RdRp, which retained specific activity for synthesis of VfEV dsRNA.

RdRp activity can also be detected in the crude microsomal fraction of cultured rice cells that contain OsEV. Like VfEV RdRp activity, this RdRp activity was also highest in the presence of all four nucleotide triphosphates and Mg^{2+} ions, and was resistant to inhibitors of DNA-dependent RNA polymerases. This RdRp activity increased approximately 2.5-fold in the presence of 0.5% deoxycholate. Treatment of the purified microsomal fraction with proteinase K plus deoxycholate suggested that the RdRp enzyme complex, with its own 14-kb RNA template, is located in vesicles. So far, RdRp activity has been found only in two endornavirus-containing plants, broad bean containing VfEV and rice containing OsEV. Therefore, the available data concerning endornavirus replication are limited. There is a need to identify and characterize the endornavirus-and/or host-encoded proteins that are involved in endornavirus replication.

Molecular Evolution of Endornaviruses

Endornaviruses have been found in two ecospecies of cultivated rice (temperate *japonica* rice cultivars in Japan and tropical *japonica* rice cultivars in the Philippines), both of which are classified as *O. sativa*. They have also been found in one strain (W-1714) of wild rice (*O. rufipogon*, an ancestor of *O. sativa*). A comparison of the nucleotide and deduced amino acid sequences of the core regions of the RdRp domains of these three endornaviruses (OsEV-N, OsEV-G, and OrEV) indicates that the three endornaviruses are evolutionarily related and that OsEV-N is evolutionarily closer to OsEV-G than to OrEV. The relationships between these endornaviruses are consistent with the evolutionary relationships between the host plants. Therefore, the endornaviruses found in the genus *Oryza* are likely to have been transmitted vertically through seeds at least since the time when *O. sativa* and *O. rufipogon* diverged from each other several thousand years ago. These endornaviruses have probably evolved independently within their own host plants, which have always generated self-pollinated progeny.

Similar evolutionary divergence of endornaviruses within host plants has been reported for the bottle gourd (*L. siceraria*) endornaviruses. Large dsRNAs (*Lagenaria siceraria endornavirus*) are found in several cultivars of bottle gourd, including three Japanese cultivars and two Western cultivars. Northern blot analysis of these endornaviruses from five cultivars indicated that these endornaviruses have evolutionarily diverged from each other within their host plants. Therefore, because of their plasmid-like properties, namely vertical transmission only, endornaviruses in rice and bottle gourd are thought to have evolved within their host plants.

However, as shown in **Figure 2**(**b**), the four endornaviruses in monocotyledonous plants (OsEV, OrEV, HvEV, and ZmEV) do not form a monophyletic group in the endornavirus phylogenetic tree. Similarly, the kidney bean endornavirus (PvEV) and the broad bean endornavirus (VfEV) do not cluster together, although their hosts both belong to the family Fabaceae Therefore, the phylogenetic relationships among these endornaviruses are not consistent with the phylogenetic relationships of their host plants. There are three possible explanations for these unexpected relationships between endornaviruses and their hosts. (1) Endornaviruses have speciated independently of their hosts. Several types of endornaviruses may have diverged before monocotyledonous and dicotyledonous plants diverged, and the families Poaceae (rice and barley) and Fabaceae (kidney and broad beans) now carry at least two independent lineages of endornaviruses. (2) The ancestors of endornaviruses were horizontally transmissible. (3) Some endornaviruses are horizontally transmissible, but horizontal transmissions occur only very rarely. The last two explanations may conceivably be possible, because the rare transmission events could have occurred during a sufficiently long time, over millions of years.

dsRNAs of various sizes are frequently found in plants, fungi, protozoans, and insects; in fact, dsRNAs (or dsRNA viruses) with plasmid-like properties can be considered to be widely distributed throughout all four eukaryotic kingdoms. Plasmid-like dsRNA replicons including endornaviruses and ssRNA viruses could have evolved from a common RNA replicon ancestor, in the process developing two different propagation strategies: ssRNA viruses became independent of the host cell (e.g., developed rapid replication of its genome RNA(s) and extracellular stability by encapsulation within a capsid protein), and dsRNA replicons developed a highly symbiotic relationship with the host cell (e.g., developed stringent copy-number regulation and efficient vertical transmission). dsRNA replicons have probably coevolved with their host cells to be symbiotic. Indeed, efficient vertical transmission and constant copy number are likely necessary to ensure the stability of the symbiotic relationship.

Introduction

The intestinal tract, lined by replicating epithelial cells, bathed in nutrient fluids and maintained at optimal temperature provides an ideal milieu for growth of many viruses. 'Enteric viruses' represent a wide spectrum of viral genera that invade and replicate in the mucosa of the intestinal tract, and that can be grouped as follows:

- viruses causing localized inflammation at any level of the intestinal tract, predominantly in small intestinal mucosa, resulting in acute gastroenteritis, for example, rotaviruses, caliciviruses, adenoviruses, astroviruses;
- viruses that multiply at any level of the intestinal tract, causing few enteric symptoms prior to producing clinical disease at a distant site, for example, measles virus, reoviruses (in mice) , enteroviruses (including polioviruses, coxsackieviruses, enteroviruses, hepatitis A and E); and
- viruses that spread to the intestinal tract during the later stages of systemic disease, generally in an immunocompromised host, for example, human immunodeficiency virus (HIV), cytomegalovirus.

This article focuses upon the first category of viruses that cause enteric disease associated with primary replication in the intestinal tract.

Viruses Associated with Acute Gastroenteritis

Acute gastroenteritis is one of the most common health problems worldwide. More than 700 million cases are estimated to occur annually in children less than 5 years of age, resulting in few deaths in developed countries, but more than 2 million deaths in developing countries.

Worldwide, a diverse group of viral, bacterial, and parasitic pathogens cause acute enteric symptoms including nausea, vomiting, abdominal pain, fever, and acute diarrhea. Infections with viral agents, unlike those with bacterial or parasitic pathogens, cannot be treated with antibiotics, and many cannot be prevented by improvements in quality of drinking water, food, or sanitation.

Until the early 1970s most viral agents causing gastroenteritis in humans were largely unknown. Studies using electron microscopy of intestinal contents resulted in the discovery of numerous viral enteropathogens now classified as caliciviruses, rotaviruses, astroviruses, or 'enteric' adenoviruses. Caliciviruses are now recognized as the most important cause worldwide of outbreaks of viral gastroenteritis in humans of all age groups. Rotaviruses are the single most important cause of life-threatening diarrhea in children <5 years old. Astroviruses and adenoviruses also cause severe diarrhea in children. **Table 1** lists the characteristics of the major viruses associated with acute gastroenteritis. Other viruses linked to gastroenteritis in humans include coronaviruses, toroviruses, picornaviruses, and picobirnaviruses. Understanding many features of these 'enteric viruses' has been based on parallel studies of related viruses infecting animals.

Caliciviruses

History

The family *Caliciviridae* contain small RNA viruses that cause enteric disease in a wide variety of hosts including cattle, pigs, rabbits, and humans. Infections in other hosts, for example, sea lions, cats, and primates, appear to cause predominantly systemic and respiratory symptoms. Caliciviruses are small nonenveloped viruses of 27–35 nm diameter (**Figure 1**) with a genome comprising

Table 1 Characteristics of major enteric viruses causing acute gastroenteritis in humans

Characteristic Family	*Norovirus/ Sapovirus Caliciviridae*	*Rotavirus Reoviridae*	*Adenovirus Adenoviridae*	*Astrovirus Astroviridae*
	Divided into genogroups, each with distinct genetic clusters	Six groups (A–F) Group A-multiple serotypes based on outer capsid proteins.	Six subgenera, more than 50 serotypes Enteric serotypes (Ad40–41)	Eight serotypes
Virion size (nm)	28–35	70	80	28
Capsid organization	Two structural proteins (orf2–56–62 kDa, orf3–22 kDa)	Two outer capsid proteins (VP7–38 kDa, VP4–88 kDa) Two inner protein layers (VP6–41 kDa, VP2–88 kDa)	Capsomer – composed of three proteins: hexon, penton, and fiber.	Precursor cleaved into several proteins (e.g., 20 kDa, 29 kDa and 31 kDa)
Nucleic acid	ssRNA (plus sense)	dsRNA	dsDNA	ssRNA (plus sense)
Genome organization	Three open reading frames (1, 2, and 3)	11 segments which encode specific protein.	Linear chromosome with multiple transcription/ translation units	2 open reading frames (1a, 1b, and 2)

ss, single-stranded; ds, double-stranded; kDa, kilodalton.

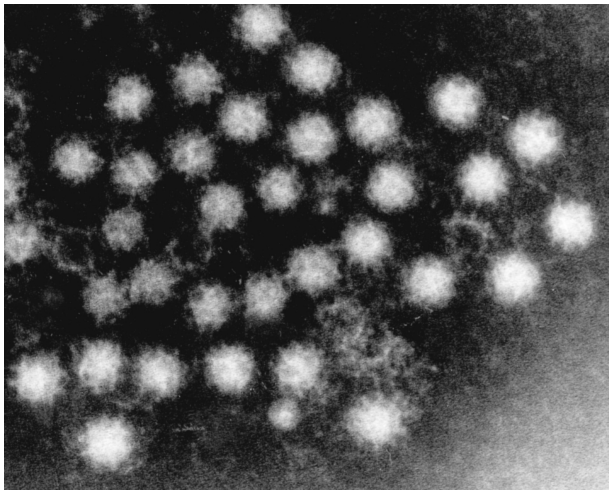

Figure 1 Electron micrograph of negatively stained calicivirus particles (NoV) in fecal extract.

a single-stranded positive-sense polyadenylated RNA genome of 7400–7700 nucleotides (nt). Typical calicivirus particles show cup-like hollows (calices) on the virus surface. Some caliciviruses have an indistinct appearance described as 'feathery'.

The 'Norwalk agent' (now classified as a calicivirus) was identified in 1972 by Kapikian and colleagues, using immune-electron microscopy (IEM) to search for the causative agent of an 1968 outbreak of gastroenteritis in humans in Norwalk, Ohio, USA. Many related viruses have been implicated as causes of gastroenteritis, and given names identifying the geographical location of the outbreak (e.g., Marin County, Snow Mountain, Hawaii, Sapporo).

Classification

Classification of caliciviruses was hampered for many years by the inability to culture these viruses, and study their genetic and protein structure. Caliciviruses causing enteric infections (in humans and other animals) are classified as belonging to the family *Caliciviridae*, which is divided into four genera. The genus *Norovirus* (NoV), and genus *Sapovirus* (SaV) cause human and animal infections. Other genera infect rabbits (*Lagovirus*) or sealions, cats, and primates (*Vesivirus*). The genome organization and reading frame usage differs between the four genera. For noroviruses, the genome contains three open reading frames (ORFs). The largest (ORF1) encodes a polyprotein which undergoes proteolytic cleavage to produce an NTPase, a 3c-like protease, and an RNA-dependent RNA polymerase (RdRp). ORF2 encodes the major capsid protein and ORF3 a putative minor capsid protein.

Noroviruses are subdivided into five genogroups (GI–GV). Genogroups GI, GII, and GIV infect humans, GIII infects cattle and GV infects mice. GI and GII contain at least 10 and 20 distinct genetic clusters, respectively. Sapoviruses are divided into genogroups (GI–GV), of which GI, GII, GIV, and GV infect humans. GI and GII are further divided into four and three genetic clusters.

The inability to culture human caliciviruses delayed the introduction of diagnostic tests, resulting in an under-appreciation of the significance of these agents for many years. Currently, over 20 different reverse transcription-polymerase chain reaction (RT-PCR) assays targeting regions on the RdRp gene and the capsid gene have been described and utilized in epidemiological studies. This large genetic diversity of human caliciviruses makes routine detection difficult.

Geographic and Seasonal Distribution

Human NoV are the leading causes of 'nonbacterial gastroenteritis' outbreaks in all age groups worldwide. Outbreaks frequently occur in communities such as

nursing homes, hospitals, schools, and cruise ships. No consistent seasonal variation has been observed. Infection involves transmission via person-to-person contact or ingestion of contaminated food and water.

Epidemiological studies have identified caliciviruses in 60–95% of outbreaks in many countries. Estimates of disease burden in USA suggest that caliciviruses are responsible annually for 23 million illnesses and 50 000 hospitalizations. Strains of NoV GII cluster 4 (GII-4) have been the most common type identified worldwide in the past 5 years (2001–2005) in both adults and children. Prevalence rates of calicivirus (predominantly NoV) in young children admitted to hospital with acute gastroenteritis in many countries range from 3.5% to 20% annually. Strains of SaV, while playing a minor role overall, are more generally associated with childhood gastroenteritis than with disease in older children and adults. Caliciviruses may be important enteric pathogens in patients with hereditary or acquired immunodeficiency.

Genetics

The genera *Norovirus* and *Sapovirus* are genetically diverse, and multiple strains co-circulate in human populations. Individual dominant strains emerge every 2–5 years, and often have a global impact, such as the GII-4 strains identified in USA, Europe, Japan, and Australia in 1995/1996 and again in 2004. NoV recombinant strains, with polymerase and capsid genes derived from different ancestral clusters, have been identified in Thailand and Australia. Repeated attempts to adapt NoV and SaV to growth in cell culture have failed. Diagnostic techniques and analysis of antigenic variation rely predominantly on molecular biological techniques. Cloning and expression of the major viral capsid protein (VP1) in baculovirus expression systems has led to the formation of virus-like particles (VLPs) morphologically similar to native virus and their incorporation into enzyme immunoassay (EIA) assays.

Pathogenesis

Pathogenesis of NoV and SaV infection is poorly understood as a result of the long-standing inability to adapt these viruses to cell culture, and the absence of a small animal model. Symptomatic enteritis in human volunteers infected with 'Norwalk agent' showed changes in jejunal biopsies (mucosal inflammation, absorptive cell abnormalities, villus shortening, and crypt hypertrophy) that persisted for at least 4 days after remission of clinical symptoms and reverted to normal after 2 weeks. No identifiable viral particles were detected by electron microscopy in any affected intestinal tissue. The recent demonstration that human noroviruses can infect and replicate in a three-dimensional cell culture model of human intestinal epithelium, should improve our understanding of the pathogenesis, and antigenic diversity of this important group of enteric viruses. These studies will also be enhanced by discovery of a norovirus that infects mice, and that replicates after transfection of cultured kidney cells.

Immune Responses, Prevention and Control

Mechanisms of immunity to NoV are unclear. Infection results in formation of IgG and IgM serum antibody that are broadly reactive within, but not between, genogroups. The role of these antibodies in immune protection is unknown. Infected individuals can develop short-term immunity to homologous viruses but the molecular diversity of NoV circulating in communities makes it difficult to predict whether long-term immunity can develop. It is unclear why a proportion of exposed individuals remain uninfected during outbreaks. Recent studies suggest that histo-blood group antigens and the secretor status may be genetic susceptibility markers for infection. At present the major control strategies for prevention of human calicivirus infection rely on prevention of contamination of food and water supplies.

Rotaviruses

History

Virus particles, later classified in the genus *Rotavirus*, were first described in 1963 by Adams and Kraft as a cause of epidemic diarrhea in infant mice (EDIM). Similar particles (NCDV) were recognized in 1969 by Mebus and colleagues as a cause of severe diarrhea in newborn calves in Nebraska, USA. Neither virus was considered relevant as a causative agent of severe diarrhea in young children until 1973 when Bishop, Davidson, Holmes, and Ruck described a 'new virus' (later shown to be antigenically related to EDIM and NCDV) in duodenal biopsies and diarrheal feces from young children admitted to hospital in Melbourne, Australia with severe acute diarrhea. Named because of their wheel-like appearance in negatively stained extracts examined by electron microscopy (rota = Latin for wheel) rotaviruses have since become established as causes of severe acute diarrhea in the young of many mammalian and avian species worldwide. Rotavirus enteritis affects all children regardless of socioeconomic status, and results in over 600 000 deaths annually in young children in developing countries.

Classification

Rotaviruses are nonenveloped icosahedral viruses of 70 nm (**Figure 2**) diameter that belong to the genus *Rotavirus*

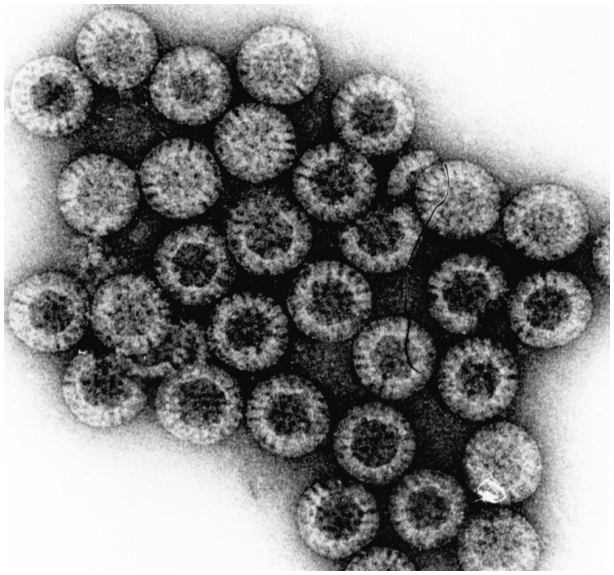

Figure 2 Electron micrograph of negatively stained triple-shelled rotavirus particles in fecal extract.

within the family *Reoviridae*. The double-stranded RNA genome is contained within a triple-layer of viral proteins (VPs) comprising a core (VP1, VP2, VP3), an inner capsid (VP6), and an outer capsid (VP4, VP7). Rotaviruses are classified into groups A to G based on serology of the VP6 protein. The majority of human and mammalian infections, due to group A viruses, are further classified into serotypes by antigenic differences on VP7 (G-serotypes) and into genotypes by genetic differences on VP4 (P-genotypes). To date there are at least 11 of 15 G-serotypes and 15 of 26 P-genotypes identified in humans. Groups B and C have been identified infrequently in humans. Groups D to G have been identified only in nonhuman mammalian or avian species.

Geographic and Seasonal Distribution

Five rotavirus serotypes G1P[8], G3P[8], G4P[8], G2P[4], and G9P[8] have been the most common serotypes causing severe human disease globally during the past 30 years. G1P [8] strains have been consistently present worldwide. Yearly winter epidemics of rotavirus disease are regularly observed in countries with temperate climates, whereas rotavirus disease is prevalent year-round in tropical climates lacking defined winter seasons.

Host Range

Group A rotaviruses infect humans and other mammals repeatedly throughout life. Most primary rotavirus infections in animals occur during the neonatal period. Most primary rotavirus infections in humans occur during the first 24 months of life. Children worldwide will experience at least one rotavirus infection by 5 years of age.

In general, group A rotaviruses are species specific. However, rotavirus strains with gene segments of feline, bovine, or porcine origin have been isolated from children, suggesting the occurrence of cross-species infection in nature. Cross-species infections can be established experimentally, and comprise one of the strategies for human vaccine development.

Genetics

The rotavirus genome consists of 11 segments of double-stranded RNA that can be separated by polyacrylamide gel electrophoresis, allowing epidemiological studies mapping the genetic diversity of strains within and between serotypes. Each gene segment encodes a separate protein, with the exception of gene segment 11 which encodes two proteins. Reassortment of genes between human strains and human and animal strains occurs *in vivo* and *in vitro*.

Pathogenesis

Rotaviruses are transmitted from person to person by the fecal–oral route, or via aerosols. Rotaviruses replicate in the cytoplasm of mature nonreplicating enterocytes lining the upper portions of the small intestinal villi, eventually causing cytolysis. Profuse watery diarrhea results from a combination of mechanisms including malabsorption secondary to loss of enterocytes responsible for absorption and digestion, activation of the enteric nervous system, and stimulation of intestinal secretion by the rotavirus nonstructural protein NSP4. Rotavirus antigenemia and viremia occur during the acute phase of severe primary rotavirus disease. As a result, complete rotavirus particles have been found in liver, lung, spleen, pancreas, thymus, and kidneys of experimental animals. It is not clear if the virus is replicating at these sites.

Clinical Features

Clinical symptoms in children are strongly influenced by age, with severe often life-threatening diarrhea occurring after primary infection in young children, and in aged people in nursing homes. Excretion of rotavirus particles in detectable numbers (by EIA, RT/PCR) continues for 5–10 days, and occasionally up to 50 days. Excretion can continue for months in immunodeficient children and animals. Reinfections occur throughout life, and are usually asymptomatic or associated with mild symptoms. Symptoms of primary infection require medical attention in 1:5 children, result in hospitalization in 1:65 children and death in 1:293 (almost all in young children in developing countries). Treatment is based upon replacement

of fluid and electrolyte loss, usually achieved by oral administration of fluids containing glucose and electrolytes. Occasionally, delayed repair of the small intestinal mucosa is associated with disaccharide or monosaccharide malabsorption leading to malnutrition.

Immune Response/Prevention and Control

Primary rotavirus infection protects against severe symptomatic disease on reinfection, and is associated with humoral and cellular immune responses to individual rotavirus proteins. Neutralizing antibody to VP4 and VP7 outer capsid proteins contribute to protection, possibly by interfering with viral replication and limiting the extent of intestinal damage. The role of immune responses to other proteins is uncertain. Virus-specific cytotoxic T cells are not essential for protection.

The importance of rotavirus disease worldwide and its contribution to childhood mortality in developing countries has resulted in strong initiatives, supported by the World Health Organization, to develop live oral rotavirus vaccines to be administered to infants before 3 months of age. Two contrasting vaccines, a single attenuated G1P[8] human rotavirus and a pentavalent human–bovine G1-G4,P[8] reassortant vaccine, have been proved to be safe and effective in preventing severe rotavirus disease. Both have the potential to radically change global childhood mortality and morbidity.

Adenovirus

History and Classification

Adenoviruses were first detected in 1953 in cultured fragments of tonsillar and adenoidal tissue from children. They are nonenveloped icosahedral viruses approximately 80 nm in diameter (**Figure 3**). The genome is composed of double-stranded DNA. The family *Adenoviridae* comprises three genera: *Mastadenovirus* (mammalian) classified into subgenera A–F representing more than 50 serotypes, *Aviadenovirus* (birds), and a newly recognized genus *Atadenovirus* identified in sheep and reptiles. Most are readily cultivatable. Adenovirus infections occur worldwide in many mammalian species, are species specific, usually associated with disease in the respiratory, urinary, and ocular systems, and are frequently shed in feces in the absence of any gastrointestinal symptoms.

In 1975, Flewett and colleagues in Birmingham, UK, noticed the presence of large numbers of adenovirus particles in negatively stained extracts of diarrheal stools examined by EM. These proved difficult to culture, were designated 'enteric' adenoviruses (EAd), and are now classified as serotypes EAd40 and EAd41 within subgenus group F. Cultivation of EAd remains difficult. The most reliable growth has been achieved in human embryonic kidney cells (293 cells) immortalized by transfection with regions of Ad5.

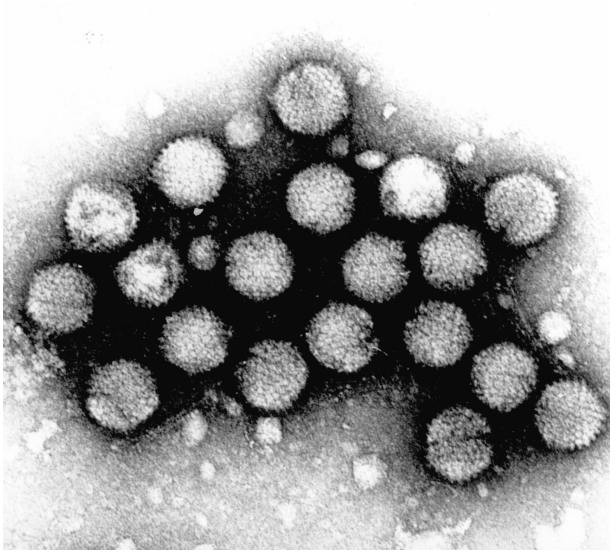

Figure 3 Electron micrograph of negatively stained 'enteric' adenovirus particles (showing characteristic hexagonal shape) in fecal extract. Courtesy of professor M. Studdert.

Geographic and Seasonal Distribution

EAd40 and EAd41 occur worldwide, causing severe acute enteritis in 5–15% of hospitalized young children. Outbreaks occur at unpredictable intervals year-round with no seasonal prevalence. Nosocomial epidemics occur in day-care nurseries and in hospital wards for children and adults. Group A adenoviruses (serotypes 12, 18, 31) have also been implicated in epidemics, usually in older age groups.

Genetics/Evolution

The adenovirus virion is composed of at least 10 different structural polypeptides and contains a linear 33–45 kbp DNA. Virus capsomers are arranged as hexons, the corners of which have antenna-like (fiber) projections presumed involved in cell attachment. The DNA genomes of groups A–F are genetically diverse, and differences can be illustrated by analysis using genome restriction endonucleases. The heterogenous genome in groups A–F makes recombination between subgenera unlikely, with exception of groups A and F which show a close evolutionary relationship.

Diagnoses of EAd infection rely on EIA that detects the hexon antigen common to groups A–F, followed by determination of restriction enzyme patterns and/or reactions in EIA incorporating neutralizing, monoclonal antibodies specific for Ed40 and 41.

Pathogenesis

EAd replicate within the epithelial cells of the small intestine. Group A adenoviruses have also been grown from mesenteric lymph nodes and appendices. The mechanisms causing diarrhea are not clear, but destruction of infected epithelial cells has a role.

Clinical Features

Adenovirus diarrhea is more common in infants <12 months old than in older children, and can be protracted with a mean duration of 12 days. Adenovirus diarrhea occurs in immunocompromised patients. Nonseasonal epidemics of EAd diarrhea occur in hospital wards, orphanages, and day-care nurseries. Occasional fatal cases have been reported in children. Evidence from animal models (with non-EAd) suggests that viremia occurs, and can lead to infection of other tissues. The natural history of disease and development of immunity is unknown.

Astroviruses

History and Classification

Astroviruses were first described in the UK in 1975 by Madeley and Cosgrove studying an outbreak of diarrhea in newborn babies in an obstetric hospital nursery. Astroviruses are small, round nonenveloped plus-stranded RNA viruses 28–30 nm diameter (**Figure 4**) occasionally exhibiting virions with a superficial star shape. They are members of the genus *Astrovirus* in the family *Astroviridae*. They have been detected in humans (children and adults) and a range of mammalian (sheep, cattle, pigs, dogs, cats, and mice) and avian (turkeys, ducks) species, usually associated with diarrhea. There are currently eight serotypes of human astrovirus, designated HAstV 1–8, based on reactivity with polyclonal antisera. HAstV 1 is most common worldwide.

Prevalence rates as a cause of diarrhea vary from 2% to 16% (hospital-based studies), and 5% to 17% (community-based studies). Most astrovirus infections have been recorded during colder months in temperate climates and year-round in tropical countries. A longitudinal study in Mayan children in a poor community in Mexico found a high prevalence (61%) of astrovirus infection in a birth cohort of 271 children followed for 3 years. Infection occurred primarily in infants <12 months old, and showed a high rate of asymptomatic infection and prolonged shedding (2–17 weeks) in many infants. Astrovirus infection has also been associated with persistent diarrhea (lasting for 14 days or more) in children in Bangladesh. Astroviruses are widespread in developed countries, causing outbreaks in day-care centers, hospitals, and nursing homes for the elderly. They are an important cause of enteritis in immunocompromised patients.

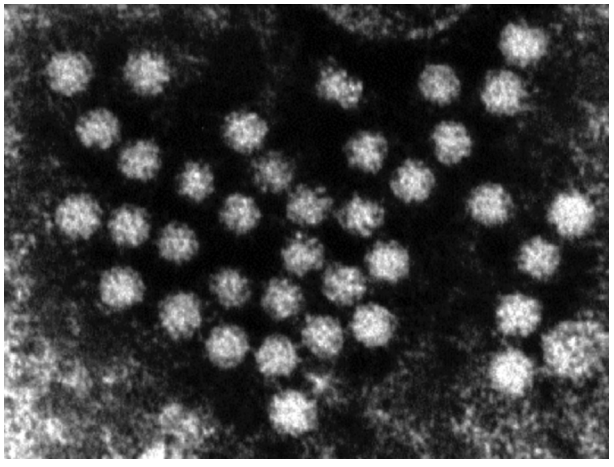

Figure 4 Electron micrograph of negatively stained astrovirus particles (showing star-shape) in fecal extract.

Genetics and Evolution

The HAst genome is a polyadenylated plus-stranded RNA molecule of approximately 7 kbp. The genome contains two open reading frames (ORFs), ORF1a and -1b, code for nonstructural proteins and ORF2 encodes for the capsid protein. Genetic diversity in all serotypes exists, but no association has been shown between serotypes and ability to cause severe gastroenteritis. Astrovirus diagnostic assays include commercially available EIA kits, electron microscopy and RT-PCR detection and genotyping of diarrheal feces.

Pathogenesis

Acute astrovirus infection induces a mild watery diarrhea in young children that lasts for 2–3 days and may be associated with vomiting, fever, and anorexia. The lack of a small animal model has hampered studies of the mechanism of astrovirus-induced diarrhea. Experimental models of astrovirus enteritis in turkeys and in gnotobiotic lambs show mild histopathological changes in the intestine (despite high mortality from severe osmotic diarrhea) together with viremia. Experimental astrovirus infection in calves is asymptomatic, with viral replication apparently targeted to M cells. It is possible that none of these animal models illuminate pathogenesis of HAstV infection in humans. Cultivation of HAstV was initially difficult, but can now regularly be achieved using a human colon cancer derived epithelial cell line (CaCo2 cells).

Coronaviruses/Toroviruses

Members of the genera *Coronavirus* and *Torovirus* are enveloped plus-strand single-stranded RNA viruses belonging to the family *Coronaviridae*. Electron microscopy shows them to be pleomorphic fringed particles 100–140 nm at maximum dimension (**Figure 5**). Coronaviruses and toroviruses can be distinguished by differences in peplomer structure and reaction in IEM using specific antisera.

Coronaviruses and toroviruses cause diarrhea, respiratory, and/or hepatic disease in many animal species, including cattle, mice, swine, cats, and dogs. In general, most of these viruses are species specific and disease is most severe in infant animals. Transmission is fecal–oral and due to virus lability may require close contact. Coronaviruses and toroviruses have been implicated in human diarrheal disease but there is still no consensus about their importance. Similar particles have been seen frequently in children without diarrhea, particularly in children in developing countries. Morphological similarities between these viruses and fragments of intestinal brush border make diagnosis difficult. Several studies have implicated coronaviruses as causative agents of necrotizing enterocolitis outbreaks in newborn babies.

Toroviruses were first described as a cause of diarrhea by Woode and colleagues in 1979 when Breda virus was identified in a severe outbreak of neonatal calf diarrhea in USA. Toroviruses are now also known to infect horses (Berne virus) and swine. Human infections were first described by Flewett *et al.* in Birmingham UK in 1984, but have rarely been reported since then.

The pathogenesis of diarrhea has been studied in animal models using infection with coronavirus (TGE) in piglets, and with Breda viruses in calves. Both replicate in epithelial cells of small intestine and descending colon causing diarrhea 24–72 h later. Breda virus also replicates in crypt cells.

Many animal coronaviruses can be propagated in cell culture. Isolation of human enteric coronaviruses is difficult and serological studies can be confounded by antibody resulting from repeated respiratory coronavirus infection. Enteric infection can be confirmed in feces by detection of viral RNA by RT-PCR, or IEM using antibodies to the viral envelope glycoproteins.

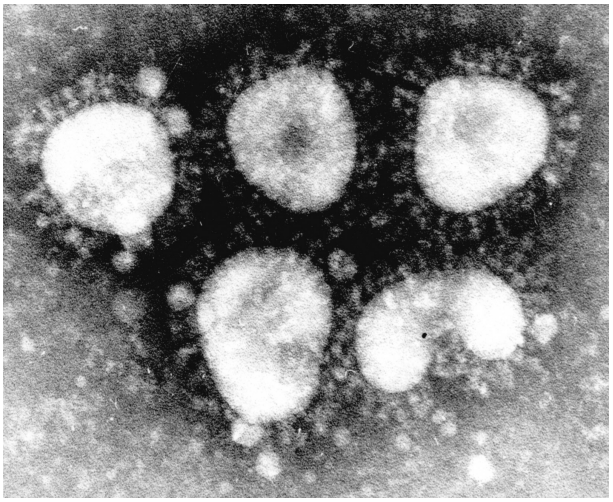

Figure 5 Electron micrograph showing large fringed pleomorphic coronavirus particles (with adherent antibody) in fecal extract.

Picornaviruses

Picornaviruses are 24–30 nm featureless spherical particles containing single-stranded positive-sense RNA. They have been found in diarrheal feces from humans but their etiological role is often not clear. The first clear evidence implicating a picornavirus as an enteric pathogen identified Aichi virus, as a cause of oyster-associated epidemics of gastroenteritis in Japan in 1989. Aichi viruses are now classified as a new genus *Kobuvirus* within the family *Picornaviridae* (kobu = Japanese for knob). Isolation of Aichi virus in Vero cells has permitted development of EIA and RT-PCR assays based on nucleotide sequence data. Serological assays show seroconversion resulting from infection and a prevalence rate for antibody of 7.2% in Japanese children aged 7 months to 4 years and rising to 80% in adults by age 35.

The new genus *Parechovirus* within the family *Picornavirideae* contains at least one serotype (previously echovirus 22) that has been implicated as an enteric pathogen in humans.

Parvoviruses

Parvoviruses are small 22–26 nm single-stranded DNA viruses comprising a genus *Parvovirus* in the family *Parvoviridae*. Some animal parvoviruses have been clearly linked to enteritis including bovine, feline, mink, and canine strains. Canine parvovirus infection emerged after 1977. This lethal neonatal enteric infection, accompanied by viremia and widespread systemic infection, shows a pathogenesis distinct from most enteropathogenic viruses. The virus infects and destroys crypt epithelial cells resulting in flat mucosa with fused and stunted villi. Damage has been likened to that caused by radiation.

Other small viruses, resembling parvoviruses, have been seen by EM in diarrheal feces in humans. Evidence linking them to causation of disease is not convincing. They have often been present as dual infections with known enteric pathogens. In addition, their resemblance to some phages makes diagnosis uncertain.

Picobirnaviruses

These are a group of currently unclassified small viruses detected in the feces of humans and animals without diarrhea. Picobirnaviruses are 35–41 nm particles with a bi- or tri-segmented dsRNA genome and have been detected in Europe, South America, and Australia. They are found significantly more often in patients with HIV-related diarrhea than those without diarrhea. Their role in gastroenteritis in healthy individuals remains unknown.

Enteroviruses of Animals

L E Hughes and M D Ryan, University of St. Andrews, St. Andrews, UK

© 2008 Elsevier Ltd. All rights reserved.

Introduction

In the 1950s, the use of monkey kidney cell cultures for the growth of poliovirus revealed the presence of simian viruses and further study showed some of these to have properties consistent with enteroviruses. In parallel, investigations of viruses infecting domestic animals also revealed the presence of enteroviruses (and enterovirus-like particles) in pigs and cattle. Enteroviruses have since been isolated from African buffalo, water buffalo, sheep, goat, deer, and impala and many have been shown to be related to bovine enterovirus isolates.

In the past, the classification of enteroviruses was primarily based upon the physico-chemical properties of virions, growth in tissue-cultured cell lines, and by serotyping. In practice, this can be difficult with some isolates being poorly recognized by the reference antisera, or, the occurrence of (misleading) cross-reactivities between serotypes. The expansion of the sequence database together with more sensitive cloning/sequencing techniques have facilitated the elucidation of the genome structures of many picornaviruses. Such analyses have replaced other techniques in the classification of picornaviruses, and this article discusses characteristics which are important for the classification of animal enteroviruses.

Animal Enteroviruses

Bovine Enteroviruses

Bovine enteroviruses (BEVs) are endemic in cattle in many regions of the world with infection typically

asymptomatic and apparently healthy animals acting as carriers. There has, however, been some association of BEVs with diarrhoea and abortion. Studies in Spain have shown that BEV is widespread and variants co-circulate in cattle around the country, with the virus less prevalent in cattle from extensive farms (69%) than in cattle from intensive farms (94%). Analysis of samples collected from a farm in the USA indicated that the virus was present in the spring in 2–4-month-old calves but that the infection had probably been cleared by summer.

Recently, it has been shown that infectious virus particles are present in water from animal watering tanks, pastures, and streams/rivers in regions where BEVs are endemic, demonstrating the ability of these viruses to survive in aqueous environments. Interest in these viruses has widened over recent years with proposals that they can be utilized as markers for fecal contamination of the environment. BEVs have also been proposed as surrogate viruses for evaluating FMDV contamination of farms and the evaluation of extraction/detection techniques.

Porcine Enteroviruses

Historically, the more economically significant diseases of pigs caused by the porcine enteroviruses (PEVs) included neurological disorders (Teschen/Talfan disease), fertility disorders, dermal lesions, pneumonia, and diarrhoea. With the major reappraisal of the taxonomy of these viruses, these diseases are now associated with the teschoviruses (see below).

Swine Vesicular Disease Virus

Swine vesicular disease virus (SVDV) causes a highly contagious disease of pigs that spreads rapidly through contact with infected pigs and a contaminated environment. The disease is variable from mild or subclinical infections to lesions on the snout and feet that are indistinguishable from those caused by FMDV. For this reason, routine surveillance of SVDV is maintained in European countries.

SVDV was first described in Italy in 1966 and since then, numerous outbreaks have occurred throughout Europe and Asia. SVDV was largely eradicated from Europe during the 1970s and 1980s, but a new strain, possibly originating in the Far East, entered Europe during 1992. This strain spread to the Netherlands, Belgium, Portugal, Spain, and Italy. In 2003–04, clinical outbreaks were only reported in Portugal (leading to the slaughter of 2168 pigs) while subclinical infections are continuously detected in southern Italy. A long-term study of pigs infected with a recent Italian isolate showed the vRNA and virus could be detected long after the initial infection, and provided good preliminary evidence that this virus can establish persistent infections.

Simian Enteroviruses

Many simian viruses – including enteroviruses – were isolated from a range of nonhuman primate tissue-cultured cells used in biomedical research and vaccine development and from primates used for biomedical research. Twenty enterovirus serotypes were defined, with cross-reactivity in some cases. All these isolates were, however, distinct in that they did not show cross-reactivity with the (then) known human enteroviruses. Very little is known about the pathogenesis of these viruses. Simian enterovirus A (A-2 plaque virus) was isolated from a human, but caused viremia in tamarin monkeys 1–2 weeks post inoculation. Virus could not be detected in fecal samples.

'Animal' versus 'Human' Enteroviruses

Viruses of the genus *Enterovirus* of the family *Picornaviridae* primarily cause infections of the gastrointestinal tract, where large numbers of progeny virions are produced and shed in the feces. The virus particles are stable in a wide range of pH, temperature, and salinity conditions and may remain infective in the environment for long periods.

A number of viruses formerly thought to be enteroviruses are now known to be members of other genera. Presently, those animal viruses assigned to the enteroviruses include SVDV, BEV-1 and -2, and PEV-9 and -10.

Currently five human and three animal species comprise the genus *Enterovirus*. The separation of the genus into human and animal species is not as clear as in the past. Nucleotide sequence and serological data strongly suggest that some viruses have passed from man to domestic animals, or vice versa. For many years, SVDV was known to have a close relationship with human coxsackievirus B5 (CBV-5) and, indeed, this animal enterovirus is now classified in the species *Human enterovirus B* (HEV-B). The antigenic and molecular relationships between the two viruses suggest that CBV-5 crossed from humans to pigs – probably in the early 1950s – and has since adapted to the new host.

Another human enterovirus, type 70 (EV70; spp. *Human enterovirus D*) first appeared in humans in 1969 causing widespread outbreaks of acute hemorrhagic conjunctivitis. In a small proportion of cases (1:10 000–1:17 000), this generally benign ocular infection was accompanied by a disease with a presentation very similar to poliomyelitis. Interestingly, studies on animal sera collected prior to the human outbreaks showed the presence of anti-EV70 antibodies in cattle, sheep, swine, chickens, goats, dogs, and wild monkeys. EV70 disappeared from the human population in the 1980s, but the data suggest that this human disease was the result of a zoonosis.

Recent sequence analyses of simian enteroviruses has shown that some of these viruses are closely related to

viruses within the species *Human enterovirus A*, while others are proposed as new members of *Human enterovirus B*. It is not surprising, therefore, that the present 'human' enterovirus classification scheme contains several animal viruses.

Genome Structure and Classification

The classification of picornaviruses has been in a state of flux for a number of years. Originally classification was based on serological, pathogenic and biophysical properties, but now genome structure is paramount. In some instances, such analyses confirmed previous classifications, while in others reclassification occurred – either by simply renaming, regrouping, or, more fundamentally, by the formation of new genera.

Entero- and Rhinovirus Genome Structures

Briefly, a viral protein (VPg), is covalently linked to the 5′ end of the genome and followed by a nontranslated region, the 5′ NTR (**Figure 1(a)**). A single, long, open reading frame (ORF) encodes a polyprotein of ~2200 aa. The N-terminal domain of the polyprotein (P1) comprises the four capsid proteins, while the replicative proteins comprise the central domain (P2) and C-terminal domain (P3) of the polyprotein. The full-length translation product predicted by the single ORF is not observed within infected cells due to rapid, intramolecular, proteolysis by the two virus-encoded proteinases, $2A^{pro}$ and $3C^{pro}$ (**Figure 1(a)**). The P1, P2, and P3 'primary' cleavage products subsequently undergo proteolytic processing to yield the individual virus proteins. After the stop codon, there is a short 3′ NTR and a poly(A) tail (**Figure 1(a)**).

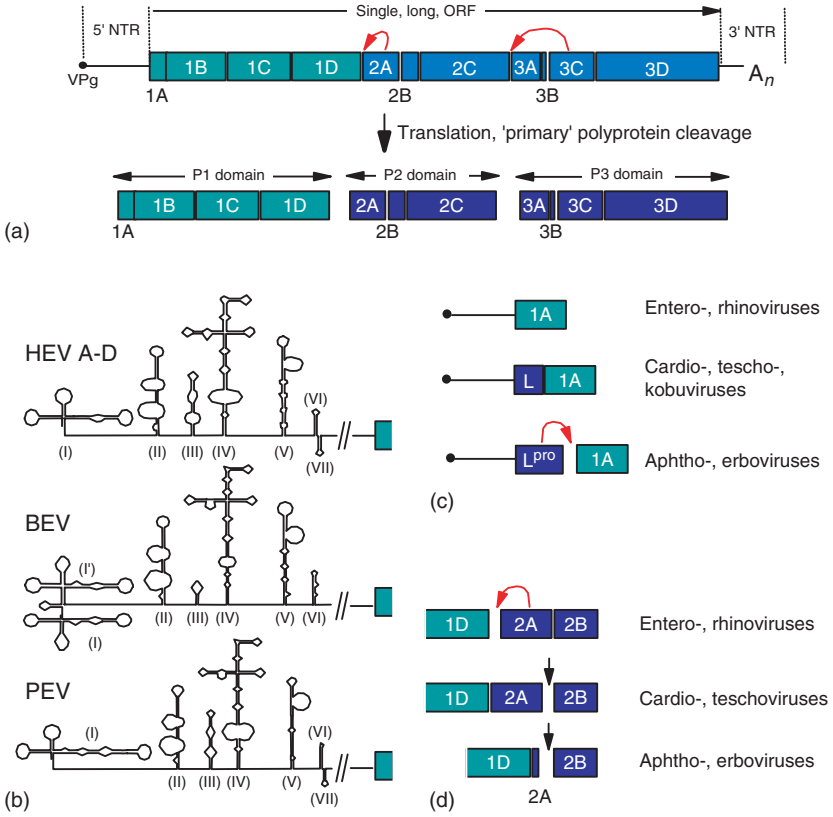

Figure 1 Enterovirus genome organization. The oligopeptide VPg (3B) is covalently attached to the 5′ terminus of vRNA. The long 5′ nontranslated region (5′ NTR) precedes the single, long, ORF (boxed area). The polyprotein comprises three domains: the capsid proteins precursor (P1; green boxed areas) and the nonstructural replication protein domains P2 and P3 (blue boxed areas). The 3′ portion of the genome comprises a short 3′ NTR and a poly(A) tail. The 'primary' (cotranslational) cleavages of the polyprotein mediated by the 2A and 3C proteinases are shown (red curved arrows) (a). The type 1 IRES RNA secondary structural features together with the individual domain features (I–VII) are shown for *Human enteroviruses A–D* (HEV A–D), bovine enterovirus (BEV), and porcine enterovirus (PEV) (b). In the case of enteroviruses, the N-terminal portion of the polyprotein is the capsid protein 1A (VP4), whereas in cardio- and teschoviruses, for example, the polyprotein starts with an L protein. Aphtho- and erbovirus polyproteins commence with an L proteinase (L^{pro}) which cleaves at its own C-terminus (c). Entero- and rhinovirus 2A proteins are proteinases ($2A^{pro}$) which cleave the polyprotein to form their own N-termini, whereas the 2A proteins of other genera (cardio-, tescho-, aphtho-, and erboviruses) mediate a cotranslational ribosome 'skipping' effect (producing an apparent prolyprotein cleavage), but these 2A proteins are not proteinases (d).

A few, but major, differences between the genomes of enteroviruses and other genera are now of prime importance in the classification of viruses within the *Picornaviridae*. Specifically, the RNA secondary structural features of the 5′ NTR (**Figure 1(b)**, the presence/absence of an L protein at the N-terminus of the polyprotein (**Figure 1(c)**), and the nature of the 2A region of the polyprotein (**Figure 1(d)**) are now taken to be the discriminative features. It has been shown, however, that comparison of VP1 (1D) sequences alone is sufficient to assign isolates to enterovirus species. Note that the high-level of recombination within noncoding regions and regions encoding nonstructural proteins (see below) means care should be taken when comparing sequences from these regions for taxonomic purposes.

The 5′ nontranslated region

The 5′ terminal ~100 nt of picornavirus vRNA folds into a cloverleaf-shaped structure (domain I; **Figure 1(b)**). A large proportion of the remainder of the 5′ NTR forms a complex secondary structure comprising multiple domains which functions as an internal ribosome entry site (IRES). This region confers a cap-independent mode of initiation of translation of the viral RNA: the ^{7me}G cap structure associated with eukaryotic mRNAs is replaced in picornaviruses by the oligopeptide 3B (or VPg) covalently linked to the 5′ terminus of vRNA. While the 5′ NTR has the same functions across the *Picornaviridae*, there are differences in the overall structure and this may be used to aid the classification of viruses. The entero- and rhinoviruses have a 'type 1' IRES (**Figure 1(b)**), while many of the other picornaviruses have a type 2 IRES.

The leader protein

A leader protein (L) is present at the N-terminus of the polyprotein in the aphtho-, erbo-, cardio-, tescho-, and kobuviruses (**Figure 1(c)**). In the cardioviruses, L has been shown to interact with Ran-GTPase disrupting nucleocytoplasmic trafficking of cellular proteins. In the aphtho- and erboviruses, however, L is a papain-like proteinase (L^{pro}). This proteinase cleaves at its own C-terminus and is involved in shut-off of host cell protein synthesis via cleavage of eIF4G. Expression of the erbovirus L protein in cells did not, however, lead to efficient inhibition of cap-dependent translation. In the entero- and rhinoviruses, no L protein is present: the N-terminus of the polyprotein is the capsid protein, VP4 (1A).

The 2A protein

Picornavirus 2A proteins are diverse in sequence and function (**Figure 1(d)**). The 2A proteins of entero- and rhinoviruses are very similar, and are structurally related to the small subclass of serine proteinases – although the active site nucleophile is not serine, but cysteine. They catalyze an intramolecular proteolytic cleavage at their own N-termini (*in cis*), separating the structural protein polyprotein domain (P1) from the nonstructural proteins (P2, P3; **Figure 1(a)**). Importantly, this virus-encoded proteinase also cleaves a host-cell translation factor (like L^{pro}), the initiation factor eIF4G, which brings about the 'shut-off' of host-cell (cap-dependent) mRNA translation.

The 2A regions of all other picornaviruses are quite different (**Figure 1(d)**). In the case of the aphtho-, cardio-, erbo-, and teschoviruses, the 2A protein is not a proteinase. This type of 2A may be identified by a C-terminal –NPG– motif. In these cases, the N-terminal residue of protein 2B is, invariably, proline. An apparent 'cleavage' of the nascent polyprotein occurs between the glycine and proline residues at the 2A/2B junction (-NPG $\Downarrow$ P-). This processing event is not, however, proteolytic but rather mediated by a translational effect termed ribosome 'skipping'.

Genome Structure of BEV

The genome organizations of several BEV isolates have been reported. BEV 5′ NTRs range from 812 to 822 nt and are unusual in that the 5′ cloverleaf-like secondary structure is duplicated (domains I and I′; **Figure 1(b)**). Furthermore, the putative domains III and VI of the IRES region differ in size and shape from other enteroviruses. The ORF varies from 6498 nt in BEV-2 to 6525 nt in BEV-1. The 3′ NTRs of BEV are 71–75 nt and although the predicted folding pattern (two stem–loop structures – a potential pseudoknot-like element) resembles other enteroviruses, no nucleotide sequence similarity exists.

Originally classified into several serotypes, only two serotypes (BEV-1 and BEV-2) are now recognized within the species *Bovine enterovirus*. A recent study has suggested, however, that the taxonomy of these viruses be revised. Sequence comparisons provided data that the bovine enteroviruses form two major clusters characterized by structural features and levels of sequence identity. These clusters have been designated BEV-A and BEV-B and appear to correlate with the two serotypes BEV-1 and BEV-2. It is also suggested that these clusters represent species, rather than serotypes. Further subgrouping within the clusters is proposed with BEV-A comprising two geno-/serotypes and BEV-B comprising three geno-/serotypes.

Genome Structure of PEV

Sequence analyses of what were formerly regarded as PEVs have shown that all but three now form the genus *Teschovirus*. Based upon the presence of an L protein and the nature of the 2A proteins, it is further proposed that one of these three, PEV-8 (together with some simian enteroviruses; see below) forms a new genus – *Sapelovirus*. The two remaining 'true' enteroviruses are PEVs 9 and 10. The 5′ NTR of PEV-9 is 809 nt (814 nt for PEV-10).

Both 5′ NTRs are predicted to adopt a secondary structure similar to that of the human enteroviruses. However, the 5′ cloverleaf has a unique insertion that enlarges domain I (**Figure 1(b)**). Interestingly, this domain has been previously shown to bind the 3CD proteinase in poliovirus and rhinovirus 14, forming a ribonucleoprotein complex required for initiation of positive-strand RNA synthesis. The long ORFs encode a polyprotein (2168 aa – PEV9; 2171 aa – PEV10) with a very similar organization to other enteroviruses (**Figure 1(a)**). The 3′ NTRs of both viruses are similar in sequence and length (72 nt – PEV9; 71 nt – PEV10), and predicted to form two stem–loop structures.

Genome Structure of SVDV

Complete genome sequences of the virulent J1′73 strain of SVDV and the avirulent H3′76 strain have been determined. Furthermore, partial sequences (5′ NTR, capsid protein VP1, protein 3BC) have been determined from a large number of isolates for epidemiological studies. The genome structure is very similar to that of the other enteroviruses (**Figure 1(a)**). Although only a single serotype, SVDV shows high genetic variability. The IRES is very similar to the human enterovirus type 1 IRES (**Figure 1(b)**; spp. HEV-B), although variability between isolates was observed in the 'spacer' region extending from the 3′ end of the IRES to the initiation codon. Indeed, several isolates had blocks of sequence (6–125 nt) deleted in this region.

A key determinant of virulence was mapped to a single residue within the 2A proteinase. Residue 20 of the avirulent H3′76 strain is isoleucine, the virulent J1′73 strain, arginine (this site is adjacent to His21, a component of the catalytic triad of $2A^{pro}$). Pigs were infected with viruses rescued from an infectious copy of the virulent strain bearing mutations at this single site. Each mutant tested showed much reduced virulence correlating with the different efficiencies of the two forms of the proteinase to promote translation of the vRNA.

Genome Structure of Simian Enteroviruses

Formerly, the 20 simian picornaviruses were provisionally classified as enteroviruses. Analysis of partial (5′ NTR, VP1, and 3D) sequences showed that the simian viruses SV2, -16, -18, -42, -44, -45, and -49 are not enteroviruses, but comprise a new genus *Sapelovirus*. The complete genome sequence of SV2 confirmed that this virus was not an enterovirus since it does not possess a type 1 IRES and is thought, like PEV-8, to possess an L protein. The sequence of the 2A protein was quite different to other picornaviruses, although the presence of the conserved motif –GxCG– (also present in PEV-8) suggests that SV2/PEV8 2A proteins may be proteinases. If these viruses do possess an L protein and a 2A proteinase, then they represent an interesting link between the enteroviruses and other genera.

Analyses of the 5′ NTR and VP1 sequences showed that A13, SV19, -26, -35, -43, -46 were members of *Human enterovirus A*, SA5 a member of *Human enterovirus B*, and SV6, N125 plus N203 were related, but apparently form a new enterovirus species most closely related to *Human enterovirus A*. The complete genome sequence of simian enterovirus A (A-2 plaque virus) showed an organization characteristic of enteroviruses (**Figure 1(a)**), but along with SV4 and SV28 forms another new enterovirus species, this time most closely related to *Human enterovirus B*.

Virus Replication

Most of the receptors identified for picornaviruses belong to the immunoglobulin superfamily or the integrin receptor family. However, the receptors for the animal enteroviruses remain to be determined. Internalization occurs via endocytosis, and as the endosome undergoes acidification, changes in the virion structure lead to the release of the vRNA into the cytoplasm. The vRNA acts as an mRNA; the first step of replication is, therefore, translation of the single, long ORF. The autocatalytic processing by the virus-encoded proteinases $2A^{pro}$ and $3C^{pro}$ produces the three 'primary' processing products P1, P2, and P3 (**Figure 1(a)**) – the full-length (predicted) translation product is not observed. Subsequently further, 'secondary', proteolytic processing of these precursors occurs mediated by $3C^{pro}$. In the case of poliovirus, it has been demonstrated that the P1 capsid protein precursor is processed not by $3C^{pro}$, but by $3CD^{pro}$ – also a proteinase. The function of the vRNA soon switches from that of an mRNA, to that as a template for –ve strand synthesis. The –ve-strand RNA then serves as a template for the synthesis of +ve-strand RNA. A large excess (~80-fold) of +ve-, over –ve-, sense RNA is observed. Although the RNA-dependent RNA polymerase ($3D^{pol}$) is an enzyme, overall the replication of vRNA is not 'enzymic' as such, since protein 3B is used to prime RNA synthesis and is covalently linked to the 5′ terminus of both +ve- and –ve-sense RNA.

A characteristic feature of picornavirus replication is the disappearance of the Golgi apparatus concomitant with the appearance of virus-induced vesicles. It is upon these structures that RNA replication occurs; proteins 2C and 3A are key players in this remodeling of the endomembrane system. An increase in the intracellular level of Ca^{2+} is also observed; protein 2B has been shown to function as a 'viroporin' releasing calcium ions stored in the endoplasmic reticulum.

Recombination occurs with high frequency, reported to be in the region of 10%. The polymerase complex, together with the nascent strand, may 'switch' template

and complete the synthesis of the vRNA from another parent. Analyses of recombinants have shown that viable progeny arise largely from template switching within noncoding regions, or regions encoding nonstructural proteins.

The process by which vRNA is encapsidated is not clear. A feature of this process is the 'maturation' cleavage of VP0 (1AB) into VP4 and VP2 (1B) – again poorly understood. Replication is rapid with cell death and release of progeny virions occurring within ~9 h for BEV and SVDV for most cell types.

Virion Structure and Properties

Particles have a buoyant density of 1.30–1.34 g ml^{-1} in cesium chloride gradients, are resistant to ether, and stable throughout a wide range of pH (3–10). The ability to tolerate low pH is seen as an adaptation to survive passage through the acidic conditions of the stomach. Under the electron microscope, particles are seen as icosahedrons, 25–30 nm in diameter (**Figure 2(a)**). Capsids are nonenveloped, comprising 60 copies of each of the capsid proteins VP4, VP2, VP3 (1C), and VP1. Capsid proteins are arranged into protomers and 60 of these structural units form an icosahedron (symmetry: pseudo $T = 3$; **Figure 2(b)**).

The atomic structures of both BEV and SVDV capsids have been determined. The folding pattern of BEV polypeptides VP1–3 is similar resulting in an eight-stranded antiparallel β-sheet structure. The VP4 protein is much smaller than the other capsid proteins, and lies across the inner surface of the capsid. The N-terminus of VP4 is close to the icosahedral fivefold axes of symmetry and the C-terminus close to the threefold axes. Furthermore, in all picornaviruses, the N-terminal residue of VP4 is covalently bonded to a myristic acid group giving the capsid five symmetry-related myristoyl moieties around the inner surface of the capsid, a channel running from the inner to outer surface at this point. It has been proposed that the myristic groups attached to the VP4 proteins may insert into the host membrane aiding entry.

A radial depth-cued image of the BEV particle is shown in **Figure 2(c)**. The topologies of the BEV major capsid proteins and the overall architecture of the virion are similar to those of related picornaviruses. Some differences were observed, however; the external loops are relatively truncated giving a comparatively 'smooth' appearance. A 'canyon' receptor binding region (running around the fivefold axes of symmetry) is observed in the structures of polio- and rhinoviruses. In BEV, this depression is partially filled by a five-residue extension of the G-H loop of VP3. The extended VP3 loop of BEV has been implicated in receptor binding, although the cell-surface receptor has not been identified. BEV is usually cultured in hamster kidney (BHK-21) cells but is known to be readily adaptable to grow in human cervical carcinoma (HeLa) cells to equivalent titer and can cause cytopathic effect in an extensive range of cell types *in vitro*. The BEV receptor is, therefore, thought to be a ubiquitous cell-surface glycoprotein. The crystal structure also revealed that the virus maintains a hydrophobic pocket within VP1, occupied by a specific 'pocket factor' which appears to be myristic acid. The pocket factor is thought to stabilize the capsid and it has been proposed that a kinetic equilibrium exists between occupied and unoccupied pocket states, with occupation inhibiting 'uncoating' of the vRNA. In purified BEV preparations, a small proportion of the precursor protein VP0 is detected and it is suggested that in a few protomers this precursor remains uncleaved. This maturation cleavage is completely absent in the genera *Parechovirus* and *Kobuvirus* – these viruses possessing only three structural proteins.

The crystal structures of two SVDV isolates, UK/27/72 and SPA/2/93, have been reported. These two structures are in agreement and are similar to those of other enteroviruses, with SVDV being most similar to coxsackievirus B3 (CBV-3). The major capsid proteins (VP1–3)

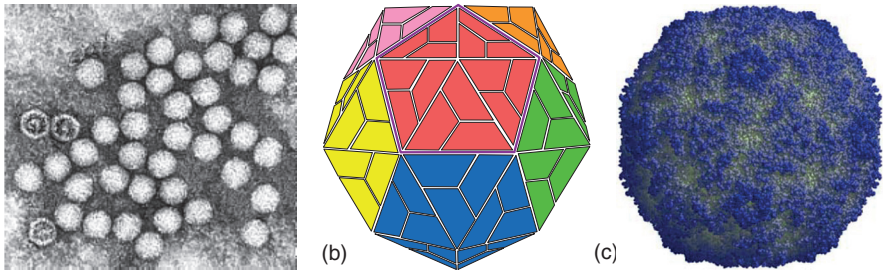

Figure 2 The structure of enterovirus particles. (a) A negatively stained electron microscopic image of enterovirus shows unenveloped particles ~25 nm in diameter. (b) The icosahedral structure of the particle is shown. Five copies each of capsid proteins 1A–D form a pentamer, twelve of which form the complete particle. (c) A radially depth-cued image produced from the X-ray crystallographic data of the BEV particle showing surface projections (dark blue) – particularly notable at the fivefold axis of symmetry. The particle is smoother than the surface of other enteroviruses. Rasmol image courtesy of Dr. J.-Y. Sgro, University of Wisconsin, USA.

possess the conserved β-sheet structure with some notable differences. VP1, making up most of the outer surface area, is often the most variable, and while the β-sheet is conserved, the connecting loops vary in length between SVDV and CBV-3. Five copies of VP1 associate to form each of the fivefold vertices, and in SVDV it has been noted that an arginine residue from each of the five VP1s form a crown at the apex of the fivefold axes of symmetry. The hydrophobic pocket formed by VP1 is also present in SVDV and electron density clearly showed that this accommodates a fatty acid pocket factor. The hydrophobic pocket situated at the base of the canyon extends from a pore on the surface inward, until it is blocked by VP1 loops. In CBV-3, the pocket factor has been identified as palmitic acid. The dimensions of the pocket are similar in CBV-3 and SVDV, but in the case of SVDV the electron density suggests that the pocket factor is a longer molecule – similar to sphingosine.

The VP2 and VP3 proteins alternate around the threefold axes of symmetry. The VP2 of SVDV possesses a puff region composed of two sequential loops between sheets E and F, with the second loop being more exposed on the surface. This is the least conserved area between SVDV and CBV-3. Furthermore, in poliovirus, this area has been implicated in the binding of the virus to its cell-surface receptor. The C-terminus of the VP3 protein is external and forms a major surface protrusion termed the 'knob'; this structure is present in SVDV and CBV-3. VP3 is also important in the stability of the pentamer with fivefold neighboring VP3 proteins forming a β-cylinder.

VP4 is situated on the inner surface of the capsid and is the most conserved of the capsid proteins. The central region of this protein was found to be disordered with little secondary structure. VP4 begins close to the fivefold axes and snakes toward the nearest threefold axes, with the C-terminus of VP4 lying close to the N-terminus of VP2. The N-terminal glycine of VP4 is covalently attached to myristic acid and the myristoyl groups of adjacent VP4s group around the fivefold axes, under the VP3 β-cylinder. In general, the surface structure of SVDV is very similar to that of coxsackieviruses.

Rather than a continuous, circular, canyon in SVDV, there are five distinct depressions. The C-terminus of VP3, the first loop of the VP2 puff, and residues of the C-terminal VP1 loop form a ridge between these depressions. Further depressions are present on the twofold axes with the enclosing four walls composed of symmetrically related pairs of VP2 and VP3. SVDV, the six CBV serotypes (CBV-1–6), and many adenoviruses share a common receptor on human cells. The coxsackieadenovirus receptor (CAR) has two immunoglobulin-like extracellular domains, a transmembrane domain and a cytoplasmic domain. Cryoelectron microscopy has provided evidence that CAR binds into the canyon of CBV-3, mostly interacting with VP1 but with contributions from VP2 and VP3. CBV-5 (thought to have given rise to SVDV in pigs) uses CAR as a primary receptor and decay-accelerating factor (DAF; CD55) as a co-receptor. Recent isolates of SVDV have been shown to have lost the ability to bind human DAF but have not developed the ability to bind pig DAF, suggesting that SVDV may have adapted to use another co-receptor which is tailored to the new host.

Concluding Remarks

Understandably, in terms of research effort, for many years the animal enteroviruses have been the poor cousins of their human 'relatives'. The greatly expanded sequence database has led to a wholescale reappraisal of the taxonomy of these viruses. It is clear that within this group close relationships exist between animal and human viruses and that viruses have passed from man to animals, and vice versa. The high mutation rate in combination with high frequency of recombination means these viruses can rapidly adapt to new host species. Animal enteroviruses are, therefore, worthy of study not only for their intrinsic interest and economic impact but, through enzoonosis, they pose an ever-present threat to human health.

Glossary

Acute flaccid paralysis (AFP) A descriptive diagnosis used in the context of poliomyelitis eradication initiative (PEI), coordinated by the World Health Organization (WHO). A case of AFP is a patient with acute onset paralytic symptoms without known etiology. Within the PEI, an AFP patient is suspected of having poliomyelitis and should be tested for poliovirus excretion.

Acute hemorrhagic conjunctivitis (AHC) A rapidly developing severe inflammatory disease of the skin covering the eyeballs, including bleeding of the inflamed skin.

Hand-foot-and-mouth disease (HFMD) An acute febrile disease of children with flat or raised red spots, which may later develop to vesicles, in the mouth as well as on palms and soles of feet.

Phylogenetic typing Determination of genetic type of an unknown strain by sequence and phylogenetic analysis of partial genome sequence.

Prime strains Virus strains showing one-way cross-reactivity with prototype strains of a serotype and thus reflecting within-serotype antigenic variation. Antisera against a prototype strain do not neutralize a prime virus strain but an antiserum against a prime strain will neutralize the prototype strain.

Introduction

Historical Aspects

Original taxonomic subgrouping of human enterovirus (EV) isolates was based on host species range and pathogenicity in humans or experimental animals. Accordingly, the strains were classified as polioviruses (PVs), coxsackie viruses of subgroup A (CVA), or B (CVB), or echoviruses (E). Each subgroup was further divided in three or more serotypes according to results of cross-neutralization assays with hyperimmune antisera raised against individual strains. Toward the end of 1960s, after initial characterization of 3 PV serotypes, 24 CVA serotypes, 6 CVB serotypes, and 34 E serotypes, it was realized that antigenic relationships did not always correlate with other phenotypic features used in the taxonomic subgrouping. Subsequently, new serotypes were no more distributed in the established subgroups but instead given a running number from 68 onward. Within a few years, five new serotypes, EV68 through EV72, were identified. However, EV72 turned out to be very different from typical EVs and was later reclassified as hepatitis A virus in a genus of its own (*Hepatovirus*) in the family *Picornaviridae*.

Development of molecular techniques in virus strain characterization, notably phylogenetic analysis of (partial) genomic sequences, enabled novel approaches in virus taxonomy and also revived taxonomical interest in EV strains in the late 1990s. The official taxonomic subclassification of the genus *Enterovirus* now includes four phylogenetically distinct EV species with strains infecting humans, *Human enterovirus (HEV) A–D* (**Table 1**).

General Features of Human Enteroviruses

Human enteroviruses (HEVs) naturally share many basic biological properties with other picornaviruses, but may also show features typical of the species, serotype, or even strain in question. Although many of the features often referred to as typical of EVs have in reality been examined only for poliovirus type 1/Mahoney, we assume here that in principle they are also likely to be true for enterovirus types 68 and beyond. Exceptions to the 'rules', if known, will be mentioned in the subsequent serotype-specific articles.

EVs are typically acid stabile, nonenveloped, icosahedral particles composed of 60 structural subunits each comprising one copy of each of the four structural proteins, capsid protein 1–4 (VP1–VP4) surrounding the about 7500 nucleotide (nt) long RNA genome. Steps of the replication cycle follow the common pattern of viruses with messenger-sense single-stranded RNA genome.

Humans are the sole natural hosts of HEVs. Transmission of EV readily takes place through close direct contacts, for example, within a family, but also through indirect contacts such as by touching by fingers objects or surfaces contaminated with feces or respiratory excreta. Out of the large number of human enterovirus serotypes, only polioviruses can be prevented today by vaccines, developed already half a century ago.

Enterovirus 68 (HEV-D)

History

Human enterovirus 68 (EV68) was originally isolated from four children with pneumonia and bronchiolitis in

Table 1 Distribution of enterovirus (sero)types in the old and new taxonomic subclasses

	Classical subgroup of enteroviruses/sero(type) number				
Species	*Poliovirus*	*Coxsackie-virus A*	*Coxsackie-virus B*	*Echovirus*	*New enterovirus*
Human enterovirus A ($N = 18$)		CVA2–CVA8, CVA10 CVA12, CVA14, CVA16			EV71, EV76[a] EV89[a]–EV92[a]
Human enterovirus B ($N = 57$)		CVA9	CVB1–CVB6	E1–E7, E9 E11–E21 E24–E27 E29–E33	EV69, EV73[a]–EV75[a] EV77[a]–EV88[a] EV93[a], EV97[a], EV–98[a] EV100[a], EV101[a]
Human enterovirus C ($N = 16$)	PV1–PV3	CVA1, CVA11, CVA13 CVA17 CVA19–CVA22 CVA24			EV95[a], EV96[a] EV99[a], EV102[a]
Human enterovirus D ($N = 3$)					EV68, EV70, EV94[a]

[a]Novel types identified by the VP1 coding sequence and registered by the Picornavirus Study Group of ICTV.
PV, poliovirus; CVA, coxsackievirus subgroup A; CVB, coxsackievirus subgroup B; E, echovirus; EV, enterovirus. Explanation for lacking numbers: CVA15 and CVA18 have been reclassified as strains of CVA11 and CVA13, respectively; CVA23 was found to be same as echovirus 9; echovirus 8 is a strain of E1; echovirus 10 has been reclassified as reovirus type 1, echovirus 28 as rhinovirus type 1A; echovirus types 22 and 23 now belong to another genus, *Parechovirus*; the initially identified echovirus 34 is a strain of E33, enterovirus 72 was classifies as hepatitis A virus in the genus *Hepatovirus*.

California in 1962. One of these simultaneous isolates, recovered from an oropharyngeal swab of a 10-month-old female, was defined as the prototype strain Fermon. Since then isolations of EV68 have been rare. Human rhinovirus 87 (prototype strain Corn) was recently shown to both antigenically and genetically represent the same enterovirus serotype as EV68. Neutralization assays with antisera raised against EV68 Fermon and HRV87 Corn demonstrated one-way cross-reactivity between these virus strains indicating that strain Fermon could be considered a prime strain of the Corn.

Epidemiology

Most of the relatively few known EV68 isolates have been obtained from respiratory specimens, but occasional isolations from stool and sewage specimens have also been made. The transmission of EV68 is more plausible by the respiratory than by the fecal–oral route. EV68 may affect persons of different ages, although it has been most often detected in young children. Despite the infrequent isolation from clinical specimens, EV68 is probably a highly common virus since antibodies against EV68 are frequently found among Finnish people.

Cellular Interactions

Isolates of EV68 have been obtained from a variety of human and monkey cell lines. Besides, at least some of the currently circulating EV68 strains are able to induce cytopathic effect (CPE) in nonprimate mouse L cells. The host cell surface molecules involved in the initiation of EV68 infection are not known, but recent studies indicate that both the decay-accelerating factor (DAF) and a yet unknown sialic acid moiety may be required. Receptor specificity of HRV87 Corn was studied among other human rhinoviruses. The requirement for the presence of sialic acids on the HeLa cells for attachment of HRV87 distinguished it from other HRVs, the receptor of which was either LDL receptor or ICAM-1. On the other hand, pretreatment of HeLa Ohio cells with a monoclonal antibody to the SCR-3 epitope of DAF inhibited both the HRV87 and EV68 induced CPE.

Clinical Presentation and Pathogenesis

EV68 has a clear association with respiratory diseases. Most clinical isolates of EV68 have been obtained from respiratory specimens of patients with respiratory tract infection. Studies on strains EV68 Fermon, HRV87 Corn, and some recent clinical EV68 isolates have shown that these viruses share important biological features with human rhinoviruses, the most prominent causative agents of common colds. Unlike typical EVs, strains of EV68 lose their infectivity in acidic environment and besides, grow more effectively at $+33\,^{\circ}C$ than at $+37\,^{\circ}C$. Clinical illness or symptoms described upon isolation of EV68 included pneumonia, bronchiolitis, upper respiratory tract infection, wheezing, asthma, emesis, respiratory distress, crackles, cough, and asthma exacerbation.

Enterovirus 69 (HEV-B)

Enterovirus 69, strain Toluca, was isolated in 1959 from a rectal swab of a healthy Mexican child. Later detections of EV69 among enterovirus isolates have remained very rare but the virus has been found in different parts of the

world, mainly in patients with nontypical respiratory disease. Respiratory excreta and stool specimens may yield the virus demonstrating typical enteroviral CPE in monkey kidney and human tumor cell lines. Further details of the replication cycle have not been elucidated. Some antigenic cross-reactivity with echovirus 6 has been reported but according to phylogenetic analysis of the entire genome, EV69 is a typical member of the species *HEV-B* with its own distinct branch in a tree constructed on VP1 sequences and variable, region-dependent clustering with other HEV-B serotypes as regards the nonstructural protein coding sequences.

Enterovirus 70 (HEV-D)

History

An emergence of a new type of viral conjunctivitis was observed in Acera, Ghana, in June 1969. The disease, locally first called 'Apollo 11 disease' because of the coincidental landing of Apollo 11 on the moon, was named as acute hemorrhagic conjunctivitis (AHC) and it spread rapidly over Africa and Asia. The causative agent was isolated in Japan, Singapore, and Morocco in 1971 and assigned as enterovirus 70 (EV70).

Phylogenetic and epidemiological analyses have confirmed that EV70 emerged from one focal place in August 1967 ± 15 months, which is about 2 years before the first recognition of the AHC pandemic. It has been speculated that EV70 may have originated from an animal or insect picornavirus. This hypothesis is supported by the wide *in vitro* host range of EV70 and detection of EV70 neutralizing antibodies from animal sera collected from Ghana and Senegal already around the estimated time of emergence of EV70.

Epidemiology

EV70 has caused two pandemics and several epidemics of AHC. The first pandemic began in Ghana and spread over Africa and Asia during 1969–1971. The largest number of cases occurred in crowded coastal areas of tropical countries. At the same time, outbreaks were also observed in some European countries. The second pandemic started in southern India in 1980 and spread extensively during 1980–1982, now also including the Western Hemisphere. The epidemic EV70 strains from Asia and America in 1980 and 1981 were shown to be genetically closely related and to differ significantly from the strains recovered during the first pandemic. Since the two large pandemics, which caused about 100 million cases of AHC, smaller outbreaks have been described at least in Singapore, China, Brazil, and Cuba in 1980s and in American Samoa, Israel, Japan, and India in 1990s.

EV70 is highly contagious and spreads fast under crowded and unhygienic conditions. The virus may be transferred by fomites as well as by direct inoculation by contaminated fingers. High levels of relative humidity prolong the survival of EV70. Transmission of EV70 occurs usually at school or home, but may also occur, for example, in eye clinics. During the epidemic, the highest number of cases is typically among school-aged children. Women in child-bearing age have been reported to be affected more frequently than men in the same age.

EV70 induces immune response, which provides only short-lived protection. Consequently, multiple epidemics have been seen in a given geographical region even within a 5-year period. Although EV70 typically causes clear-cut epidemics, the virus may continue endemic circulation in the affected population after the main outbreak. Sporadic cases of AHC or neurological diseases may occur over a period of some years.

Cellular Interactions and Pathogenesis

In humans, EV70 exhibits a restricted tropism to conjunctival and corneal cells, but like several other HEVs, it also has a propensity for infecting the central nervous system (CNS). *In vitro*, EV70 has the ability to infect a wide spectrum of mammalian cell lines, which is untypical for most HEVs.

EV70 attaches to the short consensus repeat domain 1 of DAF, on HeLa cells. However, additional sialylated binding factors on the cell surface are needed for productive infection. The DAF is also used as a receptor by several other EVs, but the requirement for the cell surface sialic acid is unique among HEVs. It has been speculated that this recognition of sialic acid attached to underlying glycans by a particular glycosidic linkage might contribute to the exceptional *in vitro* host range and tissue tropism of EV70.

Clinical Presentation and Pathology

EV70 is, together with a variant of CVA24, the leading causative agent of AHC. The typical site for EV70 entry is conjunctiva, where the virus may be transferred by fomites as well as by direct inoculation by contaminated fingers. The incubation period is about 24 h. The disease is usually localized to the eye and characteristically produces subconjunctival hemorrhage, which ranges from discrete petechiae to large patches of hemorrhage covering the bulbar conjunctiva. Symptoms include severe eye pain, photophobia, and blurred vision. Less specific symptoms like headache, nasal discharge, and sore throat may also occur. The cornea may be transiently involved in the form of epithelial keratitis. Asymptomatic EV70 infections are uncommon. Recovery is usually complete within less than 10 days with no significant ocular sequelae.

During the two EV70 pandemics, neurological manifestations were reported in about 1 out of 10 000 AHC patients. Male adults were more likely to be affected than women. The neurological symptoms resembling poliomyelitis developed as late as several weeks after the onset of AHC. Significant antibody titers against EV70 were demonstrated in the serum and more relevantly in the cerebrospinal fluid (CSF) of the patients.

Diagnosis

AHC caused by EV70 or other viruses are clinically indistinguishable. EV70 is most frequently isolated from conjunctival and oropharyngeal specimens, occasionally also from feces. Although several different cell lines may support EV70 replication, isolation of EV70 in cell culture is considered insensitive and today, EV70 infection is typically diagnosed by serological means or by reverse transcriptase-polymerase chain reaction (RT-PCR) methods. Demonstration of EV70 specific IgM antibodies in sera indicates a recent EV70 infection. The titers of IgM antibodies against EV70 begin to drop by the fifth week after onset of illness. In addition, neutralizing antibodies can be measured from sera, tears, or CSF. EV70 specific RNA by RT-PCR has been successfully detected from eyewash specimens, eye swabs, conjunctival swabs, and tears. Sequence analysis of (partial) VP1 is an useful tool for determination the origin of the outbreak.

Prospects for Prevention, Control, and Treatment

Currently no practical treatment method or effective vaccine is available for AHC caused by EV70. Preliminary studies aiming at development of the vaccine have been conducted with immunogenicity of the candidate materials tested in rabbits. Immunizations with UV-inactivated EV70 or bacterially produced EV70 VP1 protein or its nonoverlapping N and C terminal fragments were reported to elicit a classical humoral immune response including EV70-neutralizing antibodies in rabbit sera.

Disinfection and control of EV70 has been studied in experimental eye clinic conditions. When placed in eye drop solution and kept at room temperature, the infectivity of EV70 is sustained for more than 20 days. The most convenient and efficient disinfection procedures against EV70 is either drying the instruments and keeping them in a moisture-free environment or heating at 90 °C for 5 s.

Enterovirus 71 (HEV-A)

History

EV71 was initially isolated in 1969 from a case of fatal encephalitis in California. Since then it has caused several outbreaks in different parts of the world including Australia, Bulgaria, Hong Kong, Hungary, Japan, and Sweden. Clinical symptoms of infection have been various, sometimes associated with CNS involvement. In recent years Southeast Asia has suffered from large epidemics of EV71, manifested, for example, in Taiwan 1998 with 405 patients hospitalized and 78 fatalities.

Epidemiology and Genetic Characteristics

EV71 appears worldwide with both endemic and epidemic circulation. Most infections occur in children under 5 years. Infections are transmitted by feco–oral route, but respiratory droplet transmission is also possible. Epidemics occur year around with peaks in late summer and autumn, occasionally in 3-year cycles.

EV71 is a member of HEV-A species with a close genetic and antigenic relationship to CV-A16. Nucleotide and amino acid homologies are 77% and 89%, respectively, between these viruses. At least four distinct genogroups A, B, C, D, with subgroups B1–4 (5), C1–4, have been identified. The EV71 prototype strain, BrCr, is the sole member of genogroup A. Strains belonging to genogroups B and C have mainly caused the epidemics in the Asia-Pacific region. Large sets of strains worldwide have been subjected to molecular epidemiological and sequence analysis, but neurovirulence has not been connected to a single genotype and its genetic determinants have remained elusive.

Cellular Interactions and Pathogenesis

The receptor molecules involved in EV71 are not known. In the laboratory, EV71 strains replicating in Vero and RD or other primate cell lines produce CPE typical of EVs. Like other EVs, EV71 interferes with the cellular apoptosis program by inhibiting the activation during early steps of infection and then enhancing apoptosis in the later stages of the infection. It is not known if apoptosis has a significant role in the generation of symptoms *in vivo*. Immune response after infection is considered to be typical of enterovirus infection, involving both humoral and cellular responses with the humoral immunity likely to provide protection against reinfections. Animal models using either mice or monkeys have been developed for *in vivo* studies of EV infection. Alpha interferon seems to be an important component of the innate immunity limiting spread of the virus in the body. In an oral-infection model in newborn mice, the virus was found to spread from the intestines to several tissues including the spinal cord, eventually causing brain-stem encephalitis. The virus also spread to unprotected littermates and the dams. The model thus has several features similar to the human EV71 infection and is likely to be useful in future.

Clinical Presentation and Pathology

Enterovirus 71 is one of the two major HEV-A serotypes causing the relatively common hand-foot-and-mouth disease (HFMD) in children, the other being CVA16. In the western world, CVA16 has been dominating but in Southeast Asia, EV71 has caused severe outbreaks since the late 1990s with sometimes transmission of CVA16 coinciding. The usually self-limiting HFMD starts with fever followed by appearance of flat or raised red spots in the tongue, gums, and inside of the cheeks, as well as on palms, soles of feet, and occasionally buttocks. The spots may develop to blisters and in the mouth further turn to ulcers. The rash does not usually itch. Neurological complications, aseptic meningitis, encephalitis, and poliomyelitis-like polyneuritis are relatively common in EV71 but rare in CVA16 infections. In the large Southeast Asian epidemics during the last decade, meningo-encephalitis has occasionally been an alarmingly common complication with significant associated mortality especially in young children. Neurological disease may occasionally occur without recognizable rash. Pulmonary edema may contribute to the death and is considered to be secondary to dysregulation of blood circulation due to virus-induced damage in the brain stem resulting in dysregulation of glucose homeostasis, rather than putative infection of pulmonary tissues.

Diagnosis

EV71 infection has traditionally been confirmed in cell culture with virus isolation and serotyping using samples from throat swab or vesicular fluid or postmortem samples from the brainstem or spinal cord. Serological diagnosis with a high single titer or in a minority of cases a fourfold rise in antibody has also been used. New methods for rapid serotype-specific identification to replace the traditional tedious ones have been developed prompted by recent outbreaks. These include RT-PCR, real-time RT-PCR hybridization probe assay, DNA microchip array, and IgM-capture enzyme-linked immunosorbent assay (ELISA). Phylogenetic analysis of VP1 and VP4 capsid protein sequences have been used in tracing genetic origin of the strains.

Prospects for Prevention, Control, and Treatment

Severe outbreaks of EV71 in Southeast Asia have triggered studies aiming at development of vaccine and/or antiviral chemotherapy, but neither vaccine nor specific chemotherapy is available in the clinic. Initial studies in experimental animals have reported immunogenicity of Vero-cell-grown inactivated virions, baculovirus-expressed empty VP0-VP3-VP1 procapsids, and even transgenic tomatoes expressing the VP1 protein, but no clinical studies have been published by mid-2006. Spreading of the virus via both respiratory and feco–oral routes restricts the efficacy of attempts to control spreading of the virus in human populations. Pregnant women have been advised to avoid contacts with children suffering from HFMD although no data have been accumulated to suggest that maternal EV71 infection would be more dangerous to the fetus than infections in general. *In vitro* and animal model studies suggest that alpha interferon and lactoferrin may limit EV71 replication. In cell culture, siRNAs targeted to different genomic regions of EV71 were found to have antiviral activity.

The Newly Discovered HEV Types

History

Nontypable enterovirus isolates have been detected as long as enterovirus isolations have been carried out. Between 1970 and 2000, they were more or less ignored, and their existence perhaps interpreted by assuming that they might represent prime strains of known serotypes, rare serotypes not represented in the antiserum pools used, or mixtures of two EVs too difficult to sort out in the neutralization assays. By the end of 1990s, it became evident that phylogenetic analysis of VP1 coding sequences of conventionally serotyped enterovirus isolates results in defined clusters showing complete agreement with the phenotypic serotype. Subsequently, several groups have used this approach to identify nontypable isolates in historical collections of enterovirus strains, or among new isolates. The Picornavirus Study Group of ICTV has by mid-2006 listed almost 30 new types and the running number of the next new serotype is beyond 100. It is interesting that new enterovirus types have been described in all four HEV species and that most of them are in the species *HEV-B,* already traditionally the largest HEV species (**Table 1**).

For all the newly discovered enterovirus types, detection of perhaps only one or at the best, a handful of independent isolates have been reported. For most strains, only the source of origin and the VP1 sequence is known. Therefore, it is not possible to describe in further detail more than a few examples of these novel types.

New Types Forming a Subcluster within the Species HEV-A

Four of the new HEV-A serotypes have been studied in some detail. All but one of the altogether 19 isolates were derived from Bangladeshi children with acute flaccid paralysis (AFP) and collected in 1999–2002. The remaining isolate was from an adult gastroenteritis patient in France from 1991. It is not clear if these infections had any role in the generation of the recorded symptoms. Sequences of the VP1 coding region formed four serotype-like clusters

close to but separated as a group from the classical HEV-A cluster as well as from the simian enterovirus isolates tentatively classified in the HEV-A species. Eleven strains, including the French one, were given type number 76 while two, four, and two strains segregated in the clusters labeled EV-89, EV-90, and EV-91, respectively. Sequences of the entire capsid coding region confirmed this clustering and monophyletic origin of each new type as well as that of the new subcluster within HEV-A. The observed monophyletic segregation of the new types from the classical HEV-A serotypes extended to the nonstructural protein coding part of the genomes. Hence, evidence for recombination between these new HEV-A types and the classical ones (or the simian ones) was not obtained. Analysis of larger numbers of independent sequences may be required before final conclusion about the matter but it is possible that this subcluster has diverged from the other HEV-A strains far enough so that functional combatibility of genomic parts joined in putative recombination events is too poor to produce viable progeny with sufficient fitness for enrichment and widespread transmission.

Selected New Types of the Species HEV-B

Epidemiological background and some genomic features of HEV types 73–75 and 77–78 have been published. While parts of these strains are derived from poliovirus surveillance, either from patients with AFP or their contacts, a significant proportion is from patients suffering from a variety of clinical entities typical of classical HEV-B infection, ranging from acute respiratory infection to aseptic meningitis. In phylogenetic analysis, these new types do not form a subcluster within HEV-B but are rather distributed in different parts of the multipronged tree of HEV-B.

HEV-94, A Proposed New Type in the Species HEV-D

During environmental polio surveillance in Egypt four nonpoliovirus strains were isolated from sewage specimens in L20 B cells, a recombinant murine cell line expressing human poliovirus receptor. The VP1 sequences of these isolates clustered together and showed less than 70% nucleotide and less than 80% amino acid sequence similarity to the closest established enterovirus serotype, EV70. This suggests that the isolates form a new enterovirus type, EV94, within the species *HEV-D*. In parallel with this finding AFP surveillance in the Democratic Republic of Congo revealed two nonserotypable virus strains whose VP1 sequences clustered very close to those of the above Egyptian isolates suggesting that they belong to the same serotype. Altogether, VP1 sequences of all these six EV94 isolates formed a monophyletic group within the species *HEV-D*. Enterovirus 94 cannot be considered as a new virus type although just recently discovered, since, according to the results of seroprevalence studies carried out in Finland, neutralizing antibodies to this virus strain were common already two decades ago.

Comparison of the whole genome sequence of the prototype strain of EV94 with those of EV68 and EV70 revealed no evidence for recombination between the prototype strains of these three HEV-D serotypes. In further characterization, the prototype strain turned out to be acid resistant suggesting that this virus strain, unlike EV68 and some strains of EV70, is a typical enteric pathogen capable of surviving the acidic stomach during the passage to the presumed intestinal replication sites.

The natural host range and the cellular receptor for EV94 are not yet known. Although two strains of EV94 were isolated from stool specimens of patients with AFP, it is not yet known whether these virus strains could be causative agents of neurological symptoms.

Future Prospects

It is likely that the number of human enterovirus (sero) types will still increase as more and more previously nontypable isolates will be characterized genetically. While genetic and serological identification of the HEV serotype usually is in good agreement, there are exceptions to this rule. Some serotypes contain strains showing wide genetic divergence in the VP1 coding region and sometimes strains of genetically relatively homogenous clusters show strong antigenic variation. On the other hand, it is unlikely that anybody would take the trouble and serotype all the new genetically identified types in the classical way using monotypic antisera. Serotyping of isolates is a tedious and expensive procedure and may in the future remain as a research tool only. For identification of clinical isolates, genetic tools are more rapid and useful, for example, in tracking the transmission routes.

Entomopoxviruses

M N Becker and R W Moyer, University of Florida, Gainesville, FL, USA

© 2008 Elsevier Ltd. All rights reserved.

Introduction

The entomopoxviruses (EVs) comprise the *Entomopoxvirinae*, one of the two subfamilies of the family *Poxviridae*. EVs infect insect hosts and were first described in 1963. These viruses are found in a number of insect species but are particularly well characterized within the butterflies and moths. The other subfamily of poxviruses is the *Chordopoxvirinae*, which contains the well-known variola virus, the causative agent for smallpox, and vaccinia virus (VV), the vaccine strain for smallpox. The EVs possess a number of the same features as the chordopoxviruses (CVs); however, there are striking differences between the two subfamilies. The similarities include general virion morphology, a double-stranded DNA genome, and a cytoplasmic life cycle. The differences include the host range of the viruses, the presence of occluded virus in EVs, the composition and organization of the DNA genome, differences in gene regulation, and the optimal temperature for growth, which is 27 °C for EVs versus 37 °C for CVs. Although a large number of EVs have been identified, very little is known about most of them with the exception of the *Amsacta moorei* EV (AMEV), which is amenable to growth in culture.

Phylogeny

Within the subfamily *Chordopoxvirinae* are eight genera. The causative agent of smallpox (variola virus) and the virus used for vaccination against smallpox (VV) are members of the genus *Orthopoxvirus*. Other CVs that cause human disease are cowpox virus and monkeypox virus within this same genus and molluscum contagiosum virus in the genus *Molluscipoxvirus*.

Within the subfamily *Entomopoxvirinae* are three genera, recently renamed by the International Committee on Taxonomy of Viruses: *Alphaentomopoxvirus*, *Betaentomopoxvirus*, and *Gammaentomopoxvirus*. The genera are defined predominantly by the host range of the viruses and by the morphology of the virus particle. The genus *Alphaentomopoxvirus* contains members that infect beetles (coleopterans), and the type species is *Melolontha melolontha entomopoxvirus*. Little is known about the molecular biology of the members of this genus. The genus *Betaentomopoxvirus* contains the best-studied members of the EVs. Betaentomopoxviruses infect either butterflies and moths (Lepidoptera) or grasshoppers and locusts (Orthoptera). The type species is *Amsacta moorei entomopoxvirus*. The host of AMEV is the red hairy caterpillar from India, a member of the tiger moths. Members of the genus *Gammaentomopoxvirus* infect flies, mosquitoes, or midges (Dipterans), and the type species is *Chironomus luridus entomopoxvirus*. There are also a number of unclassified EVs. Included in this group is the well-studied virus from the grasshopper, *Melanoplus sanguinipes* (MSEV). Formerly classified as a betaentomopoxvirus owing to its host range, this virus has been reclassified based on genomic sequencing data and comparison to the genomic sequence of AMEV. Evolutionary trees based on the DNA polymerase sequence indicate not only that the EVs are distinct and evolutionarily separated from the CVs, but that AMEV and MSEV are also highly divergent from each other. There are other unclassified EVs that infect Hymenoptera (bees and wasps). The best studied of these is *Diachasmimorpha* EV, whose host is the parasitic wasp, *Diachasmimorpha longicaudata*.

Virion Structure

The general virion structure is similar to that of the orthopoxviruses in that it consists of an inner core of electron-dense material surrounded by one or two lateral bodies (**Figure 1**). Within the core are the double-stranded DNA genome and a number of proteins required for the cytoplasmic life cycle of the virus. The entire virion is enveloped by a membrane. **Table 1** indicates the differences in virion size and shape of the lateral bodies of virions from different genera.

One of the unique features of EVs in comparison to CVs is that in nature they exist in an occluded form (**Figure 1**). A variable number of virions are embedded within a paracrystalline protein matrix consisting almost exclusively of a single protein, spheroidin. This is a large protein of 100–115 kDa that is abundant at late times during infection. Spheroidins from different viruses infecting hosts of the same insect order have greater than 80% identity to each other; however, spheroidins from viruses that infect hosts from different orders, such as coleopterans versus lepidopterans, have little similarity. The baculoviruses are another family of double-stranded DNA insect viruses that also produce occluded virus. In baculoviruses, it is the polyhedrin protein that forms the occlusion bodies (OBs). Despite a similar function, spheroidin has little similarity to the baculovirus polyhedrin protein. A large number of cysteines are present with the spheroidin protein, leading to the hypothesis that the OB structure is held together by disulfide bonds.

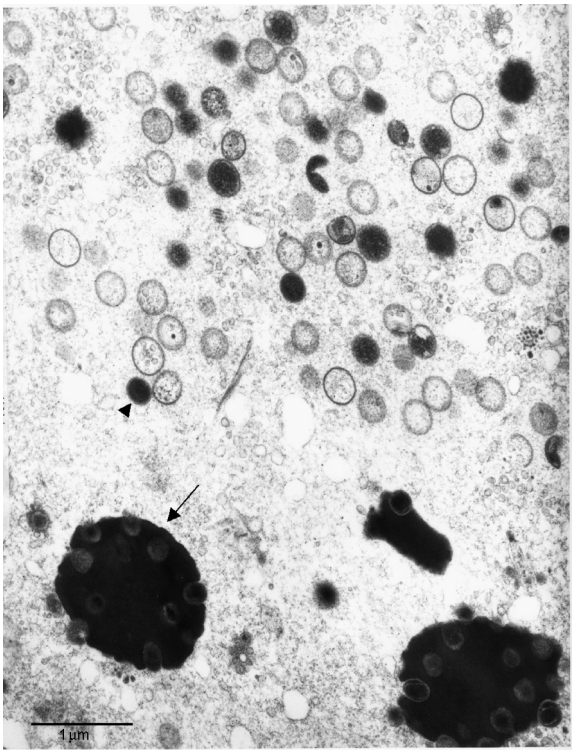

Figure 1 AMEV-infected *Lymantria dispar* cell (cell line Ld652). Different stages of virion development are seen, including mature virions indicated by an arrowhead and OBs indicated by an arrow.

The function of the OBs is to provide stability for the virus in the environment until ingested by another caterpillar. OBs contain a variable number of virion particles and only mature virions are occluded. OBs are alkaline sensitive, consistent with the high pH of the insect gut. Spheroidin is not required for virulence and the gene is nonessential in tissue culture. Nonoccluded virus is poorly infectious in caterpillars when ingested, but quite virulent when injected. OBs can be induced to form in the absence of virions by the expression of spheroidin protein in cell culture. An alkaline protease is associated with some preparations of EV OBs, and may be useful for dissolution of the OB in the insect gut. AMEV OBs are associated with an alkaline protease when isolated from insects, but not when the virus is grown in culture.

Pathology

EVs infect primarily the larvae of insects rather than the adult insects. There are reports of infections of adult insects within laboratory settings, however. Most EVs have a restricted host range, although MSEV does infect several grasshopper species. Infection occurs primarily through an oral route with the ingestion of OBs. Once in the gut, the OBs are dissolved by the alkaline environment. The released virions attach to the midgut epithelium and then appear to fuse with the cell membrane. The virus then infects the fat body of the insect and this becomes the primary site of replication for the virus.

Table 1 Properties of EV virions

	Alphaentomopoxvirus	*Betaentomopoxvirus*	*Gammaentomopoxvirus*
Size	450 × 250 nm	350 × 250 nm	320 × 230 × 110 nm
Core	Unilateral concave core	Cylindrical	Biconcave
Lateral body	Single	Sleeve shaped	Two
Virion shape	Ovoid	Ovoid	Brick

EVs are reported to infect the hemocytes and AMEV does infect primary hemocytes in culture. Some researchers argue that the presence of virus in the hemocytes *in vivo* represents phagocytosis rather than infection. As the disease progresses within the insect, the hemolymph frequently turns white with OBs, and the larva itself can take on a whitish or white spotted appearance. The fat body disintegrates and the virus is disseminated throughout the body.

Infected larvae are lethargic and uncoordinated and exhibit a decrease in feeding. The duration of the instar phase is increased before progression to the next instar and few infected larvae continue through pupation. In some EV infections, this is thought to be due to the increased levels of juvenile hormone. There are reports of regurgitation and defecation of AMEV particles by infected *Estigmene acrea* larvae. The time to death of an infected insect is dependent both on the dose of virus received and the larval instar stage. Younger larvae appear to be more susceptible to lower doses of virus and die more quickly than older larvae. The lowest reported LD_{50} is 2.4 spheroids. *Melanoplus sanguinipes* larvae succumbing to an MSEV infection within less than 12 days are reported to lack OBs, although infections of greater than 14 days do possess OBs. The shorter time to death is the result of larger doses of virus.

Fusolin/Spindles

In addition to spheroidin, some, but not all, members of the alphaentomopoxviruses and many of the lepidopteran members of the betaentomopoxviruses produce another protein termed fusolin that forms crystalline spindles. Among the viruses known to produce spindles are *Melolontha melolontha* EV, *Heliothis armigera* EV, *Choristoneura fumiferana* EV, *Choristoneura biennis* EV, *Pseudaletia separata* EV, and *Anomala cuprea* EV (ACEV). Spindles do not contain virions, though spindles are occasionally found within the OBs of these viruses. Similar to spheroidin, fusolin is highly expressed at late times during infection and is a smaller protein of 38 kDa.

Spindles purified from EV infections enhance the infectivity of a number of baculoviruses. One proposed mechanism of this enhancement is through dissolution of the noncellular peritrophic membrane found within the insect gut. An alternate hypothesis is that the spindles increase the amount of baculovirus-to-cell fusion. Spindles from ACEV have also been demonstrated to enhance the infectivity of ACEV. Clearly, spindles are not required for pathogenicity as evidenced by their absence from most members of the gammaentomopoxviruses and the orthopteran betaentomopoxviruses. It should be noted that although AMEV is a lepidopteran virus it does not produce spindles or encode a gene for fusolin.

Genome Organization

Genome sizes of the EVs are larger than that of the best-studied CV, VV. The estimated sizes for EV genomes range from 200 to 390 kbp. Two EV genomes have been sequenced, those of AMEV and MSEV. The genome size of AMEV is 232 kbp and of MSEV is 236 kbp. Both genomes are highly A + T-rich, with an A + T content for each genome of approximately 82%, which is in line with DNA melting experiments for EV genomes. In comparison, VV has a genome that is 67% A + T. Both the MSEV and AMEV genomes contain inverted terminal repeats at the ends of the genome.

The organization of the AMEV and MSEV genomes is surprisingly unlike that of the orthopoxviruses. Within the orthopoxviruses there is a core of conserved genes flanked by variable genes involved in pathogenesis and host range. Although many of the same genes are present in EVs, the collinear core is not conserved in either MSEV or AMEV. In fact, it is the lack of conservation of genome organization between AMEV and MSEV, both originally classified as betaentomopoxviruses, that resulted in MSEV being removed from this genus and listed as an unclassified virus.

The available sequence data from the EVs has been included in recent bioinformatics analysis of all available poxvirus sequences. From this analysis, 49 gene families were identified that are conserved across all species of poxviruses. Homologs of the VV G3L gene have recently been identified in AMEV and MSEV, bringing the total of conserved gene families to 50. These 50 genes presumably comprise the minimal complement of genes required for poxvirus function. These conserved gene families include proteins necessary for DNA replication and transcription, polyadenylation of mRNA, and the major structural proteins found within the virion core. An analysis of CVs alone increases the number of conserved genes from 50 to 90. Clearly, the inclusion of the EVs in this type of analysis refines the minimal core of proteins required by a poxvirus.

Replication

Like other poxviruses, EVs complete their life cycle entirely within the cytoplasm of the cell. A number of enzymes required for DNA synthesis and for temporal regulation of RNA expression are encoded by EVs. These include DNA polymerase, RNA polymerase, poly(A) polymerase, topoisomerase, and a number of transcription factors. Replication within the insect host occurs primarily within the fat body. Many EVs then proceed to infect the hemocytes and other tissues. In cell culture, DNA replication occurs between 6 and 12 h post infection (hpi). At the optimum temperature of 27 °C, the life

cycle takes approximately 18–24 h. By 9 hpi, host-cell protein synthesis is shut off. The sites of DNA replication and virion assembly are known as viroplasms or viral factories. Although many virions are packaged into OBs, some are not. Those virions that are not occluded proceed to bud through the cell membrane into the hemocoel of the insect or the cell culture medium *in vitro*. These nonoccluded virus particles are infectious and are thought to be responsible for virus spread with the organism.

RNA production occurs in a temporal fashion with early gene expression occurring from 0 to 6 hpi. Included in the early gene products are transcription factors required for intermediate and late gene production. No intermediate genes have been studied in the EVs, but homologs of several VV intermediate genes are present within both the AMEV and MSEV genomes. Late gene expression appears to follow DNA replication and begins at 9 hpi. The DNA regulatory elements that are present in VV to control this temporal gene expression are present in both AMEV and MSEV, although the functionality of these elements during an EV infection has not been explored. Among the conserved regulatory elements are the TTTTTNT termination sequence at the end of early genes, and the consensus late promoter TAAATG. Similar to the CVs, there is no RNA splicing of EV transcripts.

A unique discovery within the late genes of AMEV is the presence of discrete late transcripts. The late transcripts of VV lack specific 3′ termini, resulting in polydisperse 3′ ends. The rare exceptions to this are several genes that have been identified as having discrete 3′ RNA termini that are formed via cleavage of polydisperse transcripts. A number of major late transcripts of AMEV are discrete in length, unlike what is observed in VV. These include the transcripts for the structural proteins p4a and p4b, the superoxide dismutase, and RAP94, a component of the early RNA polymerase. The spheroidin transcript is also discrete.

Molecular Biology

Since the sequencing of two EV genomes, a number of interesting features of the EVs have come to light. One of these is the apparent absence of some members of the RNA polymerase complex. There are eight components of the RNA polymerase complex in VV and these are conserved among all sequenced CVs. Three of these proteins have no obvious homologs in AMEV and MSEV. Whether these subunits are not required in an insect cell environment or whether their roles are fulfilled by other nonhomologous proteins is not yet clear. Several transcription factor homologs are also missing from the EVs. Together, this might indicate that the EVs regulate transcription in a different fashion from their orthopoxvirus relatives.

In vitro transcription catalyzed by permeabilized AMEV virions requires different conditions from those needed for transcription from VV virions. Unlike VV reactions, which use low levels of detergent and reducing agent, AMEV transcription requires higher levels of reducing agent and the requirement for detergent is less stringent, as transcription can occur in the absence of detergent but not in the absence of reducing agent. AMEV reactions are optimal when an ATP-generating system is present. Such a system is not required for VV virion-mediated transcription. This indicates that the structure of the AMEV virion is different in its response to both reducing agents and detergents. Our attempts to isolate AMEV cores with methodology optimized for the preparation of VV cores has also indicated that key AMEV core proteins partition differently from their VV counterparts.

The transcripts of AMEV are polyadenylated at the 3′ termini, but the composition of the poly(A) polymerase complex appears to be different from that of VV. In VV, poly(A) polymerase is a heterodimer. AMEV has two homologs of the small VV subunit in addition to one homolog of the large subunit. This raises the question of whether both small subunits are involved in polyadenylation or whether there might be tissue or temporal specificity conferred on the complex by the different subunits. It is not clear how common two small poly(A) polymerase subunits are among EVs, since the only other fully sequenced EV (MSEV) only has one small subunit. Spheroidin and other transcripts from EVs have been shown to contain a nonencoded 5′ poly(A) head similar to that reported for a number of VV transcripts.

Protein gel analysis of ^{35}S-labeled virions indicates that AMEV contains 36–37 structural proteins and MSEV contains 39–45. The proteolytic processing of the large structural proteins that is detected in VV infections has not been found in EV infections. The enzymes thought to be responsible for this proteolytic cleavage in VV are the products of the I7L and G1L genes. These genes are conserved in AMEV and MSEV, indicating that protein processing may occur even though it is as yet undetected.

Both AMEV and MSEV encode an NAD^+-dependent DNA ligase. In contrast, VV encodes an ATP-dependent DNA ligase. The AMEV DNA ligase is capable of joining singly nicked DNA fragments. These are the first examples of an NAD^+-dependent DNA ligase outside of the eubacteria. The recently sequenced crocodile poxvirus has also been reported to encode an NAD^+-dependent DNA ligase.

Poxviruses are known for the wide variety of proteins that they encode to evade the host immunomodulatory response. VV and other orthopoxviruses encode serine protease inhibitors as well as chemokine binding molecules and decoy receptor molecules. Due to the host range of the

EVs, they encode other types of defense molecules. Among these are the *inhibitor of apoptosis* (*iap*) genes. The *iap* of AMEV has been well characterized and functionally inhibits apoptosis. A related AMEV gene that functions to inhibit apoptosis is a homolog of the baculovirus pan-caspase inhibitor, p35.

Another novel protein expressed by AMEV is a Cu–Zn superoxide dismutase (SOD). Although a number of the orthopoxviruses encode genes with homology to this class of SODs, neither the VV or myxoma virus proteins are functional in that capacity, although they are present within the virion. The SOD expressed by AMEV is functional as an SOD but is not essential for virus growth in culture. The deletion of the *sod* gene from AMEV appears to have no effect on the growth of the virus in gypsy moth larvae.

Summary

It is clear that this large subfamily of the family *Poxviridae* provides a wealth of possible information about the basic mechanisms of the poxvirus lifecycle. There appear to be a number of interesting variations on the molecular details which define this overall family of viruses. There are clear similarities to the vertebrate poxviruses in virion morphology, double-stranded DNA genome, cytoplasmic life cycle, and RNA expression. Yet the differences between the CVs and EVs are significant and represent an area of research that has not been fully explored. The data that have been obtained from genomic sequencing has been essential to identifying some of the different proteins that are present in the EVs, as well as identifying potentially missing homologs of VV proteins. It is important to note that there are large differences at the DNA level between the two sequenced EVs, indicating that there is probably a wide variety of unique features within the EVs as a group. As more sequence information becomes available, the diversity of this family of viruses may become more evident.

Epidemiology of Human and Animal Viral Diseases

F A Murphy, University of Texas Medical Branch, Galveston, TX, USA

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Airborne transmission Transmission via large droplets and via very small droplet nuclei (aerosols) emitted from infected persons during coughing or sneezing or from environmental sources.

Case-control study An epidemiological study in which the risk factors of humans or animals with a disease are compared with those without the disease.

Cohort study Attempt to identify the cause of a disease by comparing exposed and nonexposed (control) populations in a prospective epidemiological study.

Common vehicle transmission Pertains to fecal contamination of food and water supplies.

Direct contact transmission Involves actual physical contact between an infected subject and a susceptible subject (e.g., kissing, biting, coitus).
Epidemic Major increase in disease incidence affecting either a large number of humans or animals or spreading over a large area.
Epidemiology The study of the determinants, dynamics, and distribution of diseases in populations.
Fomite An inanimate object that may be contaminated with virus and become the vehicle for transmission.
Herd immunity The immune status of a population that affects viral transmission rates. Often used in describing the elimination of a virus from a population when there are too few susceptible hosts remaining to sustain a transmission chain.
Horizontal transmission The transfer of infectious virus from one human or animal to another by any means other than vertical transmission.
Iatrogenic transmission Transmission via health care procedures, materials, and workers (e.g., physicians, nurses, dentists, veterinarians).
Incidence rate (or attack rate) A measure of the occurrence of infection or disease in a population over time – it refers to the proportion of a population contracting a particular disease during a specified period.
Mathematical model (epidemiological) A means to convey quantitative information about a host-virus interaction, such as an epidemic or an emerging disease episode, by the construction of a set of predictive mathematical algorithms.
Nosocomial transmission Pertains to infections acquired while a patient, human or animal, is in hospital.
Prevalence rate The ratio, at a particular point in time, of the number of cases currently present in the population divided by the number of subjects in the population at risk; it is a snapshot of the occurrence of infection or disease at a given time.
Species jumping (or host range extension) Referring to a virus that derives from an ancient reservoir life cycle in animals, but has subsequently established a new life cycle in humans or a different animal species and no longer uses, the original animal reservoir.
Transmission The process by which a pathogen is shed from one host and infects the next.
Vector-borne transmission Involves the bites of arthropod vectors (e.g., mosquitoes, ticks, sandflies).
Vertical or transplacental transmission Occurs from mother to fetus prior to or during parturition, either across the placenta, when the fetus passes through the birth canal, or via colostrum and milk.
Vertical transmission Transmission of virus from parent to progeny through the genome, sperm, or ovum or extracellularly (e.g., through colostrum or across the placenta).
Zoonosis Disease which is naturally transmitted to humans from an ongoing reservoir life cycle in animals or arthropods, without the permanent establishment of a new life cycle in humans.

Introduction

Viral disease epidemiology is the study of the determinants, dynamics, and distribution of viral diseases in populations. The risk of infection or disease in a population is determined by characteristics of the virus, the host, and the host population, as well as behavioral, environmental, and ecological factors that affect virus transmission from one host to another. Epidemiology attempts to meld these factors into a unified whole. The depiction of the interaction of factors favoring the emergence of a viral disease (**Figure 1**), called 'the convergence model', is taken from the US Institute of Medicine study, Microbial Threats to Health, Emergence, Detection and Response (National Academy Press, 2003). At the center is a box representing the convergence of factors leading to 'the black box', reflecting the reality that many unknown interactions are important virologically and epidemiologically.

The foundations of epidemiology predate the microbiological and virological sciences, starting with Hippocrates, the Greek physician and father of medicine, who in the fourth century BC made important epidemiologic observations on infectious diseases. John Snow is called the father of modern epidemiology because he developed excellent quantitative methods while studying the source of a cholera outbreak at the Broad Street pump in London in 1849. Snow was followed by William Farr, who in the 1870s advanced the use of vital statistics and clarified many of the principles of risk assessment and retrospective and prospective studies. Their vision is reflected in the fast-changing science of epidemiology which is now supported by advanced computer technology, sophisticated statistical methods, and very sensitive and specific diagnostic systems.

Assessment of Disease Occurrence and Outcome

By introducing quantitative measurements of disease trends, epidemiology has come to have a major role in improving our understanding of the overall nature of

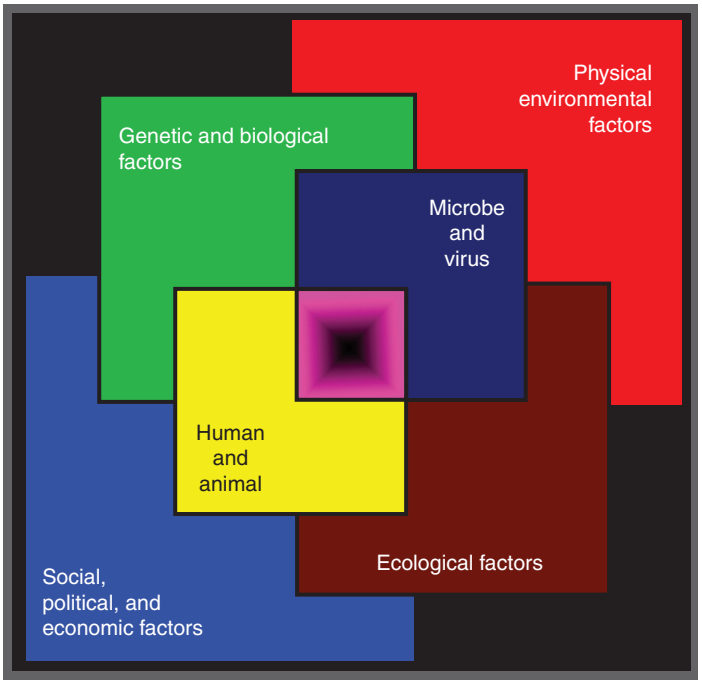

Figure 1 The Convergence Model. Factors contributing to the emergence of viral diseases. At the center is a box representing the convergence of factors leading to the emergence of a viral disease. The black center represents unknown interactions, 'the black box'. Reproduced from: Smolinski MS, Hamburgh MA, and Lederburg J (eds.) (2003) *Microbial Threats to Health, Emergence, Detection and Response*, **Figure 1** p. 3. Washington, DC: National Academies Press. Reprinted with permission from the National Academy Press, copyright (2003), National Academy of Sciences.

disease and in alerting and directing disease control activities. Epidemiology is also effective in (1) clarifying the role of particular viruses and viral variants as the cause of disease, (2) clarifying the interaction of viruses with environmental determinants of disease, (3) determining factors affecting host susceptibility, (4) unraveling modes of transmission, and (5) field testing of vaccines and antiviral drugs.

The comparison of disease experience between populations is expressed in the form of 'rates'. The terms 'incidence rate' and 'prevalence rate' are used to describe quantitatively the frequency of occurrence of infection or disease in populations. 'Incidence rate' (also called attack rate) is defined as the ratio of new cases occurring in a population to the size of the population during a specified period of time. Prevalence rate is the ratio of the total number of cases occurring in a population to the size of the population during a specified period of time. 'Seroprevalence rate' relates to the occurrence of antibody to a particular virus in a population. Because viral antibodies, especially neutralizing antibodies, often last a lifetime, seroprevalence rates usually represent cumulative experience with the virus. The term 'case–fatality rate' is used to indicate the percentage of subjects with a particular disease that die from the disease. All these rates may be affected by various attributes that distinguish one individual from another: age, sex, genetic constitution, immune status, pregnancy, nutritional status, and various behavioral and medical care and patient management parameters. The most widely applicable attribute is age, which may encompass immune status as well as various physiological variables.

A viral disease is characterized as 'endemic' when there are multiple or continuous chains of transmission resulting in continuous occurrence of disease in a population over a period of time. 'Epidemics' are peaks in disease incidence that exceed the endemic baseline or expected rate of disease. The size of the peak required to constitute an epidemic is arbitrary and is related to the background endemic rate and the anxiety that the disease arouses (e.g., a few cases of rabies is regarded as an epidemic, whereas a few cases of influenza is not). A 'pandemic' is a worldwide epidemic.

Epidemiologic Studies

A proper description of an outbreak of disease or an epidemic must include the parameters of 'person (or subjects in the case of animals), place, and time'. Such descriptive information is a necessary first step in describing the occurrence, distribution, course, threat, and anticipated action response to the initial recognition of a cluster of cases of disease. Much of the initial

investigation called for rests in common sense, observational acuity, and an insightful 'index of suspicion'. Much of the initial investigation has been termed 'shoe-leather epidemiology'. The trigger for such initial investigation is most often an astute clinician (physician or veterinarian) or an astute pathologist.

Case-Control Studies and Cohort Studies

There are two basic analytic techniques used to investigate relationships between cause and effect and to evaluate risk factors of disease. These are the 'case-control study' and the 'cohort study'. In the case-control study, investigation starts after the disease has occurred – it is a retrospective study, going back in time to determine causative events. Although this kind of study does not require the creation of new data or records, it does require careful selection of the control group, matched to the test group so as to avoid bias. The retrospective case-control study lends itself to quick analysis and is relatively inexpensive to carry out. In the cohort study, the prospective study, investigation entails the gathering of new data to identify cause–effect relationships. This kind of study is expensive and does not lend itself to quick analysis as groups must be followed until disease is observed. However, when cohort studies are successful, proof of cause–effect relationship is often incontrovertible.

Molecular Epidemiologic Studies

The term 'molecular epidemiology' is used to denote the use of any of a large number of molecular biological methods in support of epidemiologic investigations. For example, with herpesviruses, restriction endonuclease mapping has provided a means of identification of unique viral genotypes – in an epidemiologic study recognized as the first based upon viral molecular characterization, the source of herpes simplex virus 1 causing disease in a hospital newborn nursery was traced to one persistently infected nurse rather than any of several other possible shedders. With rotaviruses and bluetongue viruses, polyacrylamide gel electrophoresis of the segmented viral RNA has been used epidemiologically, for example, to unravel outbreaks involving multiple viral variants. Panels of monoclonal antibodies have been used to distinguish virus variants for epidemiologic purposes; they have been particularly useful in elucidating host-range and geographic variants of rabies virus. Today, partial sequencing has become the most commonly used molecular epidemiologic methodology; partial sequencing of poliovirus isolates recovered from patients indicates whether they are wild type (even local or introduced wild type), attenuated vaccine type, or a vaccine type that has reacquired neurovirulence during human passage. Partial sequencing of foot-and-mouth disease viruses can offer the same kind of geographic information of virus movement as has proved so useful in polio control and eradication programs, but because of political sensitivities in some countries a robust international reference laboratory system has not been established that could provide the same kind of practical disease control information as has been the case with polio. Thus, with many human and animal viruses molecular epidemiologic studies are flourishing, but more such studies should lead to international reference laboratory systems to guide prevention and control actions. Such studies are developing rapidly today to deal with the threat of a human pandemic of avian influenza, but there are many more viral diseases, especially animal diseases, in need of this kind of development.

Etiologic Studies and the Proof of Causation

One of the landmarks in the history of infectious diseases was the development of the Henle-Koch postulates which established the evidence required to prove a causal relationship between a particular infectious agent and a particular disease. These simple postulates were originally drawn up for bacteria, but were revised in 1937 by Rivers and again in 1982 by Evans in attempts to accommodate the special problem of proving disease causation by viruses (**Table 1**). In many cases, virologists have had to rely on indirect evidence, 'guilt by association', with associations based on epidemiologic data and patterns of serologic positivity in populations. Today, many aspects of epidemiologic investigation play roles, especially in trying to distinguish an etiological, rather than coincidental or opportunistic relationship between a virus and a given disease.

For example, early in the investigation of human acquired immunodeficiency syndrome (AIDS), before its etiology was established, many kinds of viruses were being isolated from patients and many candidate etiologic agents were being advanced. Prediction that the etiologic agent would turn out to be a member of the family *Retroviridae* was based upon years of veterinary research on animal retroviruses and animal retroviral diseases. This prediction was based upon recognition of common biologic and pathogenetic characteristics of AIDS and animal retroviral diseases. This prediction guided many of the early experiments to find the etiologic agent of AIDS; later, after human immunodeficiency virus (HIV1) was discovered, its morphological similarity to equine infectious anemia virus, a prototypic member of the genus *Lentivirus*, family *Retroviridae*, was the key to unraveling confusion over the fact that the human virus killed host lymphocytes rather than transforming them as typical oncogenic retroviruses would do. Ever since, this essence of comparative medicine has been guiding HIV/AIDS research in many areas, including drug design,

Table 1 Criteria for disease causation: a unified concept appropriate for viruses as causative agents of disease, based on the Henle–Koch postulates, and modified by A. S. Evans

1. Prevalence of the disease is significantly higher in subjects exposed to the putative virus than in those not so exposed.
2. Incidence of the disease is significantly higher in subjects exposed to the putative virus than in those not so exposed (prospective studies).
3. Evidence of exposure to the putative virus is present more commonly in subjects with the disease than in those without the disease.
4. Temporally, the onset of disease follows exposure to the putative virus, always following an incubation period.
5. A regular pattern of clinical signs follows exposure to the putative virus, presenting a graded response, often from mild to severe.
6. A measurable host-immune response, such as an antibody response and/or a cell-mediated response, follows exposure to the putative virus. In those individuals lacking prior experience, the response appears regularly, and in those individuals with prior experience, the response is anamnestic.
7. Experimental reproduction of the disease follows deliberate exposure of animals to the putative virus, but nonexposed control animals remain disease free. Deliberate exposure may be in the laboratory or in the field, as with sentinel animals.
8. Elimination of the putative virus and/or its vector decreases the incidence of the disease.
9. Prevention or modification of infection, via immunization or drugs, decreases the incidence of the disease.
10. ''The whole thing should make biologic and epidemiologic-sense.''

diagnostics, and vaccine development. HIV/AIDS epidemiologic research has often been intertwined with research on the several simian immunodeficiency viruses (SIVs).

Seroepidemiologic Studies

Seroepidemiology is useful in public health and animal health investigations and in research to determine the prevalence or incidence of particular infections, to evaluate control and immunization programs, and to assess past history when a 'new' virus is discovered. When paired serum specimens are obtained from individuals several weeks apart, the initial appearance of antibody in the second specimen or a rise in antibody titer indicates recent infection. Similarly, the presence of specific immunoglobulin M (IgM) antibody in single serum samples, indicating recent infection, may be used in seroepidemiologic studies. Correlation of serologic tests with clinical observations makes it possible to determine the ratio of clinical to subclinical infections.

Sentinel Studies

Because of advanced diagnostic/serologic methods, sentinel studies can yield many valuable data in timely fashion about impending disease risks. For example, sentinel chicken flocks are set out for the early detection of the presence of arboviruses such as West Nile virus in the United States. These flocks are bled and tested weekly for the presence of virus or antiviral antibody; they provide an early warning of the levels of virus amplification that occur before epidemics.

Vaccine Trials

The immunogenicity, potency, safety, and efficacy of vaccines are first studied in laboratory animals, followed by small-scale closed trials, and finally in large-scale open trials. Such studies employ epidemiologic methods, rather like those of the cohort (prospective) study. In most cases, there is no alternative way to evaluate new vaccines, and the design of trials has now been developed so that they yield maximum information with minimum risk and acceptable cost.

Virus Transmission among Individuals

Viruses survive in nature only if they are able to be transmitted from one host to another, whether of the same or another species. Transmission cycles require virus entry into the body, replication, and shedding with subsequent spread to another host.

Virus Entry

Portals of virus entry into the body include the skin, respiratory tract, intestinal tract, oropharynx, urogenital tract, and conjunctiva. In some cases, viruses use a particular portal of entry because of particular environmental or host-behavior factors and in other cases because of specific viral ligands and host-cell receptors. In many cases, disruption of normal host-defense mechanisms leads to entry that might otherwise be thwarted; for example, papillomaviruses may enter the deep layers of the skin via abrasions, acid-labile coronaviruses may enter the intestine protected by the buffering capacity of milk, and influenza viruses may enter the lower respiratory tract because a drug has dampened cilial action of the respiratory epithelium.

Virus Shedding

The exit of virus from an infected host is just as important as entry in maintaining its transmission cycle. All portals used by viruses to gain entry are used for exit. The

important elements in virus shedding are virus yield (from the standpoint of the virus, the more shedding the better) and timeliness of yield (again, the earlier the shedding the better). Viruses that cause persistent infections often employ remarkable means to avoid host inflammatory and immune responses so as to continue shedding. For example, the epidemiologically important shedding of herpes simplex viruses 1 and 2 that perpetuates the viruses in populations requires recrudescence of persistent ganglionic infection, centrifugal viral genomic transit to peripheral nerve endings, and productive infection of mucosal epithelium, all in the face of established host immunity.

Modes of Virus Transmission

Virus transmission may be 'horizontal' or 'vertical'. The vast majority of transmission is horizontal, that is, between individuals within the population at risk. Modes of horizontal transmission of viruses can be characterized as direct contact, indirect contact, common vehicle, airborne, vector-borne, iatrogenic, and nosocomial. Vertical or transplacental transmission occurs between the mother and her fetus or newborn. Some viruses are transmitted in nature via several modes, others exclusively via one mode (see **Table 2**).

'Direct contact transmission' involves actual physical contact between an infected subject and a susceptible subject (e.g., kissing, Epstein–Barr virus, the cause of mononucleosis, biting (e.g., rabies); coitus (sexually transmitted viral diseases)). Indirect contact transmission occurs via 'fomites', such as shared eating utensils, improperly sterilized surgical equipment, or improperly sterilized non-disposable syringes and needles.

'Common vehicle transmission' pertains to fecal contamination of food and water supplies (e.g., norovirus diarrhea). Common vehicle transmission commonly results in epidemic disease.

'Airborne transmission' typically results in respiratory infections (and less typically in intestinal infections), but these infections may also be transmitted by direct and

Table 2 Examples of human and animal virus transmission patterns

Infectious agent/disease	*Mode of transmission*	*Portal of entry*
Influenza virus/influenza	Contact/direct/indirect via droplets and droplet nuclei	Respiratory tract
Rhinoviruses/common cold	Contact/direct/indirect via droplets and droplet nuclei and fomites	Respiratory tract
Rubella virus/congenital rubella	Contact/direct/indirect via droplets and droplet nuclei	Respiratory tract
	Vertical/congenital	Transplacental
Rotaviruses/diarrhea	Contact/direct/indirect via fomites	Intestinal tract (oral)
Poliovirus/poliomyelitis	Contact/direct/indirect via fomites	Intestinal tract (oral)
Norovirus/diarrhea	Common vehicle/fecal contamination of water	Intestinal tract (oral)
Hepatitis A virus/hepatitis	Common vehicle/fecal contamination of food	Intestinal tract (oral)
Variant Creutzfeldt–Jakob disease prion/prion disease (spongiform encephalopathy)	Common vehicle/bovine spongiform encephalopathy prion contamination of beef or beef products	Intestinal tract (oral)
Herpes simplex virus/genital herpes	Contact/direct (sexual)	Genital tract
Human immunodeficiency virus 1/acquired immunodeficiency syndrome (AIDS)	Contact/direct (sexual), contact/direct (blood) Vertical/congenital	Genital tract, bloodstream, transplacental, at birth and via breast feeding

Sin Nombre and related viruses	Zoonotic/contact/direct (rodent urine, saliva and feces)	Respiratory tract
Lassa virus	Zoonotic/contact/direct (rodent urine, saliva and feces)	Respiratory tract and intestinal tract (oral)
Ebola and Marburg viruses	Zoonotic/reservoir host unknown; secondary cases contact/direct/nosocomial and iatrogenic	Index cases unknown, likely respiratory tract or skin and mucous membranes; secondary cases, contact and iatrogenic (injection)
Leukemia viruses/leukemias (proven only in animals)	Vertical/germ-line	Transmitted as genetic trait

indirect contact. Airborne transmission occurs via large droplets and via very small droplet nuclei (aerosols) emitted from infected persons during coughing or sneezing (e.g., influenza) or from environmental sources. Large droplets (>10 μm in diameter) settle quickly, but droplet nuclei evaporate forming dry particles (<5 μm in diameter) which remain suspended in the air for extended periods. Droplets may travel only a meter or so while droplet nuclei may travel over much longer distances.

'Vector-borne transmission' involves the bites of arthropod vectors (e.g., mosquitoes, ticks, and sandflies).

'Iatrogenic transmission' involves health care procedures, materials, and workers (e.g., physicians, nurses, dentists, and veterinarians).

'Nosocomial transmission' pertains to infections acquired while a patient, human or animal, is in hospital.

'Vertical or transplacental transmission' occurs from mother to fetus prior to or during parturition. Certain retroviruses are vertically transmitted in animals via the integration of viral DNA directly into the DNA of the germline of the fertilized egg. Other viruses are transmitted to the fetus across the placenta; yet others are transmitted when the fetus passes through the birth canal. Another vertical transmission route is via colostrum and milk. Vertical transmission of a virus may or may not be associated with 'congenital disease' (i.e., disease that is present at birth) which may be lethal (and the cause of abortion or stillbirth) or the cause of congenital abnormalities. The herpesviruses, especially cytomegaloviruses, and rubella virus cause important congenital diseases in humans, and pestiviruses, such as bovine viral diarrhea virus, in animals.

Common Patterns of Virus Transmission

Enteric infections are most often transmitted by direct contact and by fomites in a 'fecal–oral cycle' that may include fecal contamination of food and water supplies; diarrheic feces may also splash to give rise to aerosols (droplets and droplet nuclei). Respiratory infections are most often transmitted by the airborne route or by indirect contact via fomites in a 'respiratory cycle', that is, virus is shed in respiratory secretions and enters its next host through the nares during inhalation. The respiratory cycle is responsible for the most explosive patterns of epidemic disease in humans and all domestic animal species.

Perpetuation of Viruses in Nature

Perpetuation of a virus in nature depends upon the maintenance of serial infections, that is, a chain of transmission; the occurrence of disease is neither required nor necessarily advantageous.

Influence of the Clinical Status of the Host

Infection without recognizable disease is called 'subclinical' or 'clinically inapparent'. Overall, subclinical infections are much more common than those that result in disease. Their relative frequency accounts for the difficulty of tracing chains of transmission, even with the help of laboratory diagnostics. Although clinical cases may be somewhat more productive sources of virus than subclinical infections, because the latter do not restrict the movement of the infected host, they can be most important as sources of viral dissemination. In most acute infections, whether clinically apparent or not, virus is shed in highest titers during the late stages of the incubation period, before the influence of the host-immune response takes effect. Persistent infections, whether or not they are associated with episodes of clinical disease, also play an important role in the perpetuation of many viruses in nature. For example, prolonged virus shedding can reintroduce virus into a population of susceptibles all of which have been born since the last clinically apparent episode of infection. This is important in the survival of rubella virus in some isolated populations. Sometimes the persistence of infection, the production of disease, and the transmission of virus are dissociated; for example, togavirus and arenavirus infections may have little adverse effect on their reservoir hosts (arthropods, birds, and rodents), but transmission may be very efficient. On the other hand, the persistence of infection in the central nervous system, as with measles virus in subacute sclerosing panencephalitis (SSPE), is of no epidemiological significance, since no infectious virus is shed from this site.

Influence of Virulence of the Virus

The virulence of the infecting virus may directly affect the probability of its transmission. The classic example of this is rabbit myxomatosis. In Australia, mosquito-borne transmission of myxoma virus was found to be most effective when infected rabbits maintained highly infectious skin lesions for several days before death. Highly virulent strains of the virus were found to kill rabbits so quickly that transmission did not occur, and naturally attenuated strains were found to produce minimal lesions that healed quickly and did not permit transmission. Virus strains at either extreme of this virulence spectrum were found not to survive in nature, but virus strains of intermediate virulence have circulated for many years.

Influence of Host Population Immunity

With most viruses, endemic or epidemic transmission leads to a level of immunity in the host population that affects or even interrupts further transmission. The 'herd immunity' effect is countered in some cases by viral

antigenic variation. For example, influenza viruses undergo genetic variations ('shift' and 'drift') such that persons immune to previously circulating virus strains are susceptible to new strains. Assessing these genetic changes is the main objective of laboratory-based surveillance programs, which in turn are the basis for decisions on the formulation of each year's influenza vaccine.

Influence of Population Size

It is self-evident that the long-term survival of a virus requires that it be continuously transmitted from one host to another. In general, for rapidly and efficiently transmitted viruses such as many respiratory viruses, local survival of the virus requires that the susceptible host population be very large. A virus may disappear from a population because it exhausts its potential supply of susceptible hosts as they acquire immunity to reinfection with the same virus. Depending on duration of immunity and the pattern of virus shedding, the 'critical population size' varies considerably with different viruses and with different host species. The most precise data on the importance of population size in acute nonpersistent infections come from studies of measles. Persistence of measles virus in a population depends upon a continuous supply of susceptible children. Analyses of the incidence of measles in large cities and in island communities have shown that a population of about half a million persons is needed to ensure a large enough annual input of new susceptible hosts, by birth or immigration, to maintain measles virus in the population. Because infection depends on respiratory transmission, the duration of epidemics of measles is correlated inversely with population density. If a population is dispersed over a large area, the rate of spread is reduced and the epidemic may last longer, so that the number of susceptible persons needed to maintain transmission chains is reduced. On the other hand, in such a situation a break in the transmission chain is much more likely. When a large proportion of the population is initially susceptible, the intensity of the epidemic builds up very quickly and attack rates are almost 100% ('virgin-soil epidemic'). On the other hand, when measles vaccination programs are implemented properly the virus disappears completely from the regional population.

Influence of Zoonotic Transmission Cycles

Because most viruses are host-restricted, most viral infections are maintained in nature within populations of the same or related species. However, there are a number of viruses that may have multiple hosts and spread naturally between several different species of vertebrate host, for example, rabies and eastern equine encephalitis viruses. The term 'zoonosis' is used to describe multiple-host infections that are transmissible from animals to man. The zoonoses, whether involving domestic or wild animals or arthropods, usually represent important problems only under conditions where humans are engaged in activities involving close contact with animals or exposure to arthropods.

Influence of Arthropod Transmission Cycles

Many viral zoonoses are caused by arboviruses. Arboviruses have two classes of hosts, vertebrate and invertebrate. Over 500 arboviruses are known, of which about 100 cause disease in humans and 40 in domestic animals; some of these are transmitted by ticks, some by mosquitoes, and yet others by phlebotomine flies (sandflies) or *Culicoides* spp. (midges). Arthropod transmission may be 'mechanical', where the arthropod acts as a 'flying pin', or more commonly, 'biological', involving replication of the virus in the arthropod vector. The arthropod vector acquires virus by feeding on the blood of a viremic person or animal. Replication of the ingested virus, initially in the arthropod's gut, and its spread to the salivary glands takes several days; the interval varies with different viruses and is influenced by ambient temperature. Virions in the salivary secretions of the vector are injected into human or animal hosts during subsequent blood meals. Most arboviruses have localized natural habitats in which specific receptive arthropod and vertebrate hosts are involved in the viral life cycle. Vertebrate reservoir hosts are usually wild mammals or birds; humans are rarely involved in primary transmission cycles, although the exceptions to this generalization are important (e.g., Venezuelan equine encephalitis, yellow fever, and dengue viruses). Humans are in most cases infected incidentally, for example, by the geographic extension of a reservoir vertebrate host and/or a vector arthropod. Ecological changes produced by human activities disturb natural arbovirus life cycles and have been incriminated in the geographic spread or increased prevalence of arbovirus diseases.

Mathematical Modeling

From the time of William Farr, who studied epidemic disease problems in the 1870s, mathematicians have been interested in 'epidemic curves' and secular trends in the incidence of infectious diseases. With the development of computer-based mathematical modeling techniques, there has been a resurgence of interest in the population dynamics of infectious diseases. There has also been a resurgence in controversies surrounding the use of models; critics say 'for every model there is an equal and opposite model'. So, the proof of the value of models lies in their practical application, and in recent years there have been more and more successes. For example, when for counterterrorism reasons universal

smallpox vaccination was being considered, models that showed that vaccine could be used effectively after rapid detection of a terrorism incident led to a decision to stockpile, but not widely use vaccine. As another example, when a foot-and-mouth disease epidemic raged in the United Kingdom in 2001, a model showed that only the most vigorous stamping-out campaign could get ahead of the movement of the virus across the country. The model, seeming eminently logical now, importantly provided the kind of veracity and political will needed to accelerate the stamping-out campaign.

Models may be used to determine (1) patterns of disease transmission, (2) critical population sizes to support the continuous transmission of viruses with short and long incubation periods, (3) the dynamics of endemicity of viruses that become persistent in their hosts, and (4) the variables in age-dependent viral pathogenicity. Computer modeling also provides useful insights into the effectiveness of disease control programs. Much attention has been given to modeling the future of the AIDS epidemic in the United States and the rest of the world. Such models usually start with historical data on the introduction of the etiologic virus, HIV1, proceed to the present stage of the epidemic where the disease has become well established in many countries and in fewer countries subject to prevention and treatment strategies, and then proceed to project its course into the future. During the first 10 years of the AIDS epidemic in the United States, African countries, and then in Asian countries, most models underestimated developing trends; more recently models have become more accurately predictive – but in many places more and more sobering.

Implications for Disease Prevention

Knowledge of the epidemiology and modes of transmission of infectious diseases is critical to the development and implementation of prevention and control strategies. Data on incidence, prevalence, and mortality contribute directly to the establishment of priorities for prevention and control programs while knowledge of viral characteristics and modes of transmission are used in deciding prevention strategies focusing on vaccine development and delivery, environmental improvements, enhancement of nutritional status, improvement in personal hygiene, and behavioral changes.

Epstein–Barr Virus: General Features

L S Young, University of Birmingham, Birmingham, UK

© 2008 Elsevier Ltd. All rights reserved.

Taxonomy and Genome Structure

Epstein–Barr virus (EBV; species *Human herpesvirus 4*) is a member of the genus *Lymphocryptovirus*, which belongs to the lymphotropic subfamily *Gammaherpesvirinae* of the family *Herpesviridae.* EBV is closely related to the lymphocryptoviruses (LCVs) present in Old World nonhuman primates, including EBV-like viruses of chimpanzees and rhesus monkeys. These viruses share homologous sequences and genetic organization, and infect the B lymphocytes of their host species, resulting in the establishment of latent infection *in vivo* and transformation

in vitro. A transforming, EBV-related virus has also been isolated from spontaneous B-cell lymphomas of common marmosets and is thus the first EBV-like virus to be identified in New World primates. The genome of this marmoset LCV revealed considerable divergence from the genomes of EBV and Old World primate EBV-related viruses, suggesting that this virus represents a more primitive predecessor of the LCVs infecting higher-order primates.

The EBV genome is composed of linear, double-stranded DNA, approximately 172 kbp in length. EBV has a series of 0.5 kbp terminal direct repeats (TRs) and internal repeat sequences (IRs) that divide the genome into short and long, largely unique sequence domains. EBV was the first herpesvirus to have its genome completely cloned and sequenced. Since the EBV genome was sequenced from an EBV DNA *Bam*HI fragment cloned library, open reading frames (ORFs), genes, and sites for transcription or RNA processing are frequently referenced to specific *Bam*HI fragments, from A–Z, in descending order of fragment size. The virus has the coding potential for around 80 proteins, not all of which have been identified or characterized.

History

In 1958, Denis Burkitt described a lymphoma that represented the most common tumor affecting children in certain parts of East Africa. The geographical distribution of this malignancy suggested that the development of Burkitt lymphoma (BL) might be due to an infectious agent possibly related to malaria. In 1964, the successful establishment of cell lines from explants of BL enabled Tony Epstein and Yvonne Barr to identify herpesvirus-type particles by electron microscopy within a subpopulation of tumor cells *in vitro* (**Figure 1**). Werner and Gertrude Henle subsequently demonstrated that BL-derived cell lines expressed antigens that were recognized not only by sera from patients with BL but also by sera from patients with infectious mononucleosis (IM). Similar seroepidemiological studies also suggested a link between infection with this virus (now called Epstein– Barr virus after its discoverers) and undifferentiated nasopharyngeal carcinoma (NPC), leading to the subsequent direct demonstration of EBV DNA in the tumor cells of NPC. The ability of EBV to immortalize B lymphocytes efficiently *in vitro* and to induce tumors in nonhuman primates established this virus as a putative oncogenic agent in humans. Over the last 20 years EBV has been implicated in a variety of other lymphoid and epithelial malignancies (**Table 1**).

Geographic and Seasonal Distribution

EBV is ubiquitous, being found as a widespread and largely asymptomatic infection in all human communities.

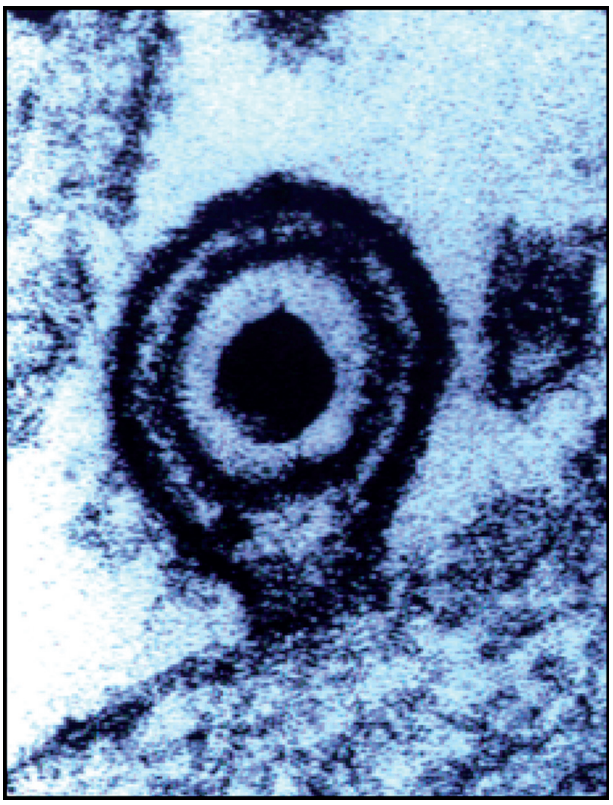

Figure 1 Electron micrograph of the Epstein–Barr virus virion.

Table 1 EBV-associated tumors

Tumor	*Subtype*	*EBV genome +ve (%)*
Burkitt's lymphoma	Endemic	100
	Sporadic	10–20
	AIDS	30–40
Nasopharyngeal carcinoma	Undifferentiated	100
	SCC	10–40
Hodgkin's disease	Mixed cellularity	>80
	Nodular sclerosing	30–40
	Lymphocyte predominant	<10
T-cell lymphoma	Nasal	100
	Others	10–40
Immunoblastic lymphoma	Transplant	100
	AIDS	>90

Primary infection often occurs early in life, particularly in tropical areas and in persons of lower socioeconomic class. Thus, in tropical Africa and New Guinea primary EBV infection is common in the first year of life whereas in Western communities infection is continually acquired throughout childhood and early adulthood. Although the EBV-associated malignancies BL and NPC exhibit an unusual geographic distribution, this appears not to be due to differences in EBV infection but due to additional cofactors.

Host Range and Virus Propagation

Humans are the natural host for EBV infection. EBV has a unique ability to transform resting B cells into permanent, latently infected, lymphoblastoid cell lines (LCLs) in which every cell carries multiple copies of circular, extra chromosomal, viral DNA (episomes) and produces a number of latent proteins, including six EBV-encoded nuclear antigens (EBNAs 1, 2, 3A, 3B, 3C, and -LP) and three latent membrane proteins (LMPs 1, 2A, and 2B); this form of infection is referred to as latency III. When peripheral blood lymphocytes from healthy EBV seropositives are placed in culture, the few EBV-infected B lymphocytes that are present regularly give rise to spontaneous outgrowth of EBV-transformed LCLs, provided that immune T lymphocytes are either removed or inhibited by the addition of cyclosporin A to the culture. LCLs can also be generated by direct infection of resting B lymphocytes with EBV derived from the throat washings of seropositive individuals or from producer B-cell lines. LCLs have provided an invaluable, albeit incomplete, model of the lymphomagenic potential of EBV.

Certain nonhuman primates, particularly the cotton-top tamarin, have been used as experimental hosts for EBV, but virus infection in these animals is associated with the induction of lymphomas. LCLs generated by EBV transformation of cotton-top tamarin B lymphocytes *in vitro* spontaneously produce large amounts of virus compared with their human counterparts and as such have been used as a source of EBV; for example, the prototype strain of EBV is B95.8, which is produced from a tamarin LCL originally immortalized with EBV from a patient with IM. However, the lack of a fully permissive system for propagating EBV *in vitro* has hampered our understanding of virus replication and prevented the generation of EBV mutants. Over recent years a number of systems have been developed for the generation of recombinant forms of EBV which rely on the manipulation of the entire virus genome within bacteria followed by rescue and propagation in human cells.

Genetics and Strain Variation

EBV isolates from different regions of the world or from patients with different virus-associated diseases are remarkably similar when their genomes are compared by restriction fragment length polymorphism analysis. However, variations in repeat regions of the EBV genome are observed among different EBV isolates. Analysis of the EBV genome in a number of BL-cell lines revealed gross deletions, some of which account for biological differences. For example, P3HR-1 virus, which is nontransforming, has a deletion of the EBNA2-encoding gene. Strain variation over the EBNA2-encoding (*Bam*HI WYH) region of the EBV genome permits all virus isolates to be classified as either 'type 1' (EBV-1, B95.8-like) or 'type 2' (EBV-2, Jijoye-like). This genomic variation results in the production of two antigenically distinct forms of the EBNA2 protein that share only 50% amino acid sequence homology. Similar allelic polymorphisms (with 50–80% sequence homology depending on the locus) related to the EBV type occur in a subset of latent genes, namely those encoding EBNA-LP, EBNA3A, EBNA3B, and EBNA3C. These differences have functional consequences as EBV-2 isolates are less efficient in *in vitro* B-lymphocyte transformation assays compared with EBV-1 isolates. A combination of virus isolation and seroepidemiological studies suggest that type 1 virus isolates are predominant (but not exclusively so) in many Western countries, whereas both types are widespread in equatorial Africa, New Guinea, and perhaps certain other regions.

In addition to this broad distinction between EBV types 1 and 2, there is also minor heterogeneity within each virus type. Individual strains have been identified on the basis of differences compared with B95.8, ranging from single-base mutations to extensive deletions. While infection with multiple strains of EBV was originally thought to be confined to immunologically compromised patients, more recent studies demonstrate that normal healthy seropositives can be infected with multiple EBV isolates and that their relative abundance and presence appears to vary over time. Coinfection of the host with multiple virus strains could have evolutionary benefit to EBV, enabling the generation of diversity by genetic recombination. Such intertypic recombination has been demonstrated in human immunodeficiency virus (HIV)-infected patients and appears to arise via recombination of multiple EBV strains during the intense EBV replication that occurs as a consequence of immunosuppression.

The possible contribution of EBV strain variation to virus-associated tumors remains contentious. Many studies have failed to establish an epidemiological association between EBV strains and disease and suggest that the specific EBV gene polymorphisms detected in virus-associated tumors occur with similar frequencies in EBV isolates from healthy virus carriers from the same geographic region. However, this does not exclude the possibility that variation in specific EBV genes is responsible for the distinct geographic distribution of virus-associated malignancies. In this regard, an LMP1 variant containing a 10-amino-acid deletion (residues 343–352) was originally identified in Chinese NPC biopsies and has oncogenic and other functional properties distinct from those of the B95.8 LMP1 gene. It is therefore likely that variation in LMP1 and other EBV genes can contribute to the risk of developing virus-associated tumors, but more biological studies using well-defined EBV variants are required.

Evolution

EBV, like other herpesviruses, has probably evolved with humans. The relatedness of the LCVs at both the genomic and protein levels does not correlate with the evolutionary relatedness of their Old World primate hosts. This implies that the selective pressures governing the evolution of these viruses are different from those responsible for the evolution of primate species. It has been suggested that the specific tissue tropism of LCVs may have constrained their evolutionary divergence. A comparison of marmoset LCV with the LCVs present in Old World primates provides some insight into LCV evolution approximately 35 million years before the appearance of EBV. The acquisition of accessory genes by Old World LCVs supports the contention that these viruses have coevolved with their hosts possibly as a means of maintaining their biological properties.

The evolutionary relationship between the type 1 and type 2 strains of EBV remains obscure. They may have evolved from a common progenitor virus or through recombination of the ancestral LCVs infecting Old World primates. The pronounced (but not exclusive) segregation of EBV-2 isolates within equatorial regions suggests that environmental factors (including immunological competence) may have influenced EBV evolution and may still be responsible for the effective competition between EBV-2 isolates and the ubiquitous EBV-1 family.

EBV Primary Infection and Persistence

EBV infects the majority of the world's adult population and, following primary infection, the individual remains a lifelong carrier of the virus (**Figure 2**). In underdeveloped countries, primary infection with EBV usually occurs during the first several months to few years of life and is often asymptomatic. However, in developed populations, primary infection is more frequently delayed until adolescence or adulthood, in many cases producing the characteristic clinical features of IM. EBV is orally transmitted, and infectious virus can be detected in oropharyngeal secretions from IM patients, from immunosuppressed patients, and at lower levels from healthy EBV seropositive individuals. These observations, together with the fact that EBV-transformed LCLs *in vitro* tend to be poor producers of the virus and B lymphocytes permissive of viral replication have not been demonstrated *in vivo*, suggest that EBV replicates and is shed at epithelial sites in the oropharynx and/or salivary glands. This is supported by the demonstration of replicating EBV in the differentiated epithelial cell layers of oral 'hairy' leukoplakia, a benign lesion of the tongue found in immunocompromised patients. However, it is also likely that EBV-infected B cells are reactivated within the local mucosal environment and that this contributes to virus shedding at oropharyngeal sites (**Figure 2**).

The inability to detect EBV routinely in normal epithelial cells and the demonstration that EBV can be completely eradicated by irradiation in bone marrow transplant recipients suggests that B lymphocytes are the main site of EBV persistence (**Figure 2(b)**). This is supported by the B lymphotropism of EBV which is mediated by the binding of the major viral envelope glycoprotein gp350 to the CR2 receptor on the surface of B cells. Virion penetration of the B-cell membrane requires further interactions between the EBV glycoprotein gp42 (which forms a ternary complex with gH and gL viral glycoproteins) and human leukocyte antigen (HLA) class II molecules. It appears that the presence or absence of HLA class II in virus-producing cells influences the tropism of EBV for B cells or epithelial cells by affecting the availability of gp42. Other CR2-independent pathways may be responsible for EBV infection of epithelial cells, including secretory component-mediated immunoglobulin (Ig) A transport, integrin interactions with polarized epithelium, and direct cell-to-cell contact, but these are relatively inefficient and of unknown relevance to EBV infection *in vivo*.

The B-cell tropism of EBV and its ability to establish a latent infection in these cells both *in vitro* and *in vivo* further supports the contention that B lymphocytes are the reservoir of lifelong persistent infection (**Figure 2(b)**). Detailed examination of EBV infection *in vivo* has shown that the virus persists in the $IgD^{-}CD27^{+}$ memory B-cell subset and that these cells have downregulated the expression of most, if not all, viral genes. The precise route of entry of EBV-infected B cells into the memory compartment remains a subject of much debate. This reservoir of infected cells is stably maintained thereafter, apparently subject to the same physiologic controls as the general mucosa-associated memory B-cell pool. EBV persistence within this B-cell population brings with it the possibility of fortuitous antigen-driven recruitment of infected cells into germinal centers (GCs), leading to progeny that either re-enter the circulating memory pool or differentiate to plasma cells that may migrate to mucosal sites. The different forms of latency that are manifest in virus-associated malignancies (discussed below) may represent latency programs that have evolved to accommodate such changes in host cell physiology (**Figure 2**). Thus GC transit appears to activate a latency program where only the genome maintenance protein EBNA1 is expressed (latency 0), while exit from GCs is possibly linked to the transient expression of the EBV-encoded latent membrane proteins, LMP1 and LMP2 (latency II). The ability of these proteins to mimic the key signals required for B cells to undergo a GC reaction, namely T-cell help via the CD40 pathway (constitutively provided by LMP1) and activation of the cognate B-cell receptor (augmented by LMP2A), supports this strategy whereby EBV exploits the physiological process of B-cell differentiation to access and maintain persistent

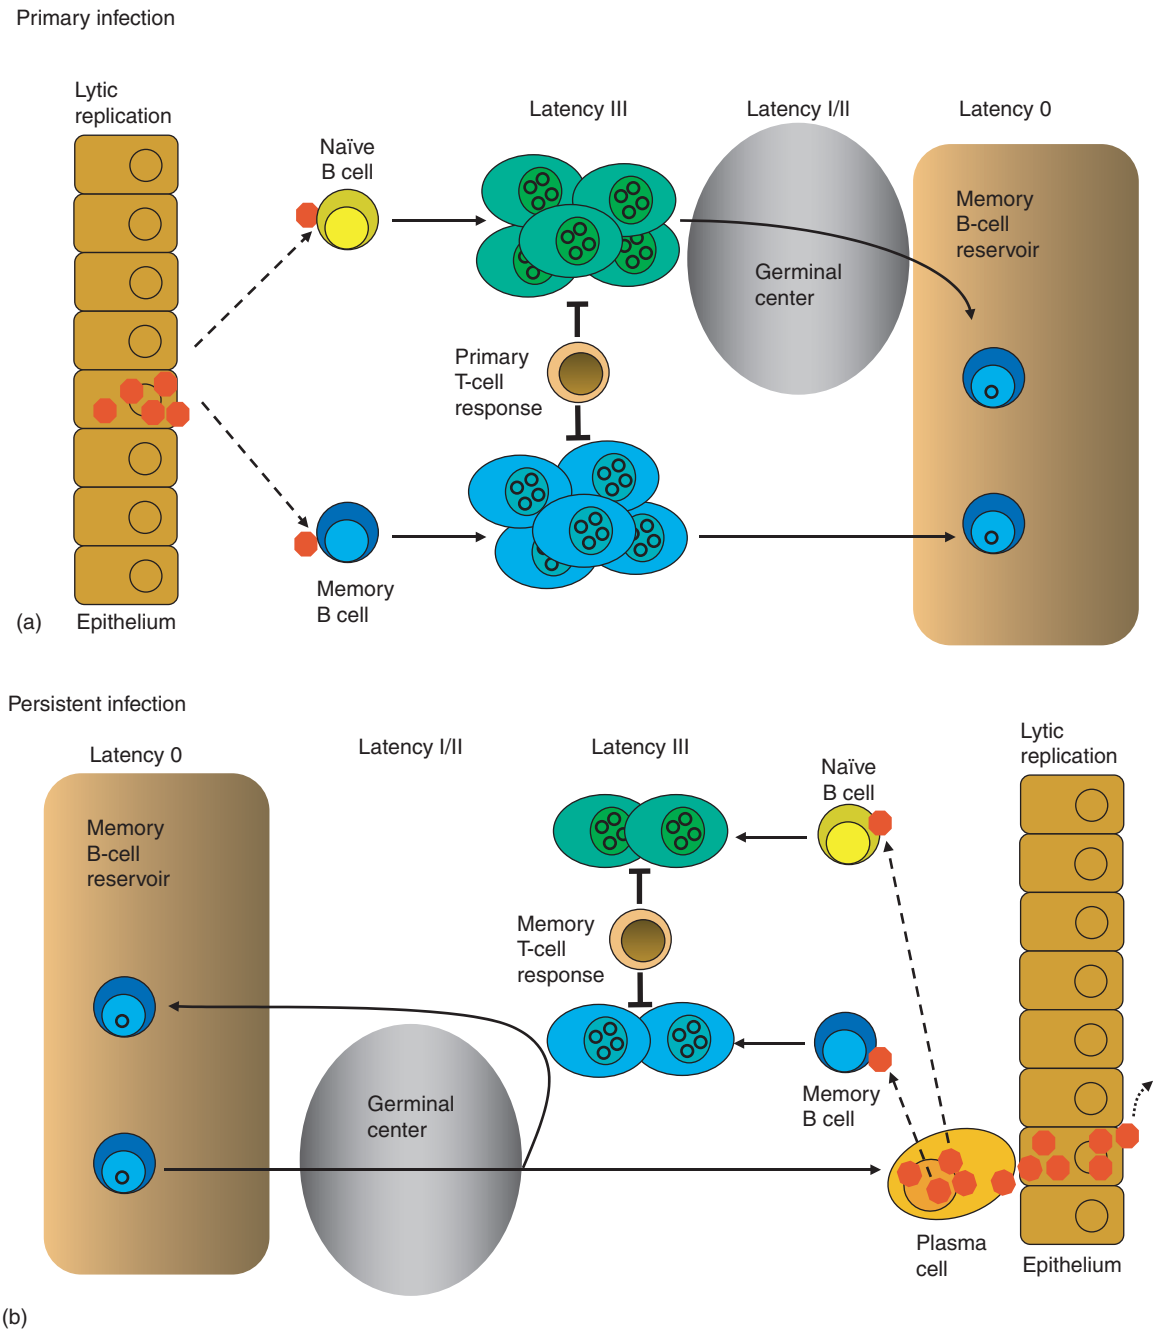

Figure 2 EBV primary infection and persistence. Diagram showing putative *in vivo* interactions between EBV and host cells. (a) Primary infection. EBV replicates in epithelial cells and spreads to lymphoid tissues as a latent growth-transforming (latency III) infection of B cells. Many infected B cells are removed by the emerging EBV-specific T-cell response. Some infected cells escape by downregulating EBV latent genes to establish a stable pool of resting virus-positive memory B cells. (b) Persistent infection. EBV-infected memory B cells become subject to the physiological controls governing memory B-cell migration and differentiation. Occasional recruitment into germinal center (GC) reactions resulting in activation of different EBV latency programs and re-entry into the memory cell reservoir or plasma cell differentiation with activation of virus lytic cycle. Infectious virions then initiate foci of EBV replication in epithelial cells and also new growth-transforming infection of naïve and/or memory B cells.

infection in the memory B-cell pool. The possible commitment of these cells to plasmacytoid differentiation may trigger entry into lytic virus replication, thereby providing a source of low-level virus shedding into the oropharynx. There may also be circumstances in which infected cells in the reservoir can reactivate back to proliferative infections similar to those of an EBV-transformed LCL.

Immune Response

EBV elicits both humoral and cell-mediated immune responses in infected hosts. Primary infection with EBV is associated with the rapid appearance of antibodies to replicative antigens such as viral capsid antigen (VCA), early antigen (EA), and membrane antigen (MA; gp350/220) with a later serological response to EBNA proteins. In IM, these responses are exaggerated and are accompanied by autoantibodies such as rheumatoid factor as well as a heterophile antibody response directed against antigens on the surface of sheep erythrocytes. These autoantibodies are the result of EBV-induced polyclonal B-cell activation. In the chronic asymptomatic virus carrier, antibodies to VCA, MA, and EBNAs are found, the titers of which remain remarkably stable. Of these antibodies, those against MA are particularly important as they have virus-neutralizing ability and can also mediate antibody-dependent cellular cytotoxicity. As discussed below, the levels of these EBV-specific antibodies are elevated in different EBV-associated diseases.

As with other persistent viruses, cell-mediated immunity plays an important role in controlling EBV infection. Primary EBV infection elicits a robust cellular immune response and the lymphocytosis observed in IM is a consequence of the hyperexpansion of cytotoxic CD8+ T cells with reactivities against both latent and lytic viral antigens. These reactivities are subsequently maintained at high level (up to 5% of the total circulating pool) in the CD8+ memory T-cell pool. An EBV-specific CD4+ T-cell response also contributes toward the control of EBV infection and, along with the CD8+ response, appears to be important in preventing the unlimited proliferation of EBV-infected B cells. Thus, impairment of the T-cell response, either by immunosuppressive drug therapy or by HIV infection, is responsible for the development of polyclonal lymphoproliferations that can progress to frank monoclonal non-Hodgkin's lymphomas (see below). These lesions can be controlled by adoptive therapy with EBV-specific T cells. The growth and survival of BL, NPC, and Hodgkin's lymphoma (HL) in immunocompetent individuals implies that the tumor cells can evade EBV-specific T-cell surveillance. This may be achieved by restricting EBV latent gene expression to those viral proteins not efficiently recognized by the T-cell responses (i.e., away from expression of the highly immunogenic EBNA3 family) and/or by downregulation of target cell molecules required for immune recognition such as major histocompatability complex (MHC) class I and the antigen-processing machinery.

EBV-Associated Diseases

Infectious Mononucleosis

Primary infection with EBV in childhood is usually asymptomatic but when delayed until adolescence or early adulthood can manifest clinically as IM, a self-limiting lymphoproliferative disease associated with the hyperexpansion of cytotoxic $CD8^+$ T cells that are reactive to both lytic and latent cycle viral antigens. These reactivities are subsequently maintained in the $CD8^+$ T-cell memory pool at high levels (up to 5% of circulating $CD8^+$ T cells), even in individuals with no history of IM. The incidence of IM is low in developing countries where asymptomatic primary infection predominantly occurs in childhood. In certain poorly defined situations, IM-like symptoms can persist, resulting in chronic active EBV infection associated with elevated antibody titers to virus lytic antigens but low titers to the EBNAs.

Lymphomas in Immunosuppressed Individuals

Patients with primary immunodeficiency diseases such as X-linked lymphoproliferative syndrome (XLP) and Wiscott–Aldrich syndrome are at increased risk of developing EBV-associated lymphomas. Because these tumors are extremely rare, little is known about the precise contribution of EBV and the associated pattern of viral gene expression in these lymphomas. Mortality from XLP is high with around 50% of patients developing fatal IM after primary infection with EBV and an additional 30% of patients developing malignant lymphomas. The defect responsible for XLP is mutation of an adaptor molecule, SAP, which mediates signaling in a wide range of immune cells and is involved, via its interaction with the SLAM family of receptors, in both innate and adaptive immune reactions.

Allograft recipients receiving immunosuppressive therapy and patients with acquired immune deficiency syndrome (AIDS) are also at increased risk for development of EBV-associated post-transplant lymphoproliferative disease (PTLD) and lymphomas. These lesions range from polyclonal EBV-driven lymphoproliferations, much like that observed *in vitro* in virus-transformed LCLs (latency III, **Figure 3**), to aggressive monoclonal non-Hodgkin's B-cell lymphomas (NHLs) in which additional cellular genetic changes (e.g., mutation of p53) are present. The incidence of both PTLD and B-cell lymphomas in allograft recipients varies with the type of organ transplanted and with the type of immunosuppressive regimen used. Allogeneic bone marrow or solid organ transplantation into EBV seronegative children is a particular risk factor for the development of these lesions. A proportion of these lesions in post-transplant patients resolve in response to a reduction in immunosuppression or to targeted therapies such as anti-CD20 monoclonal antibody or adoptive EBV-specific T cells.

The incidence of NHL in AIDS patients is increased approximately 60-fold compared to the normal population. Around 60% of these tumors are large B-cell lymphomas like those found in allograft recipients, 20% are primary brain lymphomas, and 20% are of the BL type. EBV

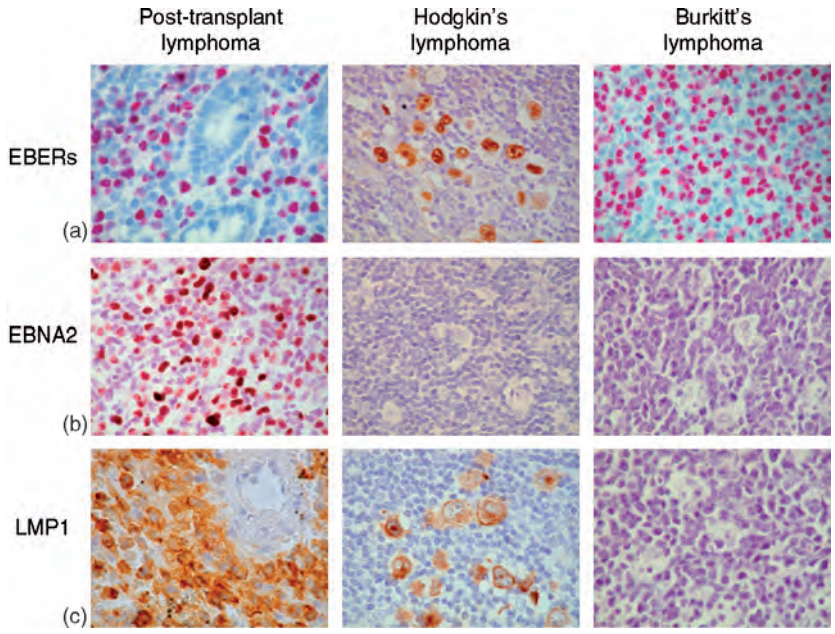

Figure 3 EBV-associated lymphomas display different patterns of virus latent gene expression. While the post-transplant lymphomas associated with EBV infection express a pattern of latent gene expression similar to that observed in virus-transformed B cells *in vitro* (latency III), Hodgkin's lymphoma (HL; Latency II) and Burkitt's lymphoma (BL; Latency I) express more restricted forms of EBV latency. (a) Upper panels show *in situ* hybridization for the abundant nonpolyadenylated EBER transcripts, which are expressed in all forms of EBV latent infection. (b) The middle panels depict immunohistochemical staining for the EBNA2 protein, which is only expressed in post-transplant lymphoma and not either HL or BL. (c) The bottom panels show immunohistochemical staining for the LMP1 protein, which is expressed in post-transplant lymphoma and HL but not in BL.

infection is present in approximately 50% of AIDS-related NHL, nearly all the primary brain and Hodgkin's lymphomas, and around 40% of the BL tumors.

Burkitt's Lymphoma

The endemic form of BL, which is found in areas of equatorial Africa and New Guinea, represents the most common childhood cancer (peak age 7–9 years) in these regions with an incidence of up to 10 cases per 100 000 people per year. This high incidence of BL is associated with holoendemic malaria, thus accounting for the climatic variation in tumor incidence first recognized by Denis Burkitt. More than 95% of these endemic BL tumors are EBV-positive compared with 20% of the low incidence, sporadic form of BL which occurs worldwide. In areas of intermediate BL incidence, such as Algeria and Malaysia, the increased number of cases correlates with an increased proportion of EBV-positive tumors. The pattern of EBV gene expression in BL is generally restricted to EBNA1 and the nonpolyadenylated EBER transcripts (latency I), although broader virus gene expression involving the EBNA3 proteins has been observed in a subset of tumors (**Figure 3**).

A consistent feature of BL tumors, irrespective of geographical location or EBV status, is chromosome translocations involving the long arm of chromosome 8 (8q24) in the region of the c-myc proto-oncogene and either chromosome 14 in the region of the Ig heavy-chain gene or, less frequently, chromosomes 2 or 22 in the region of the Ig light-chain genes. The cell surface phenotype of BL cells and the presence of ongoing Ig gene mutation supports the GC origin of this tumor.

Seroepidemiological studies have demonstrated elevated antibody titers to EBV VCA and EA in BL patients compared to children without the tumor. These elevated antibody titers have been found to precede the development of BL and can therefore be used to screen 'at risk' individuals. Most early cases of BL can be successfully treated using chemotherapeutic regimens that include cyclophosphamide. However, access to drugs and advanced tumor presentation have limited the efficacy of such therapies.

Hodgkin's Lymphoma

Epidemiological studies originally suggested a possible role for EBV in the etiology of HL. Thus, elevated antibody titers to EBV antigens have been detected in HL patients and these are present before the diagnosis of the disease. Furthermore, there is an increased risk of HL following IM. EBV has been demonstrated in around 40% of HL cases with both viral nucleic acid and virus-encoded latent proteins (EBNA1, LMP1, LMP2 – latency

II) localized to the malignant component of HL, the so-called Hodgkin's and Reed–Sternberg (HRS) cells (**Figure 3**). These malignant B cells tend to carry nonproductive Ig genes consistent with their GC origin and implicating EBV infection in the rescue of these crippled cells from their usual apoptotic fate. The association of HL with EBV is age-related; pediatric and older adult cases are usually EBV-associated whereas HL in young adults is less frequently virus-positive. The proportion of EBV-positive HL in developing countries is high, consistent with a greater incidence of HL in children and more frequent prevalence of the mixed cellularity histiotype; the histological subtype of HL in which EBV infection is most frequently detected. Although the incidence of HL is relatively low (1–3 per 100 000 per year), this tumor is not geographically restricted, making its association with EBV significant in world health terms.

Virus-Associated T-Cell and NK-Cell Lymphomas

EBV-positive monoclonal lymphomas of either CD4+ or CD8+ T-cell origin are more frequently found in Southeast Asian populations, arising as a consequence of either virus-associated haemophagocytic syndrome (VAHS) or in the setting of chronic active EBV infection. A more aggressive extranodal tumor predominantly expressing the CD56 natural killer (NK) cell marker is also EBV positive and manifests as an erosive lesion (lethal midline granuloma) of the nasal cavity.

Nasopharyngeal Carcinoma

The association of EBV with undifferentiated NPC (WHO type III) was first suggested by serological evidence and then confirmed by the demonstration of EBV DNA in NPC biopsy material. NPC is particularly common in areas of China and southeast Asia, reaching a peak incidence of 20–30 cases per 100 000 per year. Incidence rates are particularly high in Cantonese males, highlighting an important genetic predisposition as well as a role for environmental cofactors such as dietary components (e.g., salted fish). NPC tumors are characterized by a prominent lymphoid stroma, and the interaction between these activated lymphocytes and adjacent carcinoma cells appears to be crucial for the continued growth of the malignant component. EBV latent gene expression in NPC is restricted to EBNA1, the LMP2A/B proteins, the EBER transcripts, and the *Bam*HI-A rightward transcripts (BARTs), with around 20% of tumors also expressing the oncogenic LMP1 protein (**Figure 4** – latency II). The presence of monoclonal EBV episomes in NPC indicates that virus infection preceded the clonal expansion of the malignant cell population. More detailed analysis of the genetic changes in NPC suggests that some of these (particularly deletions in chromosomes 3p and 9p) occur early before EBV infection. Extensive serological screening for EBV-specific antibody titers in high-incidence areas, in particular IgA antibodies to VCA and EAs, have proved useful in diagnosis and in monitoring the effectiveness of therapy. More recent studies have demonstrated that the quantitative analysis of tumor-derived EBV DNA in the blood of patients with NPC using real-time polymerase chain reaction (PCR) is of both diagnostic and prognostic utility. EBV infection is also associated with the more differentiated forms of NPC (WHO types I and II) particularly in those geographical regions with a high incidence of the type III tumor. EBV-positive carcinomas, which morphologically resemble NPC (undifferentiated carcinomas of nasopharyngeal type), have been described at other anatomical sites (e.g., thymus, tonsil, lungs, skin) but the extent of the association of these tumors with EBV is geographically variable.

Gastric Carcinoma and Other Epithelial Tumors

EBV infection is also present in around 10% of typical gastric adenocarcinomas, accounting for up to 75 000 cases per year. These tumors resemble NPC in carrying monoclonal EBV genomes, having a restricted pattern of EBV gene expression (EBERs, EBNA1, LMP2A, BARTs, and BARF1) and in the appearance of virus infection as a relatively late event in the carcinogenic process. The geographical variation in the association of EBV with gastric adenocarcinomas probably reflects ethnic and genetic differences. EBV-positive tumors have distinct phenotypic and clinical characteristics compared with EBV-negative tumors.

A number of other more common carcinomas such as breast cancer and liver cancer have been reported to be infected with EBV. Difficulties in confirming these associations have raised concerns about the use of PCR analysis to detect EBV infection and about the specificity of certain monoclonal antibody reagents. It is possible, however, that a small proportion of tumor cells can be infected with EBV, perhaps sustaining a low-level replicative infection, and that this might contribute to the growth of the carcinoma.

Prevention and Control of EBV Infection

The significant burden of EBV-associated tumors worldwide has prompted the development of novel therapeutic strategies that either specifically target viral proteins or exploit the presence of the virus in malignant cells. Pharmacological approaches include the use of agents to induce the expression EBV lytic cycle antigens, including virus-encoded kinases (EBV thymidine kinase and

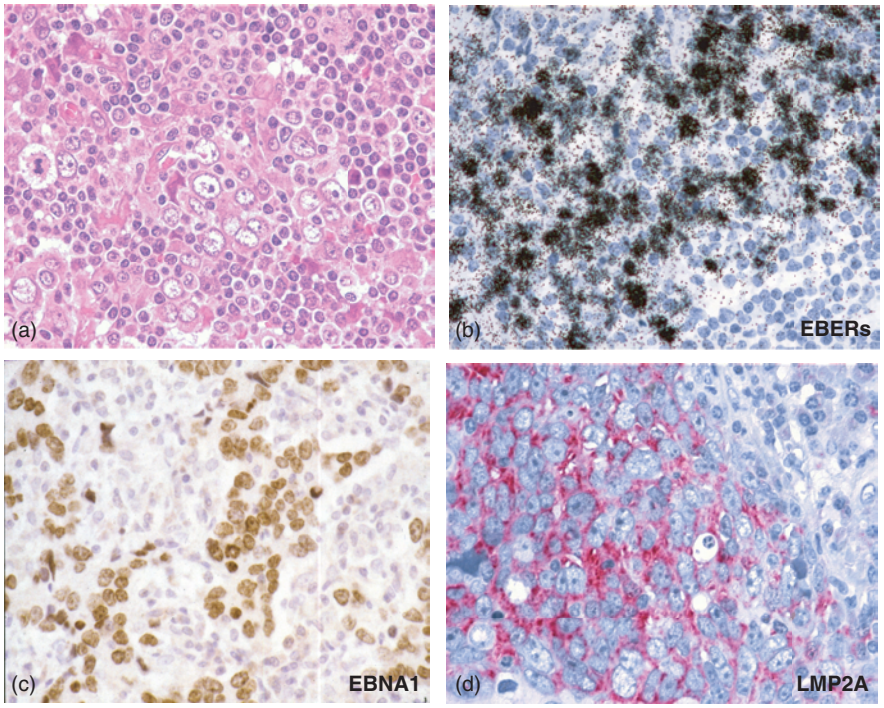

Figure 4 EBV gene expression in nasopharyngeal carcinoma (NPC). (a) shows a hematoxylin and eosin stain of a NPC tumor showing the intimate association between the undifferentiated carcinoma cells (large nuclei) and the activated lymphoid stroma (small intensely staining nuclei). (b–d) *in situ* hybridization for the EBER transcripts and immunohistochemical staining for EBNA1 and LMP2A.

BGLF4, a protein kinase) that will then phosphorylate the nucleoside analog gancyclovir to produce its active cytotoxic form. Demethylating agents such as 5′ azacytidine are able to de-repress lytic, as well as potentially immunogenic, latent genes and are currently in early-stage clinical trials in patients with NPC, HL, and AIDS-associated lymphoma. Hydroxyurea is a chemotherapeutic agent that can induce loss of EBV episomes and has shown some clinical efficacy in patients with EBV-positive AIDS-related central nervous system lymphoma. Other approaches are based on the more specific targeting of individual EBV proteins using either single-chain antibodies, siRNA, or dominant-negative molecules. The use of adoptive EBV-specific T-cell therapy for the treatment of existing PTLD and in the prophylactic setting has been extremely successful. This approach is also showing signs of clinical efficacy in the treatment of NPC and HL but in this setting the use of T cells enriched for reactivities to subdominant targets (e.g., LMP2A and EBNA1) is important. More direct vaccine approaches to treat patients with EBV-associated tumors or to prevent disease development are being examined including (1) whole EBV latent antigens delivered by a virus vector or in autologous dendritic cells; (2) peptide or polytope vaccination; and (3) prophylactic vaccination against MA (gp350/220) to generate a neutralizing antibody response.

Future Perspectives

EBV was discovered over 40 years ago and its DNA was fully sequenced in 1984. Much work has contributed to the unequivocal identification of EBV as oncogenic in humans. In more recent years, the nature of the interaction of EBV with the immune host has become clearer, illustrating the complex mechanisms that the virus exploits to persist in the memory B-cell pool. The fine detail of this interaction with normal B cells is still in its infancy, and a major question remains over the replicative lifecycle of EBV *in vivo*, particularly with regard to the relative role of B cells versus epithelial cells in this process. The development of more efficient *in vitro* systems for studying EBV infection and replication in different cell types will help to unravel the complex interplay between the virus and the cell. The use of EBV recombinants continues to shed light on the role of latent genes in the transformation process, on the requirements for the efficient production of progeny virus, and on the role of membrane glycoproteins in the infection process. Understanding the host cell–virus interaction will be dependent on the generation of appropriate *in vitro* models, particularly systems which allow a more detailed understanding of the tumor microenvironment and the role of the local cytokine milieu. There are many interesting aspects of EBV that remain to be understood, including the role of virus-encoded

microRNAs and the possible contribution of lytic cycle antigens to virus persistence and oncogenesis. The challenge will be to exploit these new mechanistic insights both to gain a better understanding of EBV infection *in vivo* and to develop novel therapies for treating virus-associated disease.

Properties of the Virion

The morphology of the virion of Epstein–Barr virus (EBV; species *Human herpesvirus 4*, genus *Lymphocryptovirus*, family *Herpesviridae*) is typical of all herpesviruses, and comprises four major components. At the core is the viral genome, which is encased within an icosadeltahedral nucleocapsid that consists of 162 capsomeres and is approximately 100 nm in diameter. The tegument represents the amorphous proteinaceous region between the nucleocapsid and membrane envelope, the latter of which the virus acquires as the nucleocapsid buds through cellular membranes. Analysis of virion protein content by mass spectrometry has identified 6 viral capsid proteins, 12 glycoproteins, and as many as 17 tegument proteins. The tegument also contains several host proteins, for example, actin and Hsp70. The most abundant viral glycoprotein is gp350, which binds to the major cellular receptor for EBV attachment on B cells, CD21.

Properties of the Genome

Organization and Coding Potential

The EBV genome is a double-stranded (ds) DNA molecule of approximately 172 kbp. In its linear configuration, as within the virion, it is bounded on both ends by a variable number of 538-bp direct terminal repeats (TRs). The genome is separated into short (12 kbp) and long (134 kbp) predominately unique sequence domains by 7–10 copies of a 3-kbp repeat, IR1. Moreover, the long unique domain is divided into four shorter domains (U2–U5) by repetitive elements containing short direct repeats (IR2–IR4) (**Figure 1**). Each of the noted internal repeats contributes coding information to a viral protein. Based on identification of potential translational open reading frames (ORFs), the existence of approximately 75 genes was initially predicted from the genomic nucleotide sequence of the B95–8 isolate of EBV. Further, a 12-kbp deletion from the B95–8 genome removes three ORFs present in wild-type isolates, and sequence analyses of EBV cDNAs have identified several additional genes that were not apparent from the genomic sequence due to the highly spliced nature of their mRNAs. Thus, currently there are an estimated 80–85 EBV proteins, though not all have been confirmed. In addition to these, EBV expresses two classes of noncoding RNAs: EBV-encoded small RNA (*EBER*) 1 and 2, which are highly structured RNAs of 167 and 172 nucleotides, respectively, and two clusters of micro-RNAs (miRNAs) derived from two different loci.

The majority of EBV genes contribute to the production of progeny virus, and their expression is limited to

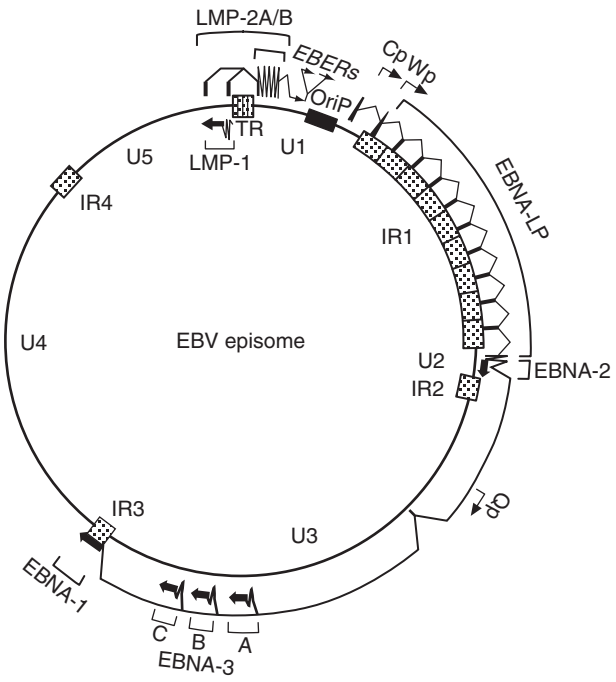

Figure 1 Structure and latency-associated transcription of the EBV genome. The episomal form of the genome that is maintained in latently-infected cells is shown; repeat elements (TR, IR1–IR4), unique sequence domains (U1–U5), and the latent-infection origin of DNA replication *oriP* are indicated, as are the latency-associated mRNAs and *EBERs*. The common EBNA-gene promoters Cp and Wp, and the EBNA-1 exclusive promoter Qp are depicted by bent arrows. Exons that contain ORFs are bracketed. The *BARTs* (not shown; see **Figure 2**) originate in U4 and terminate in U5.

the virus replicative or lytic cycle of infection. Up to an additional 12 genes, plus the *EBERs* and miRNAs, are expressed during the latent (nonproductive) programs of EBV infection. Few lytic-cycle mRNAs are spliced, and those that are in this class are relatively simple, generally containing only a single splice that removes a relatively short intron of no more than a few hundred base pairs. A discussion of the many lytic-cycle-specific genes is beyond the scope of this article, but their organization within the EBV genome and mRNA structures may be followed up via the 'Further reading' section. By contrast, all of the latency-associated gene mRNAs are spliced, and most splicing is extensive and occurs over 8–90 kbp. The nine known latency-associated proteins of EBV are grouped into two classes: the latent membrane proteins (LMP-1, LMP-2A, and LMP-2B) and the EBV-encoded nuclear antigens (EBNA-1, EBNA-2, EBNA-3A, EBNA-3B, EBNA-3C, and EBNA-LP). A transcriptional map of the EBV genome displaying the structures of the mRNAs encoding these proteins is presented in **Figure 1**. Notably, expression of the EBNA proteins is from a common transcription unit that spans 90 kbp of the viral genome, the primary transcripts from which are alternatively spliced to yield individual EBNA mRNAs. Moreover, the common highly spliced 5′ portion of the EBNA mRNAs contains an ORF composed primarily of a two-exon repeat, derived from each of the 7–10 IR1 elements, that encodes EBNA-LP (leader protein). A similar level of complexity is displayed by the LMP-2A and LMP-2B genes, each of which has a unique transcriptional promoter and 5′ exon, but share exons 2–9. A translational start codon is present in the unique exon of the LMP-2A mRNA, whereas the start codon for the LMP-2B ORF is within the common second exon, in frame with the LMP-2A ORF; consequently, LMP-2A differs from LMP-2B by the presence of 119 amino acid residues at its N-terminus. Further, because transcription of the LMP-2 genes traverses the fused TRs, they can only be expressed from the circular, latency-associated form of the EBV genome. The remaining latency-associated gene encodes for a family of alternatively processed and polyadenylated RNAs that co-terminate in the *Bam*HI-A restriction fragment of the EBV genome – hence their designation *Bam*HI-A rightward transcripts, or *BARTs* (**Figure 2**). These appear to arise from a common promoter, and contain several short ORFs. However, while there is ample circumstantial evidence to support protein expression from several of these ORFs, this has yet to be demonstrated with certainty in the context of EBV infection.

Genetic Diversity

There are two distinct genetic strains or subtypes of EBV, EBV-1 and EBV-2 (alternatively subtypes A and B), which were initially defined by specific sequence differences in their respective EBNA-2 ORFs. This was subsequently extended to the EBNA-3 ORFs (EBNA-3A, EBNA-3B, and EBNA-3C), which appear to have arisen through gene duplications from a common progenitor, and the *EBERs*. The respective degree of amino acid sequence identity between the EBNA-3 proteins of EBV-1 and EBV-2 ranges from 72% to 88%. The complete nucleotide sequence has recently been determined for the prototypic EBV-2 isolate, AG876, and no additional genetic loci were identified that would segregate with the type 2 genotype. Thus, the defining differences between EBV-1 and EBV-2 are limited to a subset of genes associated exclusively with the latent form of EBV infection. However, the biological significance of this divergence is currently unclear. *In vitro*, EBV-2 has an apparently lower transformation efficiency than EBV-1 isolates, such as B95–8. This is perhaps not surprising given that EBNA-2, EBNA-3A, and EBNA-3C are essential for B-cell immortalization. However, the molecular basis for this is unclear, as there is no strong evidence to indicate that these EBV-2 proteins differ significantly in function from their EBV-1 counterparts. The observation that EBV-2 isolates are more

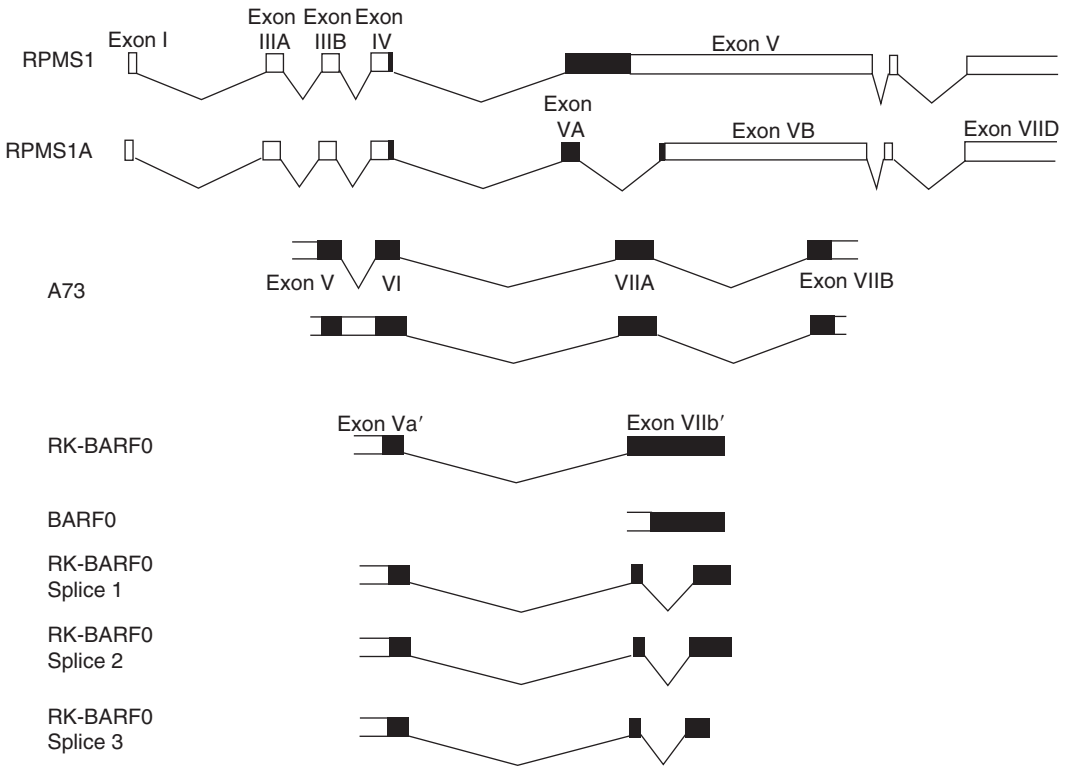

Figure 2 Structure of the latency-associated *BART* RNAs of EBV. Shown are portions of the 5′ and 3′ co-terminal *BARTs* that may encode protein. Potential ORFs within these highly spliced RNAs are shaded in black, and are designated RPMS1, A73, RK-BARF0 and BARF0; shorter versions are also indicated that arise through alternative splicing, but maintain the same translational reading frame. Transcription of the *BART* gene originates from a promoter upstream of exon I, and extends through the 3′-most exon (VII) that contains the ORF BARF0. Note that the three groups of *BARTs* are not shown as aligned relative to each other.

restricted geographically, notably to areas in which EBV-positive Burkitt lymphoma (BL) is endemic, initially raised the possibility of a link between this subtype and pathogenic potential. However, EBV-1 isolates also circulate in areas where EBV-2 is present, and the relative association of either subtype with BL more likely reflects its respective prevalence within the local population.

In addition to genetic differences that define EBV subtype, a number of sequence polymorphisms at various loci have been noted relative to the reference strain B95–8, and the LMP-1 ORF in numerous EBV isolates has a 30-bp deletion in the region encoding the C-terminal domain of this oncoprotein. Although EBV isolates with the LMP-1 deletion appear to be relatively widespread, the nondeleted form generally represents the more common strains circulating within any given population. Significant but non-type-specific differences have also been detected in the EBNA-1 ORF. Although clinical significance has at times been ascribed to some of these genetic variations, such reports are largely anecdotal. Another notable genetic anomaly within the EBV genome is a 6.8–7.4-kbp deletion that removes a portion of the EBNA-LP ORF and the entire EBNA-2 and BHLF1 ORFs (the latter encodes a protein of unknown function expressed during the lytic cycle of infection). Recent work has demonstrated that perhaps as many as 15% of BL tumors carry EBV with this deletion. Interestingly, these tumor cells often also carry the wild-type EBV genome, though it appears to be transcriptionally silent, such that EBV gene expression originates only from the deleted genome. This deletion likely reflects a selection against cells that express EBNA-2, the expression of which is normally repressed through epigenetic mechanisms within BL cells and during normal establishment of long-term latency within the B-cell reservoir of EBV (see below). Thus, deletion of the EBNA-2 locus may represent an alternative, albeit accidental, pathway in lymphomagenesis leading to BL.

Molecular Biology of Infection

Current knowledge of the EBV life cycle at the molecular level has come almost exclusively from *in vitro* studies, largely by necessity due to the lack of a representative and tractable animal model of EBV infection. These have primarily employed either lymphoblastoid cell lines (LCLs) generated by EBV immortalization of primary

human B lymphocytes *in vitro*, or lines established from BL tumors. Regardless of their origin, these B-cell lines characteristically restrict EBV infection to its latent phase, through which *in vivo* the virus is able to persist within its host and potentially contribute to malignancy. Currently, there is a considerably better understanding of EBV latency than of the viral replicative cycle, at least from the perspective of viral protein functions. This is primarily the consequence of the more intense effort over the past four decades to define the oncogenic nature of EBV, which is derived from its latency-associated gene functions, and the lack of an experimental cell system that efficiently supports EBV replication *in vitro*. Nonetheless, virus replication is a fundamentally important aspect of the EBV life cycle, as it is essential for maintenance of the virus in the human population.

Virus Replication

Although some latently infected B-cell lines can be induced to replicate EBV in response to chemical agents such as phorbol esters and inhibitors of histone deacetylases, or by crosslinking of cell-surface immunoglobulin, the efficiency of induction is generally poor in that 20–30% of the treated cells, at best, will actually produce virus. Further, these do not necessarily represent physiological pathways of reactivation. While epithelial cells are thought to be significant sites of EBV replication *in vivo*, epithelial cell lines are difficult to infect. This may reflect alternative pathways of cell entry, such as cell-to-cell spread (e.g., through contact with productively infected B cells) or IgA-mediated entry into epithelial cells via the receptor for the dimeric form of IgA that is bound to EBV virions. Further, other factors, such as the differentiation state of the cell, influence whether infected epithelial cells will support virus replication or establishment of a latent infection.

Despite these drawbacks, the general process of EBV replication is reasonably well understood owing to parallels that can be drawn to the replication of other herpesviruses, notably the herpes simplex viruses that replicate well in cell culture and for which an extensive body of knowledge exists. This is aided by comparative sequence analyses of the mammalian herpesvirus genomes, which have revealed blocks of conserved genes that are expressed during the respective viral replication cycles. Thus, while EBV also possesses a subset of unique lytic-cycle genes that contribute to its distinct biology and ability to occupy a specific niche within the host, its replication is believed to occur through a basic process common to all herpesviruses. This occurs through a highly ordered cascade of viral gene expression that is initiated by the immediate-early class of genes (those that do not require *de novo* protein synthesis for transcription), followed by expression of the early and then the late genes. In general, immediate-early and early proteins regulate or contribute to viral gene expression and DNA replication, whereas late proteins are either structural components of the virion or are required for functions such as assembly and egress of the virus particle. A discussion of the unique aspects of EBV replication as they contribute to the EBV life cycle in the host is presented below.

Latency

Although EBV can exist as a latent infection in epithelial cells within the host, B lymphocytes are the major reservoir of latent EBV and the source of new virus (following reactivation) that is ultimately required to populate EBV-naïve hosts. Primary B cells can be readily infected by EBV *in vitro*, leading to direct establishment of a latent infection that promotes cell immortalization through the actions of the latency-associated EBV genes, leading to continuous growth and proliferation in culture. Shortly after infection, the TR elements of the EBV genome fuse to generate a closed circular DNA molecule or episome (**Figure 1**), a variable but relatively stable number of which (10–100) is ultimately established and maintained within the nuclei of latently infected B cells. Replication of the EBV episome in latently infected cells is mediated by the cellular DNA replication machinery, occurs once per cell division cycle, and is initiated within an origin of DNA replication, *oriP*, located in the short unique domain of the viral genome (**Figure 1**). Two functions of a single EBV protein, EBNA-1, are required for genome maintenance during latency. First, through binding to the dyad symmetry (DS) element of *oriP* that contains four EBNA-1-binding sites, EBNA-1 directs assembly of host replication proteins to initiate DNA synthesis. Second, through binding to the family of repeats (FR) element of *oriP* (20 EBNA-1-binding sites), EBNA-1 tethers the EBV genome to host chromosomes through its interaction with a cellular chromosome-associated protein, ensuring that EBV episomes are evenly partitioned upon cell division. By contrast, genome replication during the lytic cycle does not utilize *oriP*, but two origins of DNA replication (*oriLyt*) that function independent of EBNA-1 and lie 100 kbp apart within the long unique sequence domain. Further, replication of viral DNA during the lytic cycle is mediated predominantly by virally encoded DNA polymerase and accessory proteins.

Latency-Associated Gene Expression and Function

Immediately upon infection of a resting B cell, the EBNA promoter Wp is activated by cellular transcription factors, resulting initially in the expression of EBNA-LP and

EBNA-2, the ORFs for which are the first encountered within the multicistronic EBNA transcription unit. Shortly afterwards, there is an EBNA-2-mediated switch in transcription to the common EBNA promoter Cp, approximately 3 kbp upstream of Wp (**Figure 1**). In reporter gene assays, Cp can be regulated, either positively or negatively, by virtually all members of the EBNA family (see below). Thus, the switch to Cp-mediated EBNA expression is thought to afford the virus a means by which to finely regulate EBNA levels and ultimately to regulate LMP-1, LMP-2A, and LMP-2B, whose promoters are also controlled by members of the EBNA family. By approximately 24 h after infection, expression of the full complement of EBV latency-associated genes is evident, including the noncoding RNAs *EBER-1* and *EBER-2* (it is currently unclear at what point the *BARTs* and the newly discovered miRNAs are expressed). In response to expression of the latency-associated genes, the B cell is driven into the cell cycle, and thereafter is able to proliferate indefinitely as an LCL. *In vivo*, this expression of the full repertoire of latency-associated genes, known as the growth or Latency III program, serves to rapidly establish a pool of infected B cells. However, as discussed later, there is a reprogramming of EBV gene expression *in vivo* that substantially restricts viral gene expression to enable infected cells to persist in the face of the cellular immune response to EBV proteins.

EBNA-1

EBNA-1 is the only member of the EBNA family that binds to DNA in a sequence-specific manner, a property critical to its functional interaction with *oriP*. EBNA-1 also has a strong but nonspecific binding affinity for RNA, though the reason for this is unclear. As the genome maintenance protein, EBNA-1 is essential for the establishment and maintenance of latent infection, and thus the pathogenic potential of EBV. This is underscored by the fact that EBNA-1 is the only viral protein known to be expressed in all EBV-associated tumors. EBNA-1 also contributes to regulation of its own expression and that of other EBNA proteins. It does this by activating transcription from the common EBNA promoter Cp (via binding to the FR element of *oriP*) and negatively regulating its own expression from an EBNA-1 exclusive promoter, Qp (see below), which is approximately 43 kbp downstream of *oriP* and contains two EBNA-1-binding sites. The mechanisms by which EBNA-1 functions in these regards are undefined, and although it is possible that it may likewise regulate cellular gene expression, thus far there is a lack of conclusive evidence to support this. Whether EBNA-1 also contributes directly to tumorigenic potential has been examined in mice transgenic for EBNA-1. However, while the results of one group suggest that EBNA-1 can promote B-cell lymphomagenesis in this model, another group found, using independently derived transgenic lines, that EBNA-1 had no demonstrable oncogenic properties. Therefore, to date the principal functions of EBNA-1 appear limited to its roles in genome maintenance and the regulation of EBV gene expression.

EBNA-LP and EBNA-2

After EBNA-1, EBNA-2 has been one of the most extensively studied EBV latency proteins, largely due to the fact that it was the first viral protein shown to be essential for B-cell immortalization by EBV. EBNA-2's function has been studied extensively in EBV-negative B-cell lines, where it increases expression of numerous cellular genes, for example, the B-cell activation marker CD23, CD21 (the B-cell receptor for EBV attachment), the oncogenes *c-fgr* and *c-Myc*, and cyclin D2. This list has further grown with the advent of gene array technology. EBNA-2 is also a crucial transactivator of transcription from the EBV LMP-1, LMP-2A, and LMP-2B promoters, and the EBNA promoter Cp. EBNA-2 does not bind directly to DNA; instead, it is tethered to target promoters via interactions with cellular transcription factors such as CSL (alternatively known as RBP-Jκ or CBF-1), PU.1 and AUF1, allowing increased transcription through recruitment of basal transcription factors by EBNA-2's strong activation domain.

One protein targeting EBNA-2 to DNA is the ubiquitous cellular transcription factor CSL, which normally inhibits transcription by recruiting a co-repressor complex to the promoter. Through its interaction with CSL, EBNA-2 displaces this repressor complex, instead recruiting co-activators. Binding sites for CSL are found in all of the viral promoters responsive to EBNA-2 mentioned above and are key for their regulation by EBNA-2. CSL normally participates in the Notch signaling pathway. Upon ligand-mediated activation of Notch, its intracellular domain is released by proteolysis, enters the nucleus, and binds to CSL, displacing the co-repressor complex and recruiting transcriptional coactivators. Thus, EBNA-2 essentially acts as a constitutively activated Notch protein, though EBNA-2 and Notch likely possess unique functions as suggested by the observation that activated Notch can only partially rescue mutant EBV lacking an EBNA-2 gene in a B-cell immortalization assay. Although the full complement of genes targeted by CSL is unknown, Notch and EBNA-2 do appear to activate expression of many of the same EBV and cellular genes. An additional function of EBNA-2 and Notch is the ability to protect against apoptosis mediated by the nuclear hormone receptor family member Nur77 through a direct association. The fact that Notch is activated in several cancers is consistent with the belief that EBNA-2's interaction with CSL is an essential component of EBV-mediated immortalization.

A second cellular factor targeting EBNA-2 to DNA, specifically to the LMP-1/2B bidirectional promoter (**Figure 1**), is PU.1, and also the highly related protein Spi-B. Both are members of the Ets family of transcription factors, which recognize the same DNA sequence element. Whereas expression of PU.1 is restricted to and plays an important role in the development of B lymphocytes and myeloid cells, less is known about Spi-B, whose expression is limited to B and T lymphocytes. The Ets family of transcription factors, which are clearly important for B-cell development and differentiation, regulate a wide variety of cellular genes. The expression of at least some of these genes, therefore, is likely to be regulated by EBNA-2 and important in EBV-mediated control of B-cell growth and differentiation.

The activity of EBNA-2 is regulated by a number of the other EBNA proteins. Transcription mediated through CSL is repressed by the EBNA-3 proteins, which, by also binding to CSL, prevent its association with EBNA-2 and DNA, thus inhibiting activation of transcription. Relatively little is known of the function(s) of EBNA-LP other than its role as a coactivator of EBNA-2-mediated transcription. Although EBNA-LP is critical for the efficient immortalization of B lymphocytes by EBV, it is not absolutely essential. In primary B lymphocytes stimulated with the EBV gp350, expression of both EBNA-2 and EBNA-LP results in increased expression of cyclin D2. EBNA-LP also appears to specifically coactivate the viral LMP-1/2B bidirectional promoter and Cp, rather than all EBNA-2 target promoters. EBNA-LP augments transcription in a manner requiring only the activation domain of EBNA-2, suggesting that EBNA-LP may act as an adaptor between EBNA-2's activation domain and the basal transcription machinery, though only a weak direct interaction is observed between full-length EBNA-2 and EBNA-LP. Although EBNA-LP has been reported to associate with several cellular proteins, its association with Sp100, which displaces both Sp100 and heterochromatin protein 1 from PML nuclear bodies, is likely to play the most direct role in coactivation along with heat shock protein 72, also an EBNA-LP partner.

The EBNA-3 family

The EBNA-3 family (EBNA-3A, EBNA-3B, and EBNA-3C) apparently arose by gene duplication of a single progenitor, though little notable sequence homology now exists between the proteins. EBNA-3A and EBNA-3C are required for B-cell immortalization by EBV, whereas EBNA-3B is dispensable. One common function of the EBNA-3 proteins is their ability to bind CSL through a conserved domain in their respective amino termini, lending further support to the belief that these proteins are related. As mentioned in the previous section, interaction of CSL with the EBNA-3 proteins inhibits EBNA-2/CSL-mediated transcription in reporter gene assays, though this may not occur in EBV-infected cells, in which the EBNA-3 proteins are expressed at much lower levels. The fact that all three proteins bind to CSL suggests that this interaction is important, and studies with recombinant virus lacking EBNA-3 CSL-interacting domains have demonstrated that at least association of EBNA-3A with CSL plays an essential role in immortalization of B lymphocytes. Both EBNA-3A and EBNA-3C possess transactivation domains within their C termini and bind to a variety of cellular transcription factors, indicating that they likely function themselves as transcriptional activators. Indeed, EBNA-3C can maintain the levels of LMP-1 that otherwise fall in the G1 phase of the cell cycle, and reporter gene assays have demonstrated that this effect is mediated through the PU.1 site in the LMP-1 promoter. EBNA-3C can bind to PU.1 and Spi-B proteins *in vitro*, and results of chromatin immunoprecipitation assays have revealed that EBNA-3C is indeed present on the LMP-1/2B bidirectional promoter. The EBNA-3 proteins are therefore likely to influence gene expression in both CSL-dependent and -independent mechanisms.

Co-transformation assays employing rat embryo fibroblasts have demonstrated that both EBNA-3A and EBNA-3C can immortalize these cells in collaboration with an activated *ras* gene. This function is dependent on a site that mediates interaction with the cellular transcriptional repressor CtBP. The EBNA-3 proteins are implicated in preventing cell-cycle arrest that normally occurs in response to genotoxic agents, presumably by inactivating cell-cycle checkpoint controls. Thus, the EBNA-3 proteins are also likely to contribute to EBV-induced cell growth and proliferation during the Latency III program in a manner independent of their ability to regulate viral and cellular gene expression.

LMP-1

LMP-1 is unique among the EBV latency-associated proteins in that it alone induces the classic phenotypic changes associated with transformation when expressed in rodent fibroblasts. Expression of LMP-1 is essential to maintain proliferation of EBV-infected LCLs, and transgenic mice that express LMP-1 in their B cells develop lymphomas. However, LMP-1 alone is not sufficient to sustain B-cell proliferation, underscoring the importance of the contributions of the other EBV proteins expressed during the Latency III program.

LMP-1 is comprised of a small cytoplasm-orientated domain at its N-terminus, followed by six transmembrane domains and a larger cytoplasmic domain at the C-terminus. Two regions of the C-terminal domain, transformation effector sites (TES)-1 and -2, are essential for efficient B-cell immortalization by EBV. Through these domains, LMP-1 associates directly with intracellular signaling proteins of the tumor necrosis factor receptor

(TNFR) family. LMP-1 aggregates within lipid rafts of the plasma membrane, resulting in ligand-independent, constitutive activation of these signaling proteins, a critical outcome of which is activation of the transcription factor NFκB. JNK, p38/MAPK, and STAT proteins are also activated by LMP-1, though activation of STAT has been shown not to be important for LMP-1's effects in B lymphocytes. Through these pathways, LMP-1 affects the expression of cellular genes such as adhesion molecules associated with antigen activation of B lymphocytes, anti-apoptotic proteins such as Bcl-2, Bfl-1, and A20, as well as various cytokines. Additional genes activated in the presence of LMP-1 continue to be identified. The membrane proximal TES-1 site interacts with TNFR-associated factors or TRAFs, mediating a low-level activation of NFκB that drives the initial proliferation of B lymphocytes following EBV infection. TES-2, located at the very C-terminus of LMP-1, mediates the majority of NFκB activation through binding to the TNFR-associated death domain protein TRADD, and is required for the continued growth of EBV-infected B lymphocytes in culture. The TNFR family comprises members associated with the promotion of cell growth (CD40) as well as cell death (FAS receptor), and LMP-1 mimics many of the functions of CD40, partially rescuing the defects in CD40-null mice. Thus, LMP-1 plays a direct role in the immortalization associated with EBV infection.

Within epithelial cells, LMP-1 is able to activate expression of the epidermal growth factor receptor through TRAF signaling, resulting in inhibition of terminal differentiation. This pathway is likely to mediate the development of epithelial hyperplasia observed in LMP-1 transgenic mice, and suggests a significant role for LMP-1 in the more restricted Latency II program maintained in nasopharyngeal carcinoma (NPC).

LMP-2A and LMP-2B

LMP-2A and LMP-2B are integral plasma membrane proteins comprised almost entirely of 12 transmembrane domains, with both their N and C termini oriented toward the cell cytoplasm. The unique 5′ exon of LMP-2A encodes a 119-amino acid residue N-terminal domain not present in LMP-2B, which contains only the transmembrane domains and the common 27-residue C-terminal tail. It is through its N-terminal domain that LMP-2A, aggregated in lipid rafts within the plasma membrane, recruits the protein tyrosine kinase Lyn and subsequently Syk to activate a pro-survival signaling cascade that includes a number of signaling proteins in the B-cell receptor (BCR) pathway, for example, Akt/protein B kinase, phosphatidylinositol-3 kinase (PI3K), phospholipase-Cγ2 (PLCγ2), and mitogen-activated protein kinase (MAPK). Consequently, LMP-2A mimics a constitutively active BCR that provides a submitogenic survival signal important for long-term persistence of latently infected B cells. The level of signaling by LMP-2A appears to be tightly regulated through its association with Nedd4 ubiquitin ligases, which control levels of LMP-2A and its associated proteins through ubiquitin-mediated protein degradation. Also, LMP-2B, which is unable to interact with Lyn and Syk, is believed to regulate LMP-2A negatively by interfering with juxtapositioning of the N-terminal domains of LMP-2A (required for trans-phosphorylation of tyrosine motifs) within lipid rafts. LMP-2A also limits the reactivation of EBV within LCLs that can be induced by crosslinking of surface immunoglobulin, that is, the BCR. Inhibition of BCR signaling appears to occur as a result of LMP-2A-dependent reduction of Lyn available for BCR signaling. However, it is unclear whether this is a significant means of inhibiting EBV reactivation *in vivo*. LMP-2A is not essential for immortalization of B lymphocytes *in vitro*, probably because its pro-survival functions are superseded by those of LMP-1.

With the exception of the Latency I program in BL, LMP-2A is probably expressed in all latent EBV infections. Further, LMP-2A expression in NPC and EBV-positive cases of Hodgkin lymphoma implies a role for it in these human cancers. Indeed, despite being nonessential for B-cell immortalization, LMP-2A is tumorigenic when expressed in immortalized epithelial cell lines, and the pro-survival function of LMP-2A is believed to rescue the Reed–Sternberg cells of Hodgkin lymphoma – derived from germinal center (GC) B cells – from apoptosis. Transformation of epithelial cells by LMP-2A is thought to occur through stabilization of β-catenin via activation of the PI3K/Akt pathway. Inhibition of TGF-β-induced apoptosis by LMP-2A may further contribute to its tumorigenic potential within epithelial cells. LMP-2A is also able to promote migration of epithelial cells *in vitro* through upregulation of integrin-α-6 expression, suggesting that it plays an ancillary role in tumorigenesis as well by contributing to metastasis.

BARTs

The *BARTs* are expressed in all forms of EBV latency *in vitro*, and are detectable by PCR in the peripheral blood of healthy EBV carriers. While they are not essential to immortalization of B cells by EBV *in vitro*, their universal expression suggests that they play a critical role(s) in EBV biology. These are highly spliced transcripts that contain poly(A) tails on their common 3′ termini, and several putative ORFs have been identified within various members of the *BART* family, suggesting that they indeed function as mRNAs (**Figure 2**). Though proteins encoded by these ORFs can be expressed from eukaryotic expression vectors in cells following transfection, definitive identification of virally encoded proteins within infected cells has yet to be reported. There are four *BART* ORFs for which there is at least indirect evidence that they encode proteins: BARF0, RK-BARF0 (slightly longer than BARF0 due to an RNA

splicing event), RPMS1, and A73 (**Figure 2**). While serum from NPC patients does not recognize endogenous protein by immunoblotting, it will detect bacterially produced BARF0 polypeptide. Three *BART*-encoded polypeptides have been shown in yeast two-hybrid screens to interact with cellular proteins. RPMS1 and RK-BARF0 interact with components of the Notch signaling pathway: RPMS1 with CSL and its associated co-repressor CIR, and RK-BARF0 with Notch4. A73 interacts with the cytoplasmic receptor for activated protein kinase 1 (RACK1), though the functional significance of this is unclear. The interaction of RPMS1 with CSL and CIR is believed to repress promoters with CSL-binding sites (e.g., the LMP-1 promoter) by stabilizing the CSL–CIR repressor complex on the DNA. Interestingly, though different from the mechanism of EBNA-3 repression of CSL-regulated transcription, the outcome is similar. Interaction of RK-BARF0 with Notch4 results in translocation of the unprocessed form of Notch4 directly to the nucleus, which is believed to then activate expression of LMP-1. Thus, one set of functions for RPMS1 and RK-BARF0 may be analogous to those of the EBNA-3 and EBNA-2 proteins, respectively, in the regulation of LMP-1, but during the Latency II program in which these EBNA proteins are absent.

EBERs

EBER-1 and *EBER-2* are small, highly structured noncoding RNAs whose genes lie adjacent to one another immediately upstream of *oriP* (**Figure 1**) and are transcribed by cellular RNA polymerase III (Pol III). They are expressed in all forms of EBV latency and are restricted to the cell nucleus, where they are present at approximately 10^7 copies per cell (levels of *EBER-1* are approximately tenfold higher than *EBER-2*). While *EBER* expression is not essential for immortalization of B lymphocytes by EBV *in vitro*, like EBNA-LP the *EBERs* enhance the efficiency of this process. The most interesting property of the *EBERs* is their ability to enhance the tumorigenic potential of some EBV-negative BL cell lines, suggesting that they may play a role in tumor maintenance. How the *EBERs* promote tumorigenic potential is unresolved. There are numerous reports that the *EBERs* can interact with and influence the actions of proteins within the type 1 (antiviral) interferon response pathway that bind to dsRNA, namely the dsRNA-activated protein kinase PKR and RIG-I. However, as the *EBERs* are present in ribonucleoprotein complexes and unlikely to be available for interaction with these predominately cytoplasmic proteins, these interpretations of *EBER* effects *in vitro* or under experimental conditions that take the *EBERs* out of their normal intracellular context must be viewed with caution.

The *EBERs* are present in RNA–protein complexes that include La/SS-B (*EBER-1* and *EBER-2*) and the ribosomal protein L22 (predominately *EBER-1*). La is critical for the synthesis and protection from exonucleolytic digestion of small cellular transcripts generated by Pol III (e.g., tRNAs) that have a UUU-OH moiety at their 3′ termini, which is bound by La. La also retains some Pol III transcripts within the nucleus via this interaction, as it probably does the *EBERs*. As Pol III transcripts themselves, La binding to the *EBERs* probably represents a normal physiological interaction. *EBER* interaction with L22 results in retention of approximately 50% of the cellular pool of L22 within the nucleoplasm. The functional consequence of this is unknown, but presumably it influences L22 function. In bacterial ribosomes, L22 lies within the exit tunnel and regulates the passage of nascent polypeptide by interaction with a motif within the secretion monitor protein, secM. L22 may perform an analogous function in mammalian cells that is affected by *EBER-1*, though it is possible that *EBER-1* interaction with L22 influences a nonribosomal function of L22 (as yet undescribed), or imparts upon it a gain of function.

miRNAs

Two clusters of EBV miRNAs have recently been identified that are derived from two loci within the viral genome: the BHRF1 locus encoding for a pro-survival Bcl-2 homolog, and a portion of the *BART* locus. Analysis of miRNA expression in various EBV-infected cells has revealed that the *BART* miRNAs are highly expressed in latently infected epithelial cells (Latency II program), but at much lower levels in B-cell lines. By contrast, the BHRF1 miRNAs are present in high levels within B cells maintaining the Latency III program, but are very low or undetectable during the restricted latency programs in B (Latency I) and epithelial (Latency II) cell lines. Three of the *BART* and one of the BHRF1 miRNAs are induced to higher levels upon induction of the lytic cycle. The identity of the genes post-transcriptionally silenced by these miRNAs (both viral and cellular) and the contribution of virus-mediated RNA interference to EBV biology and pathogenic potential are currently unclear, but are currently the focus of an intense research effort.

Infection in the Host

For two decades after the discovery of the immortalizing effect of EBV on B lymphocytes *in vitro*, latency within LCLs was widely accepted as the model of EBV persistence within the host (although the extent of EBV gene expression in LCLs was not appreciated at the time). Increasing evidence indicated, however, that such cells are highly susceptible to killing by $CD8^+$ cytotoxic T lymphocytes (CTLs), and subsequently that this cellular immune response is directed at epitopes derived from the latency-associated proteins of EBV, particularly members of the EBNA-3 family. Thus, it was unlikely that EBV could persist within an immunocompetent host solely in

cells with the characteristics of an LCL. The subsequent observation that some BL cell lines are resistant to CTL killing, particularly at low passage in culture, was largely explained by the soon-to-follow discovery that expression of known latency-associated proteins in these cells was restricted to EBNA-1. EBNA-1, moreover, is not a good inducer of the CTL response. This is due in part to poor presentation of EBNA-1 peptides with HLA class I antigen on the infected cell surface as a consequence of self-inhibition of proteolytic processing of EBNA-1 by its substantial Gly-Ala repeat domain. Thus, B cells that limit EBV expression to EBNA-1 are not particularly vulnerable to the host's immune surveillance.

Restricted patterns of EBV gene expression were later described for other EBV-associated tumors, for example, NPC and Hodgkin lymphoma, though cells in these tumors express the LMP proteins in addition to EBNA-1. This led to the classification scheme of latency-associated gene expression patterns or programs: Latency I exemplified by BL cells (EBNA-1 only); Latency II, in which the LMP proteins are expressed in addition to EBNA-1; and Latency III or the growth program, in which expression of the full complement of latency-associated genes is supported. The *EBERs* and *BARTs* are also expressed in each of these programs, whereas the miRNAs are differentially expressed, as discussed above. Importantly, the realization that tumor cells can support alternative programs of latency-gene expression provided the basis for studies that have led to the current understanding of EBV persistence within the host. With the aid of reverse transcription-PCR and cell-isolation procedures, it has been possible to evaluate EBV gene expression in phenotypic subsets of B cells, and even approaching the single-cell level. Analyses of EBV gene expression in B cells from peripheral blood and tonsils have provided a reasonably good, though certainly not complete, picture of the pathway(s) taken by EBV to establish itself permanently within the B-cell pool of its host.

Establishment of Persistent Infection

The major cellular reservoir of EBV within the peripheral blood are resting memory B cells ($IgD^-/CD20^+$) that express the LMP-2 proteins, and probably the *EBERs* and *BARTs* (referred to as the Latency program). Periodic activation of cell division results in EBNA-1 expression via Qp (suppressed in resting cells by the retinoblastoma protein) to prevent loss of the viral genome, thereby maintaining EBV within this reservoir. The virus is believed to enter the memory cell pool not directly, but by either driving or participating in a GC reaction, the normally antigen-driven process that gives rise to the long-lived memory B cells and the plasma cells that produce high-avidity antibody. This is supported by the presence of EBV within BL cells, which are derived from GC B cells and are thought to acquire the virus early in the oncogenic process, quite possibly during the primary establishment of EBV latency. The pathway by which EBV is believed to gain entry into the memory B-cell pool is illustrated in **Figure 3**, support for which has largely come from PCR-based analyses of EBV gene expression in tonsil B cells following surgical resection associated with either acute infectious mononucleosis or tonsillitis of unknown etiology. The basic premise of this model is that EBV infects a naïve resting B cell (IgD^+), driving rapid proliferation and expansion of infected cells, much as it does *in vitro* through its Latency III program. Gradually, however, there is an epigenetic down-regulation of EBV gene expression (as in BL cells) that both enables infected B cells to evade the developing CTL response and is compatible with long-term persistence in a resting B cell.

Conclusive evidence that EBV enters the memory cell pool by participating in a GC reaction, however, has been elusive. EBV-positive B cells appear infrequently within the GCs themselves, and those that do are not undergoing somatic hypermutation of *Ig V* genes, arguing against EBV driving or participating in a classic GC reaction. These cells harbor somatically mutated *V* gene rearrangements, suggesting that EBV may gain entry into GC B cells by direct infection, but that this pool of infected cells expands without further hypermutation. However, it is unlikely that EBV directly inhibits somatic hypermutation, as BL cell lines can continue to undergo this process *in vitro* despite infection with EBV or, in EBV-negative BL cells, stable expression of the individual latency genes. An important caveat to these observations is that, as a consequence of the pathology that prompted tonsillectomy, EBV infection in these B cells may not represent entirely normal events in the establishment of long-term latent infection.

The Role of Virus Replication

It is unclear whether establishment of a persistent latent infection in B cells requires an initial round of productive infection in epithelial cells within the oropharynx, or results instead from direct infection of B cells, most likely within Waldeyer's ring of the oropharyngeal lymphoid tissue. Extended treatment of EBV-positive individuals with acyclovir, an inhibitor of herpesvirus replication, does not reduce the level of latently infected cells in the peripheral blood, suggesting that intermittent reactivation of EBV is not essential for persistence. By contrast, reactivation of EBV from latency is necessary to pass the virus onto naïve hosts to maintain the virus in the human population. This is believed to occur sporadically from latently infected memory B cells that begin to replicate virus in response to their terminal differentiation into plasma cells. Virus produced from B cells has a slightly higher tropism for epithelial cells, whereas virus produced in epithelial cells is considerably more infectious for B cells. This is due to the relative

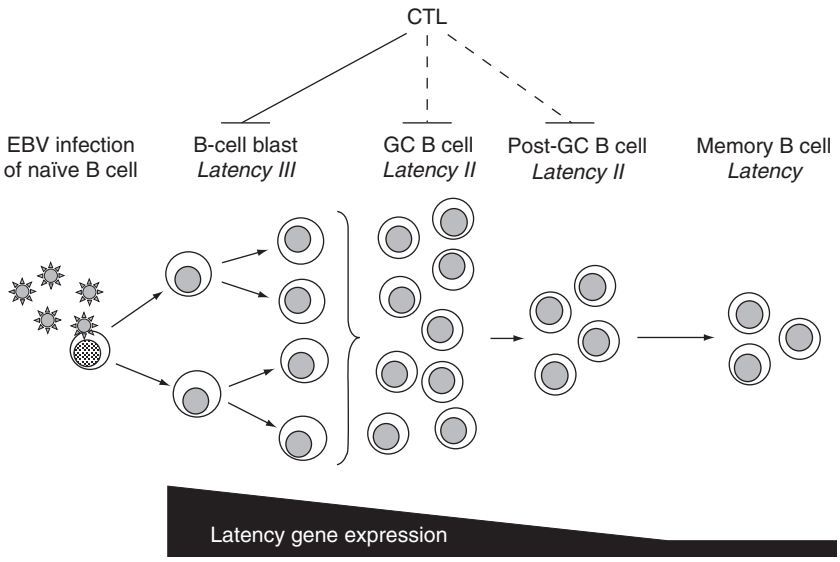

Figure 3 Establishment of persistent EBV latent infection. Shown is the currently favored model for the establishment of latency within memory B cells, the major long-term reservoir of EBV. As latently infected B cells progress from an initial stage of EBV-driven cell proliferation through a germinal center (GC) reaction, ultimately entering the memory B-cell pool, there is a restriction of latency-associated EBV genome expression. This occurs primarily through epigenetic silencing of the common EBNA promoters, Cp and Wp. The different latency-gene expression programs at the various stages are indicated in italics. The Latency program within memory B cells is similar to Latency I in BL cells, except for the expression of LMP-2A, and EBNA-1 expression is repressed; periodic cell division results in reactivation of EBNA-1 expression from the cell-cycle-regulated promoter Qp, as in Latency I. Solid to dashed lines indicate reduced potential for killing by cytotoxic T lymphocytes (CTLs) directed at epitopes derived from EBV proteins expressed in the Latency III and II programs.

amount of two EBV glycoprotein complexes on the virion envelope: gH/gL and gH/gL/gp42. B cells are preferentially infected by virions rich in gH/gL/gp42, whereas the presence of gp42 (prevalent on virus produced in epithelial cells) blocks interaction of gH/gL with its putative receptor on epithelial cells, which do not express the B-cell receptor for virus attachment, CD21, that is bound by gp350. B-cell-derived virus has lower levels of gp42 due to its interaction with HLA class II antigen (lacking in epithelial cells), which targets it for degradation. Recent evidence indicates that EBV present in saliva is programmed preferentially to infect B cells (high in gp42), suggesting that virus reactivated from B cells goes through an amplification step in tonsillar epithelium before it is secreted to be passed onto naïve hosts.

Activation of EBV replication is initiated by expression of the viral immediate early protein Zta – a protein related to the cellular AP-1 family of transcription factors – that binds to specific DNA motifs in a number of EBV early-gene promoters, initiating the cascade of lytic-cycle gene expression. This is done in collaboration with a second EBV transactivator, Rta, itself activated by Zta. Zta and Rta also participate in replication of EBV DNA during the lytic cycle through interaction with their response elements within *oriLyt* domains. An interesting property of Zta is its preference for binding DNA that has been methylated. Because the EBV genome is highly methylated within latently infected B cells *in vivo*, the propensity of Zta for methylated DNA gives further credence to the model in which new virus originates from reactivation within the memory B-cell reservoir of EBV.

To aid replication of virus in the host, EBV encodes a number of proteins that, while not directly involved in virion production, influence the intra- or extracellular milieu to enhance virus production. For example, the EBV BHRF1 ORF encodes a homolog of the cellular anti-apoptotic protein Bcl-2, and presumably enhances virus production by countering induction of programmed cell death in response to infection. Similarly, Zta and Rta, in addition to their direct contributions to EBV gene expression and DNA replication, interact with or regulate the expression of a number of cellular proteins, examples of which are p53, NFκB, pRB, p21, TGF-β and the retinoic acid receptor. These properties of Zta and Rta likely provide the optimal cellular environment for virus replication. EBV also expresses several proteins during the lytic cycle that are capable of modulating the host immune response. These include homologs of interleukin 10 (vIL-10), a negative regulator of the immune response, and a secreted form of the receptor for colony stimulating factor 1 (CSF-1) able to bind and neutralize CSF-1. Further, gp42, in addition to aiding in infection of

B cells, is able to inhibit HLA class II-mediated antigen presentation, and Zta is able to inhibit type 2 interferon signaling by downregulating expression of the γ interferon receptor.

Equine Infectious Anemia Virus

J K Craigo and R C Montelaro, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

© 2008 Elsevier Ltd. All rights reserved.

History

Equine infectious anemia (EIA), colloquially known as swamp fever, has been documented in numerous diverse geographical areas and is currently considered a worldwide disease that occurs only in members of the family Equidae. EIA was first identified as an infectious disease of horses by veterinarians in France in 1843. In 1904, the infectious organism that caused EIA was identified as a 'filterable agent', making EIA one of the first animal diseases to be assigned a viral etiology.

Despite this early identification of the equine infectious anemia virus (EIAV), the characterization of this virus was extremely slow because of the difficulties experienced in the isolation and propagation of the virus in cell culture. Thus, the major focus on the control of EIA has been the development of regulatory policies that involve the identification and elimination of EIAV-infected horses. More recently, advances in animal vaccine strategies and the demand for animal models for AIDS vaccine development have provided renewed impetus to the development of an EIAV vaccine to prevent virus infection. EIAV also offers an important model for the role of antigenic variation in a persistent retrovirus infection.

Classification

EIAV is classified as a member of the genus *Lentivirus* based on criteria of virion morphology, serological properties, and genomic sequence homologies. There has been no formal further subdivision of EIAV isolates into subtypes.

Properties of the Virion

The EIAV particle has the general morphology of a lentivirus, including an oblong core enclosed in a viral envelope with surface projections (**Figure 1**). The oblong core observed in EIAV is characteristic of lentiviruses, in contrast to the icosahedral cores found in most oncoviruses. This distinctive structural feature was the initial indication that HIV-1 was related to EIAV and a member of the lentivirus rather than the oncovirus subfamily of retroviruses. The virus particles appear roughly spherical in the electron microscope (**Figure 2**), although there are various degrees of polymorphism depending on the sample preparation. The overall diameter of the virion is approximately 100 nm. The surface projections extend about 7 nm and appear to be distributed on the viral surface in a symmetrical pattern.

Properties of the Genome

The EIAV genome consists of a dimer of single-stranded, positive-sense RNA. The genomic organization of EIAV is characteristic of a complex retrovirus, but is the simplest and smallest of characterized human and animal

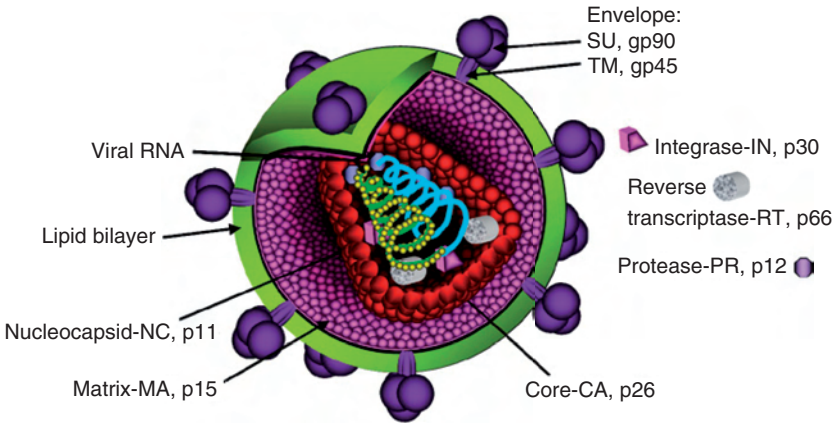

Figure 1 Virion morphology and protein organization of EIAV.

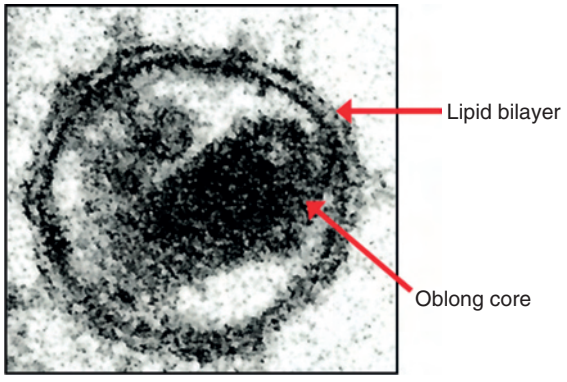

Figure 2 Transmission electron micrograph of an EIAV particle.

lentiviruses (**Figure 3**). The viral RNA contains about 8200 bp and contains three major genes (*gag, pol,* and *env*) encoding viral structural proteins and three minor genes (*tat, S2,* and *rev*) that encode nonstructural proteins that regulate various aspects of virus replication. The order of the EIAV genome is 5′-R-U5-*gag-pol-env*-U3-R-3′. The *tat* and *S2* genes are encoded as distinct alternate reading frames within the *pol–env* intergenic region, while the *rev* gene is encoded by alternate reading frames contained at the beginning of the *env* gene sequences and following the 3′ end of the *env* gene. The relatively small size of the EIAV genome compared to other lentiviruses is primarily due to the much smaller size of the *pol–env* intergenic region.

The EIAV *gag* gene encodes the four viral core proteins in the order of 5′-p15-p26-p11-p9–3′, while the *env* gene encodes the two envelope glycoproteins of the virus in the order of 5′-gp90-gp45–3′. The *pol* gene encodes a complex of enzymes with an organization of 5′-protease-reverse transcriptase-RNase H-dUTPase-integrase-3′. As with other lentiviruses, the EIAV *tat* and *rev* genes encode important regulatory proteins that either transactivate virus transcription (Tat) or control viral transcription patterns (Rev) after infection of host cells. The function of the 8 kDa protein encoded by the *S2* gene remains to be defined, although mutation studies of this gene indicate that it is not essential for *in vitro* viral replication and results in a single $\log_{10}$ reduction in viral replication in equines. The terminal LTR sequences of EIAV contain the usual complex of transcriptional regulatory domains distinctive of lentiviruses.

Properties of the Viral Proteins

The proteins encoded by the *gag* and *env* genes of EIAV constitute the major structural proteins of the virus (cf. **Figure 1**). The gp90 protein is a highly glycosylated, hydrophilic surface (SU) protein that forms the outermost knobs of the envelope projections, while the gp45 is a sparsely glycosylated, hydrophobic transmembrane (TM) protein that forms the membrane-spanning spike of the envelope projection. There are approximately 300 copies each of the envelope glycoproteins per virion, and the surface projections are composed of trimers of gp90 and gp45. The final component of the EIAV envelope structure is the fatty acylated p15 that forms a continuous matrix (MA) immediately beneath the lipid bilayer of the virus particle. The virion core shell or capsid (CA), composed predominantly of p26 molecules, encloses a helical ribonucleoprotein complex containing the basic nucleoprotein (NP), p11, and various polymerases (RT, IN, and DU) in close association with the viral RNA genome. The location of the final core protein, p9, is not certain, but it has been proposed as a linker protein between the core shell and envelope matrix. Recent experiments have indicated that the EIAV p9 protein mediates late stages of viral budding.

The *gag*-encoded proteins of the virus are present in molar amounts that are at least tenfold greater than the envelope glycoproteins, in the range of 3000–5000 copies

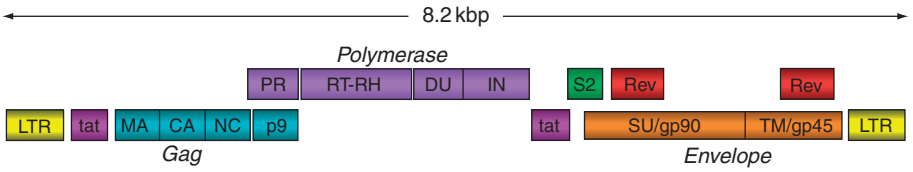

Figure 3 Organization of the EIAV genome indicating viral genes (italic print) and the respective proteins encoded by these genes (block print).

per virus particle. In contrast, the *pol*-encoded enzymes appear to be present in the virus at levels of about 10 molecules per virion.

Replication Strategy

The EIAV replication cycle is characteristic of retroviruses in general and lentiviruses in particular (summarized in **Figure 4**). Viral recognition, attachment, and penetration of target cells is believed to be mediated by specific interaction of the viral envelope glycoproteins and cellular receptor proteins contained in the plasma membrane. Until recently, there were no recognized receptors for EIAV. Recently, a cellular receptor for EIAV, designated ELR1, has been identified as a member of the tumor necrosis family of receptors (TNFRs). Once inside the target cell cytoplasm, the virus reverse transcriptase copies the single-stranded RNA genome into double-stranded DNA provirus that is then transported to the nucleus of the cell. There is no evidence for translation of the incoming EIAV genome at this stage of infection. Once inside of the cell nucleus, the EIAV integrase mediates apparently random but limited incorporation of the provirus DNA into cellular chromosomes, although some extrachromosomal viral DNA is always present in productively infected cells. There is typically a total of about 10 copies of proviral DNA per infected cell. Cytopathic infections by EIAV have been correlated with higher ratios of integrated to unintegrated proviral DNA.

Transcription of the proviral DNA by cellular polymerases produces a complex pattern of viral messenger RNA species whose relative proportions may differ depending on the virus strain and target cell. In all instances, the predominant EIAV transcripts are an 8.2 kbp transcript representing the full-length genomic RNA and translated to produce the *gag* and *pol* gene products, and a 3.5 kbp mRNA that is a singly spliced transcript translated to produce the viral envelope proteins. Lentivirus-infected cells usually contain in addition to these major viral transcripts, a heterogeneous population of small multiply spliced RNA that are used to produce the various regulatory proteins. In the case of EIAV, however, infected cells reveal only minute quantities of these small, multiply spliced RNA species. The relatively low abundance of small transcripts may in part reflect the relative genetic simplicity of EIAV and the

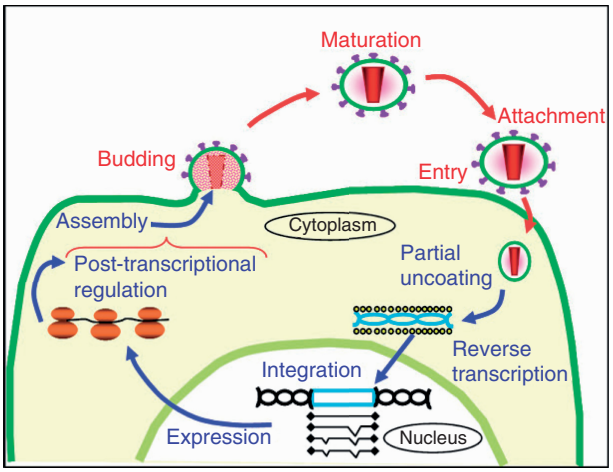

Figure 4 Schematic representation of the EIAV life cycle.

lack of extensive splicing to ensure production of all of the minor viral genes. On the other hand, it is intriguing that the 3.5 kbp transcript is in fact a tricistronic messenger that can produce by *in vitro* translation the viral Tat and Rev proteins in addition to the more abundant envelope glycoproteins. The use of a tricistronic messenger may represent a novel mechanism of maximizing genetic efficiency in EIAV replication.

The viral Gag and Env proteins are initially produced as polyproteins that are cleaved into the mature virion components by a combination of viral and cellular proteases. The only modification documented in the core proteins is a fatty acylation at the N terminus of the matrix protein, p15. The envelope proteins are modified by N linked glycosylation. Although the gp90 and gp45 polypeptides contain about 400 amino acid residues, the gp90 contains an average of 17 potential N linked glycosylation sites, while the gp45 contains only about five potential glycosylation sites. By comparison to HIV-1 gp120, it is assumed that all potential glycosylation sites are occupied by complex oligosaccharides.

The precise mechanisms of EIAV assembly have not been completely dissected, although it is assumed that it follows the general model for retrovirus assembly. It appears to be a highly concerted process that is mediated by interactions between the viral Gag polyproteins and host cofactors. Accordingly, the viral envelope

glycoproteins are initially inserted into the plasma membrane to create distinct sites of virus assembly at which the Gag polyprotein is accumulated beneath the membrane lipid. Subsequently, Gag proteins recruit host cellular components that also regulate the endocytic pathway for assembly and budding. To date, early (AP-2) and late endocytic proteins (TSG101) as well as the actin cytoskeleton have been associated with EIAV virion production. The intermediate viral proteins are next cleaved into the mature virion proteins as the particle buds from the cell surface and is released to produce progeny virions.

Epidemiology, Geographic and Seasonal Distribution

EIAV has been diagnosed in many areas of the world and is considered a worldwide disease of horses. Although localized outbreaks of disease can occur, the incidence of EIAV-infected horses is the highest in tropical and subtropical climates, presumably due to the longer warm seasons and more abundant populations of insect vectors that may transmit EIAV among horses. During the past 20 years, the EIAV infection rate reported by the USDA has dropped from about 4% to less than 0.2%. However, these testing results do not reflect the general horse population as less than 10% of the horses in the United States are tested for EIA, usually because of requirements for transportation across state lines or for participation in organized shows or races. General surveys of unregulated herds in the Southeast United States demonstrate infection rates of up to 15%. EIAV infections are especially prevalent in Central and South America, where limited surveys of Latin American countries have demonstrated infection rates in unregulated herds frequently approach 50% indicating that EIAV infection is epidemic in these areas. Although the probability of EIAV infection by insect vectors is greatest during seasons that are warm, infections can occur throughout the year via mechanical transfers of blood by hypodermic needles and other veterinary instruments. Sexual transmission of EIAV has not been demonstrated to date.

Host-Range and Virus Propagation

EIAV appears to infect only members of the family Equidae. There is no evidence to support the concept of natural or experimental infections of humans or of other mammalian species. EIAV infection of horses results in high levels of virus replication, persistent infection, and clinical disease. EIAV infection of donkeys produces only limited virus replication, presumably a persistent infection, but no signs of clinical disease.

Field strains of EIAV can only be propagated *in vitro* in cultures of equine monocyte or macrophage cells, where virus infection typically produces a cytopathic effect within several days. Large-scale production of EIAV is limited to cell culture-adapted strains of virus that can be grown in primary cultures of equine dermal cells or fetal equine kidney cells and in a limited selection of nonequine continuous cell lines, including canine fetal thymus (Cf2th) cells and the Fea and FEF feline cell lines. The cell-adapted strains of EIAV are noncytopathic to these permissive cell lines. Field strains of EIAV retain their pathogenic properties when propagated in leukocyte cultures, but usually become avirulent when adapted to other types of cell cultures. Cell-adapted strains of EIAV that retain their virulence have been produced by back passage of avirulent cell-adapted strains in ponies or horses. There is no evidence for infection of cultured human cells by EIAV.

EIAV production in cell cultures is most easily detected by the presence of viral antigens or reverse transcriptase activity in culture media.

Genetics

Like other retroviruses, EIAV replication is mediated by a virion reverse transcriptase (RT) that copies the viral RNA genome into proviral DNA that is found in the nucleus of infected cells randomly integrated into the cellular chromosome and as extrachromosomal molecules. There are typically only about 10 copies of EIAV DNA per infected cell. EIAV replication in horses is characterized by relatively rapid and diverse genomic mutations that produce an apparently wide variety of variant virus strains. Analyses of sequential antigenic variants of EIAV from experimentally infected horses suggest that the rate of mutation in the envelope gene of the virus is greater than 10^{-2} base substitutions per site per year. The fidelity of DNA synthesis by purified EIAV RT has been measured *in vitro*, and an average error rate of 1/700 bp has been estimated. This value is similar to the *in vitro* error rate calculated for human immunodeficiency virus (1/700 bp), but is significantly higher than the rate observed for oncovirus RT such as avian myeloblastosis virus (1/3000 bp). The error-prone nature of EIAV RT produces significant biological diversity that is important in EIAV persistence and pathogenesis. As demonstrated for HIV and SIV, recombination between variant EIAV genomes in infected cells may also contribute to genetic diversification during persistent infection.

Evolution

Phylogenetic analyses based on the nucleotide sequences of various retroviruses indicate that EIAV is most closely related to the ungulate lentiviruses (visna-maedi virus,

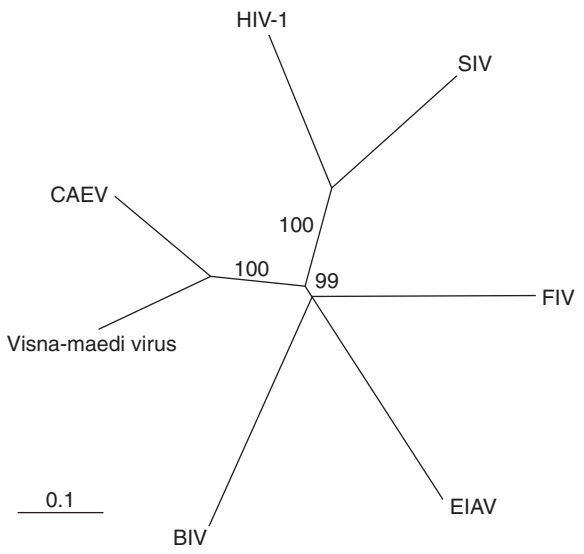

Figure 5 Phylogenetic tree of the complete genomes of identified lentiviruses.

caprine arthritis-encephalitis virus, and bovine immunodeficiency virus) and equally divergent from the human and simian immunodeficiency viruses (**Figure 5**).

Studies of EIAV evolution through analyses of sequence variation during persistent infection in experimentally infected equids have clearly identified dynamic changes in envelope sequences that alter viral antigenic properties, evidently as a result of immune selection. Variation of the envelope gene has therefore served as a distinct marker for analysis of viral population evolution. Detailed molecular characterization of envelope variation during sequential disease cycles in experimentally infected ponies revealed the presence of distinct EIAV envelope variants with each wave of viremia. Examination of inapparent stage viral populations from the plasma of ponies indicated that evolution of the viral quasispecies is continuous, even with relatively low levels of detectable virus replication in the periphery or tissues. These results suggest that even in the absence of detectable plasma virus, viral populations, most likely in tissue reservoirs, continue to replicate and evolve, seeding the plasma with new viral quasispecies.

Serologic Relationships and Variability

Field and laboratory isolates of EIAV display a remarkable variability in antigenic properties. The core proteins of the virus contain conserved antigenic determinants that are the basis of current serological diagnostic assays. The viral glycoproteins also contain a limited number of conserved antigenic determinants, but predominantly present an array of variable antigenic sites that can be distinguished by their reactivity with monoclonal antibodies or by neutralization with polyclonal immune serum from infected horses. The range of variation observed among EIAV isolates has precluded any classification of virus strains on the basis of serological properties.

Immune serum from EIAV-infected horses is reactive with the respective major core protein of most animal and human lentiviruses, but not with any of the major core proteins of oncoviruses. Immune serum taken from other species infected with a lentivirus generally do not reveal a cross-reactivity with EIAV or with other lentiviruses. This one-way serological reactivity suggests that horses infected with EIAV uniquely recognize a conserved lentivirus-specific, antigenic determinant.

Transmission and Tissue Tropism

Blood from persistently infected horses is the most important source of EIAV for transmission; *in utero* transmissions of EIAV from mare to foal are evidently very rare. This blood transfer can be affected by man or blood-feeding vectors. EIAV has been shown to remain infectious on hypodermic needles for up to 96 h, emphasizing the potential for transmission via routine animal husbandry or veterinary medical practices. However, the mechanical transmission of EIAV by arthropods, especially horseflies, is generally accepted as the major natural means of transmission in the field. Transmission of EIAV by a single horsefly carrying only approximately 10 nl of virus-infected blood has been documented under experimental conditions.

The target cell during persistent EIAV infections appears to be exclusively cells of the monocyte/macrophage lineage; there is no evidence for infection of lymphocytes as observed with some other lentiviruses. The virus burden in infected horses is predominantly in tissue macrophage found in liver, kidney, and spleen with much lower levels of virus found in lymph nodes, bone marrow, or in circulating monocytes. Thus, the relatively high levels of viremia (10^{4-6} $TCID_{50}$) observed during episodes of chronic EIA evidently result primarily from the production and release of virus from infected tissue macrophage, rather than an extensive infection of blood monocytes.

Pathogenicity

Field isolates and laboratory strains of EIAV differ markedly in their pathogenicity, ranging from avirulent to lethal strains of the virus. Little is known about the viral determinants or host factors that influence the course of virus replication and pathogenesis. In other lentiviruses, differences in viral pathogenesis have been mapped to specific changes in viral envelope genes or to changes in gene regulatory sequences in the viral genome. It is likely that variation in EIAV pathogenicity will follow a similar pattern.

Clinical Features of Infection

The clinical response of horses following artificial inoculation or natural exposure to EIAV is variable and depends in part on host resistance factors, viral virulence factors, and environmental factors (e.g., weather and work load). In general, EIAV infections can be apparent with distinctive clinical symptoms or inapparent without any clinical signs of EIA. The clinical disease is typically described as acute, chronic, or asymptomatic (**Figure 6**).

Acute EIA is most often associated with the first exposure to the virus, with fever and hemorrhages evident from 7 to 30 days after exposure. Acute disease is thought to be associated with massive virus replication in and destruction of infected macrophages. Horses in the initial phase of acute EIA will be seronegative, because the immune system has had insufficient time to respond to the viral antigens. During the peak of the febrile response in acute EIA, viremia of greater than 10^6 horse-infectious doses per ml of whole blood is often observed. The initial acute phase of EIA infection may not be seen by the veterinarian unless there is an epizootic of the infection in a group of horses. Even then, the horses must be under close supervision before the initial fever and anorexia are detected. Neither anemia nor edema is seen at this stage of disease.

The more classic clinical signs of EIA such as loss of weight, anemia, diarrhea, and edema are seen later during recurring cycles of the illness, which appear at irregular intervals ranging from a couple of weeks to several months. The frequency and severity of clinical episodes in horses with chronic EIA usually decline with time, about 90% occurring within 1 year of infection. Horses with chronic EIA are seropositive and have variable viremia levels which are the highest during the periodic febrile episodes. Although a small percentage of chronic EIA cases may result in death, the predominant clinical course of infection is a cessation of detectable clinical symptoms by the end of the first year post infection and the establishment of a lifelong inapparent carrier stage. However, animals can experience a recrudescence of viremia and disease due to stress or immune suppression from a contemporous bacterial or viral infection.

The highest percentage of EIAV-infected horses in the field are in fact inapparent carriers. These horses have no clinical illness associated with the viral infection, and viremia is usually undetectable. However, these inapparent carriers maintain high levels of EIAV-specific antibodies, suggesting a chronic low level of virus replication. Inapparent carriers can be shown to harbor infectious EIAV by transfusions of whole blood (200 ml) to recipient horses that become seropositive to EIAV within 3–6 weeks post inoculation. In addition, treatment of certain inapparent carriers with immunosuppressive drugs or exposure to extreme stress can cause the recrudescence of chronic EIA, even in some horses that have been free of clinical symptoms for years.

Pathology and Histopathology

Gross and histopathological lesions in EIAV-infected horses are variable and closely associated with levels of viral replication. In the acute stage of EIA, gross pathological lesions consist of swelling of the parenchymatous organs, and hemorrhages can be observed in most tissues.

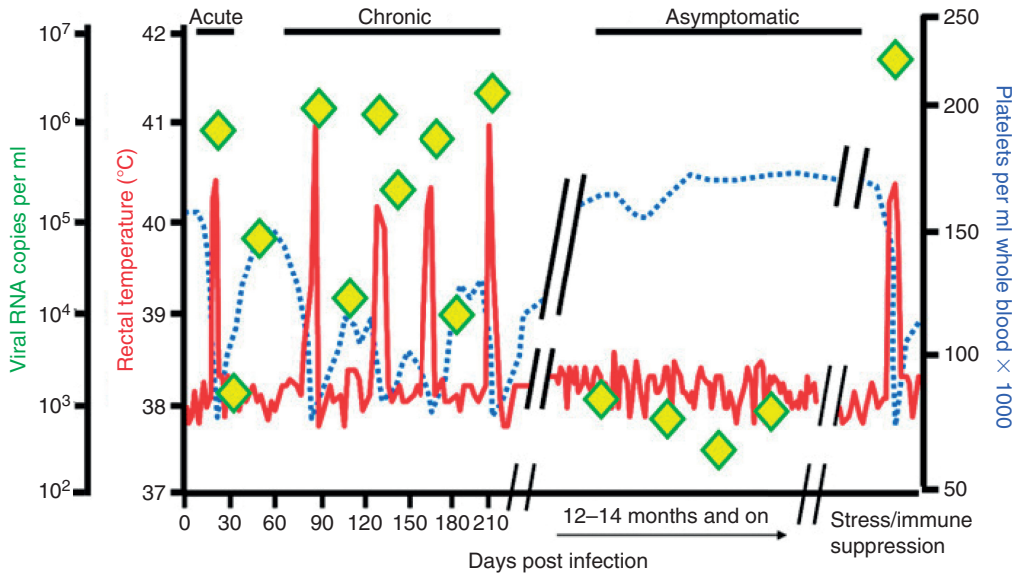

Figure 6 Clinical profile associated with EIAV infection of horses indicating the characteristic stages of EIA. Febrile episodes are defined as rectal temperatures above 39 °C (103 °F), and thrombocytopenia is defined as platelet levels below 105 000 μl^{-1} of blood.

The most pronounced histopathological lesions are hepatic and lymphoid necrosis in association with large numbers of activated macrophage and Kupffer cells. Hepatic necrosis is most severe near the central vein evidently resulting from degenerative changes in the parenchymal cells. Lesions in the spleen are characterized by degenerative erythrocytes, and small focal hemorrhages are found in the splenic capsule and adjacent tissue. Lymphocytic infiltrations can be observed in several organs including liver, spleen, lymph node, kidney, heart, and lung. The majority of these lesions are thought to be the combined effect of immune-mediated lysis of virus-infected cells and an immune complex-mediated inflammatory response.

The pathological changes in the chronic form of EIA include a developing immunological control of virus replication. Gross pathological lesions include splenomegaly, lymphadenopathy, and hepatomegaly. Microscopic changes are characterized by infiltration of lymphoid cells in almost all organs and tissues. Anemia has long been considered the hallmark of EIA. The two major causes of anemia, hemolysis and bone marrow depression, are closely associated with replicating virus. Hemolysis is immunologically mediated. Erythrocytes are coated with the viral surface glycoprotein which in the presence of specific antibodies and bound C3 induces erythrophagocytosis and complement-mediated hemolysis. Bone marrow suppression is less well characterized but appears to be associated with iron deficiency. Thrombocytopenia is frequently the earliest pathology observed during chronic EIA and can precede the detection of virus-specific antibodies. The mechanism for the marked reduction in blood platelets is unknown, but has recently been associated with cytokine dysregulation.

Immune Responses

Horses infected with EIAV typically become seropositive in standard serological assays within 21 days post infection. The humoral immune responses are predominantly against the viral envelope glycoproteins, gp90 and gp45, and the major core protein, p26. All currently approved diagnostic assays for EIAV infection are based on the detection of antibody to the major core antigen, although the antibody response to the envelope glycoproteins is at least tenfold greater than the antibody titer measured against the p26 protein. Significantly lower levels of antibody can be detected against virtually all of the other structural and nonstructural proteins encoded by EIAV. Interestingly, EIAV-specific antibody levels remain relatively constant throughout the course of chronic EIA and even in the unapparent stage of infection.

The immune responses generated during chronic EIA initially mediate significant pathogenesis in the presence of sufficient levels of EIAV antigenimia, but progressively evolve to establish a strict immunologic control over virus replication. Thus, the EIAV system is unique among lentiviruses in that the host immune responses routinely accomplish an effective control of aggressive virus replication and recurring clinical disease to maintain an indefinite inapparent stage of infection. The immune correlates of this protection remain to be defined. However, it has been shown that the neutralizing capacity of serum antibodies elicited to EIAV during the chronic stage of disease progressively increases, indicating an evolution of immune responses to the sequential generation of antigenic variants of virus. In addition, recent studies have demonstrated a lengthy and complex evolution of antibody and cellular immune responses to experimental EIAV infections of horses demonstrating a dynamic maturation process that apparently correlates with the development of protective immunity. The specific humoral or cellular immune correlates of protection have not yet been identified. The ability of the horse immune responses to overcome the array of persistence and escape mechanisms employed by EIAV suggests that a successful vaccine is feasible.

Prevention and Control

The transmission of EIAV infection has been controlled by improving animal husbandry techniques to prevent the spread of infected blood, by reducing the horsefly population in the vicinity of herds, and primarily by identifying and segregating or sacrificing horses that are seropositive for the virus. In the United States, the most common diagnostic assays are an agar gel immunodiffusion test, the Coggins assay, which was developed in the early 1970s and enzyme-linked immunoassay that was approved by the USDA as an EIA diagnostic assay in the 1980s and 1990s. Both diagnostic assay procedures are based on the detection of serum antibodies to the major viral core protein, p26. The diagnostic enzyme-linked immunosorbent assay (ELISA) assay has been engineered to produce a sensitivity that is equivalent to the previously established Coggins test. More sensitive diagnostic assays based on the detection of antibodies to the EIAV envelope glycoproteins have been developed, but have not yet been approved for commercial use. The most sensitive and specific assay for detecting EIAV infection is horse inoculation tests with 200 ml of whole blood from the horse being tested. The horse inoculation test is used only in rare cases where the standard serological assays may give ambiguous results.

There is currently no effective vaccine for the prevention of EIAV infection and disease. The primary challenge in developing an effective EIAV vaccine is overcoming the antigenic diversity intrinsic to this virus. An important

practical requirement in the development of any EIAV vaccine is compatibility with established regulatory policies and diagnostic assays. The ability of EIAV-infected horses to routinely establish immunologic control over virus replication and disease suggests that an effective vaccine can indeed be developed, if the critical natural immune correlates of protection can be elicited by a candidate vaccine. An attenuated live EIAV vaccine with a reported protection efficacy of about 70% has been used in China since the early 1980s, but the effectiveness of this vaccine remains to be confirmed outside of that country. Evaluation of other candidate EIAV vaccines (live-attenuated, inactivated whole virus, subunit vaccines, synthetic peptides, etc.) under experimental conditions has revealed a spectrum of vaccine efficacy that ranges from 'sterile protection' (prevention of infection upon inoculation with EIAV) to severe elevation of EIAV replication, and exacerbation of disease. These results indicate that immune responses to EIAV are a double-edged sword that can either mediate protection or yield vaccine enhancement. Vaccine enhancement has previously been reported for other viral infections (dengue virus, respiratory syncitial virus, feline infectious peritonitis virus) and is of special concern with macrophage-tropic viruses. Similar examples of vaccine protection and enhancement have been reported in studies of experimental vaccines for other lentiviruses, including feline immunodeficiency virus, caprine arthritis-encephalitis virus, and visna-maedi virus. These observations in several diverse animal lentivirus systems suggest that the potential for immune enhancement may be a general property of lentiviruses, including HIV-1. Current efforts in the production of a commercial EIAV vaccine are focused on the development of a vaccine that can achieve sufficient maturation of immune responses to provide protection from virus infection, but allow the serological differentiation between vaccinated and infected horses. In this regard, DNA vaccine strategies appear to be well suited to accomplish these criteria for a commercial EIAV vaccine.

Future Research

EIAV provides a dynamic system for examining the interaction between virus populations and host immune responses that are evolving in response to each other. In addition, EIAV offers a remarkable model for studying the delicate balance between immune responses to a persistent virus infection that result in disease and those that have beneficial results. A characterization of the nature of protective and enhancing immune responses can provide important information about the mechanisms of lentivirus disease and the type of immune responses to be elicited or avoided by a vaccine. The results of these studies in the EIAV system should be applicable to other lentiviruses, including HIV-1.

Glossary

Dendrogram A schematic line drawing, often tree-like, that represents evolutionary relationships between species.

Error catastrophe A threshold at which a high error rate of genome replication can no longer maintain the integrity of essential genetic information.

ERV An endogenous retroviral-like genetic element, containing a long terminal repeat

that is found in the genomes of many organisms.

Fitness landscape A hypothetical representation of a three-dimensional surface that represents relative fitness of genetic variants.

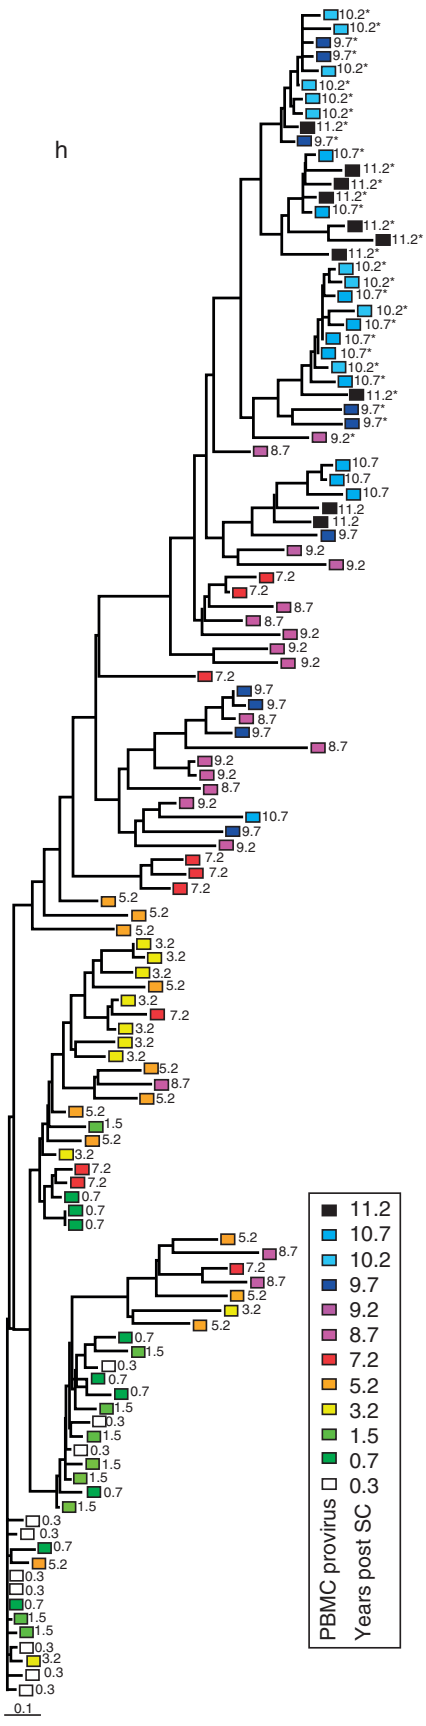
Muller's ratchet A decrease in fitness resulting from a repetition of a genetically restricted founder population.

Quasispecies A population of viral genomes that are the product of error-prone replication usually envisioned as a swarm or cloud of related genomes.

Red Queen hypothesis An evolutionary concept in which an organism must evolve at high rates in order to maintain its competitive advantage.

Reticulated evolution A pattern of evolution in which elements are derived from different ancestors represented as a tree with cross-connections between distinct branches.

Sequence space A multidimensional representation of all possible sequences for a given genome.



Introduction

The initial study of virus evolution sought to explain how virus variation affects viral and host survival and to understand viral disease. However, we now realize that virus evolution is a basic issue, impacting all life in some way. In general, the principles of virus evolution are very much the same Darwinian principles of evolution for all life, involving genetic variation, natural selection, and survival of favorable types. However, virus evolution also entails features such as high error rates, quasispecies populations, and genetic exchange across vast reticulated gene pools that extend the traditional concepts of evolution. Evolution simply means a noncyclic change in the genetic characteristics of a virus; and viruses are the most rapidly evolving genetic agents for all biological entities. Principles of virus evolution provide an integrating framework for understanding the diversity of viruses and the relationships with host as well as providing explanations for the emergence of new viral disease. Most emerging viral diseases are due to species jumps from persistently infected hosts that have long-term virus–host evolutionary histories (called natural reservoirs). Since early human populations (i.e., small bands of hunter gatherers) could not have supported the great human viral plagues of civilization (e.g., smallpox virus/variola and measles), these viruses must also have originated from species jumps that adapted to humans. In recent history, the emergence of HIV demonstrates that virus evolution continues to impact human populations. Early observation established that viruses often show significant variation in virulence. Such variation was used as an early, yet risky, form of vaccination (i.e., variolation against smallpox). The variation that occurred with passage into alternate tissue and host was also used to make various vaccines (rabies in 1880s) or attenuate viral virulence, such as live yellow fever vaccine. But variation also allows some viruses, such as influenza A, to escape neutralization by vaccination. However, variation in viral disease or virulence does not provide a quantitative basis to study evolution.

The study of virus variation and evolution is an applied science that allows the observation of evolutionary change in real time. For example, human individuals (or populations) infected with either human immunodeficiency virus 1 (HIV-1) or hepatitis C virus (HCV) show progressive or geographical evolutionary adaptation associated with the emergence of specific viral clades that affect disease therapy and progression (such as resistance to antiviral drugs). **Figure 1** shows HIV variation in an individual human patient whereas **Figure 2** shows HCV variation in the human population. Virus evolution is also important for the commercial growth of various organisms, such as the dairy industry (lactose fermenting bacteria), the brewing industry, agriculture, aquaculture, and farming. In all these applied cases major losses can result from virus adaptation to the cultivated species, often from viruses of wild species. Some organisms appear much less prone to viral adaptations (e.g., nematodes, ferns, sharks). Virus evolution can also be applied to technological innovation, as in phage display. This is a process in which a terminal surface protein of some filamentous bacterial virus can be genetically engineered for novel surface protein expression. By generating diversity *in vitro* (with up to 10^{15} types), and applying the principles of evolution (random variation) to biochemical selection (such as binding to a chemical substrate), a reiterative amplification can find solutions to problems in biochemistry, such as surface interactions or catalytic activity.

Virus Evolution as a Basic Science

Virus variation is a global issue. In the last decade it has been established that viruses are the most numerous biological entities on the planet. The oceans and soil harbor vast numbers of viral-like particles (VLPs), mostly resembling the tailed DNA viruses of bacteria. In addition, some of these environmental viruses are unexpectedly large and complex, such as the phycodnaviruses of algae or mimivirus of amoeba, a 1.2 Mb DNA virus that can encode nearly 1000 genes. Thus viruses represent a vast and diverse source of novel genes. However, the evolutionary dynamics of this population and its effect on hosts is not well understood. It is likely that this virus gene pool also affects host evolution since prophage colonization is

known for all prokaryotic genomes. Thus, this vast pool of viruses connects directly to prokaryotes and the 'tree of life'. The study of virus evolution has become an extension of all evolution.

Distinctions from Host Evolution

For the most part, virus evolution conforms to the same Darwinian principles as host evolution, involving variation and natural selection. However, viruses have multiple origins, and are thus polyphyletic. There are six major categories of viruses (+RNA, –RNA, dsRNA, retro, small DNA, large DNA) that have no common genes and hence have no common ancestor. However, these categories all have conserved hallmark genes (i.e., capsid proteins, Rd RNA pol, RT, primase, helicase, and RCR initiation proteins) which are all monophyletic and which may trace their origins to primordial host/viral gene pools. Many DNA viruses, for example, have replication strategies and polymerases that are clearly distinct from that of their host, which depends on such hallmark genes. Thus, virus evolution appears ancient but inextricably linked to its host. Also, in contrast to host evolution, viral quasispecies show a population-based adaptability that extends the selection of the fittest to include populations of otherwise unfit genomes (described below). Viruses can clearly cross the usual host-species barriers so that viral evolution can be reticulated in vast genes pools. For example, bacterial DNA viruses and +RNA viruses can show high rates of recombination across viruses that infect numerous host species. Accordingly, tailed DNA phage of bacteria appear to represent one single vast gene pool. Viruses can also violate concepts of death and extinction, reassembling genomes from parts and/or repairing lethal damage by multiplicity reactivation. In addition, damaged (defective) viruses can also affect virus and host evolution. Such defectives are found in many types of viruses and can also be found in many host genomes (as defective prophage or defective endogenous retroviruses). Such defective viruses can clearly affect host survival. In all these characteristics, viruses extend the Darwinian principles of host evolution.

A History of Virus Evolution

The coherent study of virus evolution awaited the development of sequence technology to measure mutations and genetic variation in viral populations. Concepts of natural selection, fitness, and propagation of favorable variation had long been established in the evolutionary biology literature prior to the growth of virology. Thus, mathematical models, such as Fisher population genetics, concerned with gene frequency in a (sexually exchanging) species population, had been well developed and seemed directly applicable to virus evolution, which resemble that of host genes. Here, viral fitness was typically expressed as relative replication rates (replicative fitness) but sometimes host virulence and disease were also used. However, as presented below, a comprehensive definition of viral fitness remains problematic. The first quantitative measurements of the rate of virus mutation was done in the 1940s with bacterial phage. The mutation rates were expressed as a set of ordinary differential equations that were subsequently used to develop the quasispecies equations as applied to error-prone RNA genomes (see below). However, the species definition of a virus poses a problem for evolutionary thinking and challenges how we define kinship in viruses. Unlike the sex-defined host, a virus species is currently defined as a polythetic class: a mosaic of related parts of which not all elements are shared (such as host range, genome relatedness, antigenic properties). No specific defining characteristic or gene exists for a virus species and sexual exchange need not be included. This is an inherently fuzzy definition, like defining a 'heap', which although clear, cannot be specified by its number of parts. The ensuing molecular characterization of many virus populations supports this species definition. The challenge then is to understand viral evolutionary patterns working with such fuzzy definitions. Yet, conserved patterns of virus evolution are still seen, some of which suggest viruses are indeed an ancient lineage, possibly extending into the primordial RNA world.

Error-Prone Replication and Quasispecies

In the 1970s, Manfred Eigen and also Peter Shuster developed a fundamental theoretical model of virus evolution. A set of ordinary differential equations was published that described what was called 'quasispecies'. Starting from measurements of phage mutation rates, they considered the consequences of high error rates as expected from RNA replication (an error-prone noncorrecting replication process). The resulting population shared many properties and was called quasispecies, a society (or community) of individuals that are the error products of replication. The name 'quasispecies' thus describes a chemically diverse set of molecules and was not intended to refer to a biological species (i.e., genetic exchanging). However, as discussed above, the fuzzy definition of virus species and quasispecies overlaps somewhat, which has been a source of confusion. Several premises were used to develop this theory: (1) the individual products ignore one another and interact only as individuals; (2) the system is not at equilibrium and resources are not limiting. Based on relative replication, the growth of favorable types is described which provides a mathematical definition of replicative fitness. The original equations represent an idealized generalized system of infinite population size and are not directly applicable to the real world, although they provide valuable insights into real world systems. The equations do not address variable mortality (longevity), interference, exclusion, competition, complementation, and persistence, or how such issues affect nonreplicative fitness definitions. The issue of mortality and fitness is interesting from the perspective of viruses. For example, an interfering defective virus can be considered dead, but can clearly interfere with and drive the extinction wild-type template replication in quasispecies. In some cases, the quasispecies equations appear to be mathematically equivalent to classical Wright and Fisher population genetics equations as applied by Kimura and Maroyama to asexual haploid populations at the mutation-selection balance. However, these two approaches begin with distinct perspectives, and it was the assumption of high error in the quasispecies equations that had a major impact on experimentation and our current understanding of virus evolution. This has

also led to some counter intuitive conclusions, such as the concept of selection of 'the fittest' compared to the consensus character of the master template. Quasispecies from a virus with high error rates (such as HIV-1) might be composed of all mutant progeny RNAs such that the consensus template (the mean, the fittest, or the master template) may not actually exist. With classical population genetics, an asexual clonal population should fix the clonal sequence. With quasispecies, this is not observed. The first laboratory measurements of viral quasispecies were made using Qβ RNA polymerase *in vitro*. Error estimates ranged from 10^{-3} to 10^{-4} substitutions per site per year (an error rate applicable to most RNA viruses). With Qβ, the replication of many nonviable mutants generated a genetic spectra that had a characteristic makeup. For example, separate DNA clones of Qβ were initially distinct from each other but quickly generated the same RNA quasispecies as before cloning. Additional lab measurements have shown that quasispecies can have significant adaptive fitness (above the cloned master template) and display memory; that is, they can retain information of prior selections in a minority of the population. Complementation, interference, competition suppression, and extinction have all been measured in various quasispecies, thus indicating a collective form of evolution and violating an original premise of genome independence in these equations. In addition, the sequence diversity in a quasispecies is now seen as a source of adaptive potential, not simply error (see below). Despite these results, the concept of quasispecies has still been highly useful, and not simply as a theoretical development. For example, the live poliovirus vaccine is clearly a heterogeneous quasispecies. Within this population exists a minority of neurovirulent variants that are suppressed by the majority avirulent virus. A main point of the quasispecies concept is that it provides an understanding of high adaptability from a population that has many, even lethal, mutations. It is interesting that the proposed early RNA world would have also been a collective quasispecies world.

Error Catastrophe, Sequence Space

Quasispecies theory also predicts a situation known as error catastrophe, defined as an error rate threshold at which information is lost and the system decays. If error rates are too high, or the information content (genome length) too extensive, the system will be unable to maintain its information integrity. This predicts a basic limit on the size of RNA genomes, consistent with the observation that the largest RNA genomes are only about 27–32 kbp (coronaviruses). There is a possible therapeutic use of error catastrophe: drugs (possibly Ribavarin and 5-fluorouracil) that increase the error rates of RNA polymerase can potentially push a virus beyond its error threshold and induce a catastrophe. Quasispecies is an inherently fuzzy and dynamic population that has no sharp boundaries or specific members and has been metaphorically referred to as swarms and clouds. Here, cloud is a metaphor for the population landscape that exists in high-dimensional hyperspace and cannot be readily visualized. The concept of sequence space has been used to represent topography of the distribution of all mutants. Kinship relationships between mutants can be measured by Hamming distance; the minimal steps needed to specify the difference between two mutants. In spite of high error and adaptation rates (and sometimes high recombination rates), RNA viruses are not able to explore all potential sequence space. Selection significantly limits the quasispecies, since the potential sequence space is hyperastronomical even for a moderately sized virus. For example, an RNA virus with 10 000 nt would correspond to 10^{6000} possible sequences, well beyond what could be explored by even the potentially vast number of viruses over the lifetime of the world. In addition, there are clearly mechanistic constraints that prevent many possible sequences, such as necessary domains of ± strand RNA folds, physical association with ribonucleotide proteins, virion packaging and assembly – all in addition to usual selection for gene fitness (function) that all severely limit possible adaptations. This creates a multipeak 'fitness' landscape in hyperspace (see **Figure 3**). Assuming fitness itself can have a single definition (i.e., replicative fitness, not subjected to variable and stochastic competition), we can visualize this space as many steep valleys and ledges (in this case with 10 000 dimensions). Normally we think that adaptation by natural selection is the force to explore and move through fitness landscape. But as the deep valleys are often lethal, they cannot be explored via natural selection. Here we see the major adaptive power of the quasispecies

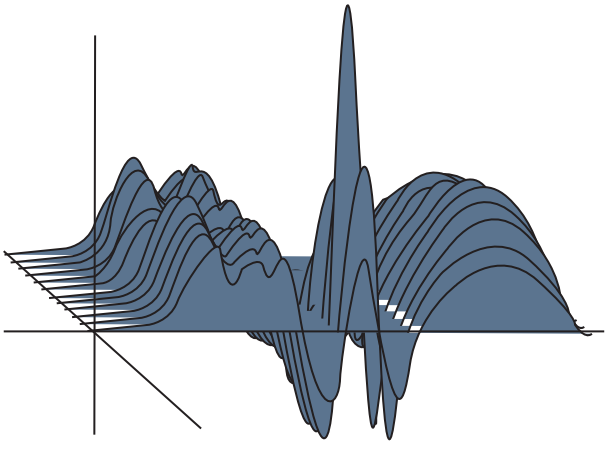

Figure 3 Hypothetical fitness landscape for an RNA virus. Assuming one definition for a nonrelativistic fitness (such as replicative fitness), the coordinates indicate relative fitness. Those below the *y*-axis are interfering or lethal variants.

collective. Since random, even lethal, errors and drift are inherent in a quasispecies, lethal valleys can be readily crossed by such variable genomes, allowing the master genome to adapt by natural selection to a new fitness peak. Thus, error-prone replication and the generation of mutant clouds allows for much better exploration of sequence space and eventual adaptability.

When viruses are transmitted to new hosts, they can experience a genetic bottleneck since a relatively small number of viral genomes could be involved (aka low multiplicity passage). If this process is serially repeated, a phenomenon known as 'Muller's Ratchet' can result in lost competitiveness as the essentially clonal RNA virus accumulates deleterious mutations (sometimes measured as pfu/plaque). However, in lab studies, virus extinction from serial passage does not occur, presumably due to plaque selection for a restored phenotype. Even a single plaque is in reality a small population (due to nonideal particle/pfu ratios and ID_{50}). However, lost competitiveness with other viruses is seen with clonal laboratory passage. However, if a quasispecies population is passed, this generally results in increased competitive fitness. Such passage can produce a seemingly never-ending better version of the virus that outcompetes all prior versions of the same virus (although virion yields and absolute replication are not necessarily improved). This has been likened to the Red Queen hypothesis in that the viruses are evolving at high rates, simply to maintain their competitive position, so as not to be displaced as the dominant viral type. Virus–virus competition is thus a crucial selection.

Never-Ending Adaptation

A real world example of the potentially never-ending virus adaptation is shown in **Figure 4**. The HA and NA genes of human influenza A virus have been monitored for several decades. As shown, the prevalent master template of the virus circulating in the human population has been continually changing, due to immune selection and stochastic viral immigration, necessitating yearly vaccine changes (also shown). Although such a population dynamic has been stably maintained in the human population, all prior versions have essentially become extinct, as they do not reappear.

Not all RNA virus populations show this dynamic of a continual change or even the diversity expected from quasispecies. Even in influenza virus A, avian isolates from natural host (waterfowl) can be genetically stable. Some RNA (and retro) viruses with high error rates can nevertheless maintain stable populations in specific hosts. For example, measles virus shows much less antigenic drift in human infections compared to influenza virus A. Hepatitis G virus (a human prevalent and distant relative of HCV) shows little variation in even isolated human populations. The filoviruses (Ebola virus and Marburg virus) have shown no genetic variation in Zaire isolates from 20 years apart. Hendra virus, isolated from Australian fruit bats, and Nipah virus from Malaysian fruit bats also show little genetic diversity. Arenaviruses and hantavirus are also genetically stable in their natural rodent host. The reasons for such population stability have not been well evaluated. In some cases (measles), purifying selection would seem likely. In other cases, persistence and low replication rates seem to apply. For example, simian foamy virus (SFV) and human T-lymphotropic virus II (HTLV-II) generate only about 10^{-8} substitutions per site per year, probably due to low replication rates.

Virus–Host Congruence and RNA Stability

There are now many examples of species-specific RNA virus/host coevolution, indicating very slow rates of virus evolution. Since error rates must be similar, this appears to be at odds with the quasispecies theory. For example, Hantavirus (genus *Bunyavirus*) coevolution with its rodent host, suggests a 20 million year association. Arenaviruses (ssRNA bisegmented ambisense) also coevolve in Old/New World rodents. These viruses are of special interest with regard to emergence as they represent the source of five hemorrhagic human fevers (such as Lassa virus). In all these examples, however, it appears that the virus causes a persistent unapparent infection in its natural host and that human disease is due to species jump.

Tools

Although viral genomes were the first to be sequenced, the initial focus was simply to identify similarity between viral genes, not to evaluate distant evolutionary relationships. The most popular tool for finding similarity is BLAST (Basic Local Alignment Search Tool) from the National Centers for Biotechnology Information (NCBI), which calculates similarity between query sequences and infers a probability based on a matrix database. Various versions of BLAST are the most used tool in bioinformatics to trace evolution. Although BLAST will identify similar genes, it is also necessary to compile and evaluate the similarities in sets of the related sequences. Multiple sequence alignment software, such as ClustalW, is used for this purpose. Phylogenetic relationships are then inferred from tree-building software. This software includes maximum parsimony, neighbor-joining, and maximum likelihood methods. The statistical significance of the tree (relative to all possible trees) can then be evaluated by algorithms such as bootstrap. More recently, Bayesian analyses, such as Bali-Phy, which implements a Markov Chain Monte Carlo (MCMC) method and calculates joint posterior

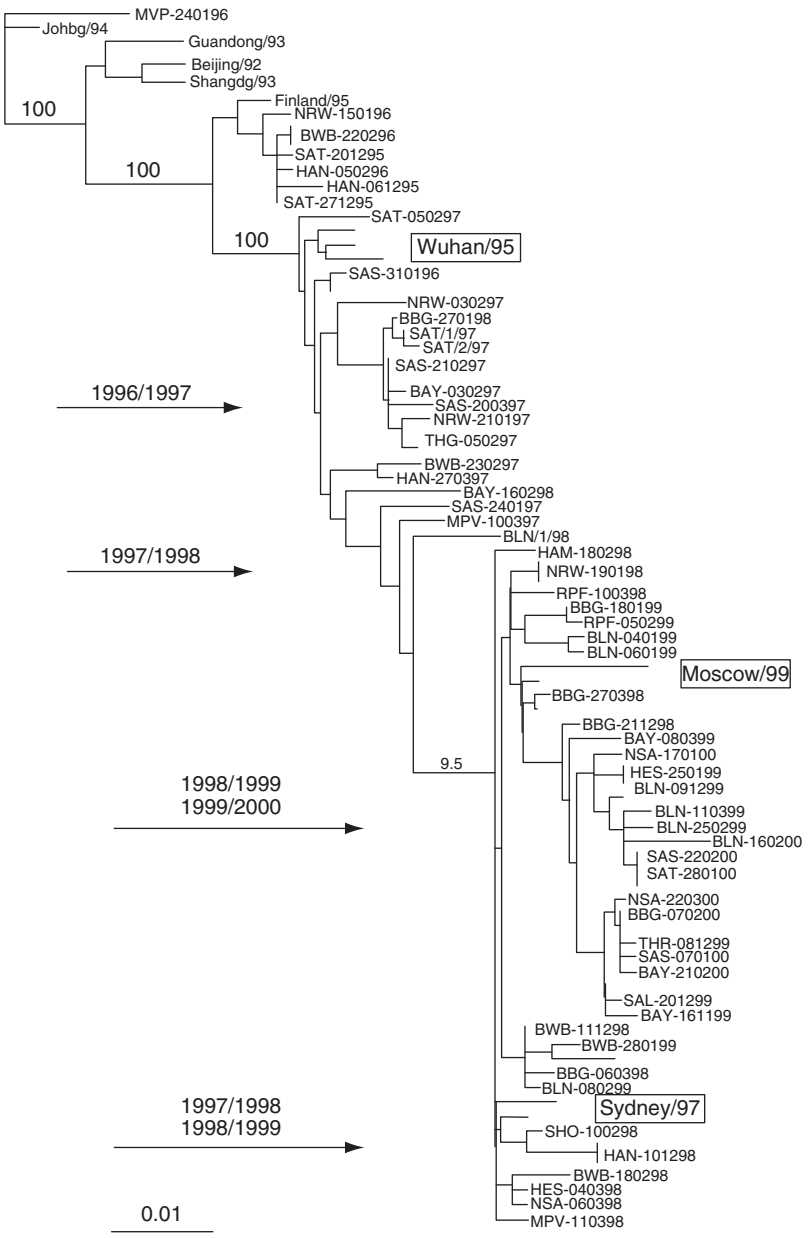

Figure 4 Phylogenetic tree of yearly influenza A/H3N2 viruses variants based on the hemaglutinin gene. Locations of specific vaccine strains are boxed. Reproduced from Schweiger B, Zadow I, and Heckler R (2002) Antigenic drift and variability of influenza viruses. *Medical Microbiology and Immunology* 191: 133–138, with permission from Springer-Verlag.

probabilities of phylogeny and alignment have become popular. This software has the added potential of using sliding windows and evaluating multiple trees, such as in virus–host coevolution. These methods, however, use the single master consensus sequence as its query and do not evaluate quasispecies, collective-based populations. Also, the clearly reticulated or hybrid character of some virus evolution is problematic. Also, distant evolutionary relationships are no longer preserved in the same sequences. Here, conservation of structural motifs, assembly patterns, gene order, and replication strategy are used to identify distant kinship.

Patterns of RNA Virus Evolution

The sometimes extreme variation of RNA virus sequence has led some to propose that most family lineages appear to be only about 10 000 years old, which is clearly at odds with much older estimates. The +RNA viruses in particular show a remarkable diversity of genomes and replicator mechanisms. These families also show much evidence of recombination and a tendency to cross host barriers. About 38 families of +RNA viruses with up to four segments are known. There are four distinct classes of replicase recognized in viruses that also share a common

genetic plan. These RNA viruses have three helicase superfamilies, two protease superfamilies, and two jelly roll capsid domains. For the most part, capsid and RdRpol sequences are congruent except for members of the families *Luteoviridae* and *Tetraviridae*, which appear to have undergone recombination between these two gene lineages. The smallest +RNA virus is a member of the bacterial virus family *Leviviridae*, which has only four genes. This simple virus appears to represent the ancestral +RNA virus. Curiously, no RNA virus has yet been found to infect archaebacteria. The largest +RNA viruses belong to the genus *Coronavirus* (27–32 kbp). The most recently described +RNA viruses are members of the family *Marnaviridae* infecting bats and marine organisms sea life, which appear to be basal to evolution of picornaviruses. However, natural populations of some +RNA viruses can be stable. For example, dengue virus (*Flaviviridae*) shows low rates of amino acid substitution (e.g., nonsynonymous to synonymous ratios). Since it is an acute arbovirus infection with high error rates, strong selective constraints likely account for this stability involving multiple (systemic) tissues and vector transmission.

Negative-strand RNA viruses have distinct patterns of evolution, which is traced via their polymerase genes. Gene order tends to be highly conserved. The unsegmented viruses, such as rhabdoviruses, lyssaviruses, and paramyxoviruses, do not undergo significant recombination so their variation tends to be by point mutations and deletions. Although high error rates, variation, and quasispecies generation can be seen in laboratory settings, natural isolates, such as lyssaviruses and measles virus, tend to be relatively homogeneous. For example, lyssaviruses show a slow rate of evolution (5×10^{-5}/site/year). Lyssavirus persistent infections in natural host might contribute to this stability. However, measles virus is a strictly human-specific acute infection so its stability is likely due to purifying selection.

Patterns of DNA Virus Evolution: Tailed Phage

Large DNA viruses of bacteria, archaea, and eukaryotes appear to be evolutionarily linked. Although little sequence conservation can be identified between the T4 phage of bacteria, the halophage of archaea, the members of the family *Phycodnaviridae* infecting algae, and the herpes viruses of vertebrate eukaryotes, all show similarities in their gene programs, DNA polymerase types, capsid structures, and capsid assembly, consistent with a common ancestor. For example, both the Enterobacteria phage T4 (T4) and herpes simplex virus 1 (HSV-1) have $T = 1$ capsid symmetry with 60 copies of capsid protein. The bacterial DNA viruses would appear to represent the ancestor of all these viruses, but the origins of these phages now appear lost in the primordial gene pool. These DNA viruses can have large genomes that could not be sustained by error-prone replication. Thus, many DNA viruses do have error-correcting DNA replication, with error rates that approach or equal those of their host cells (10^{-8}). Giant bacterial phage genomes (*Bacillus megaterium* phage G, of about 600 genes), and algal phycodnaviruses have now been characterized. Even larger DNA viruses of amoeba (acanthamoeba polyphaga mimivirus) coding for more than 1000 genes are known to be abundant in some water habitats.

The tailed phage of bacteria have been called the dark matter of genetics, due to their numerical dominance ($\sim 10^{31}$ *en toto*). This corresponds to about 10^{24} productive infections per second on a global scale. Most host-restricted phage lineages clearly conserve sets of core proteins (especially capsid genes), but others (the broader T-even phages) do not conserve any hallmark genes. Hallmark genes, when present, are usually recognized by conserved domains within proteins, such as replication and structural proteins. Replicator strategy and gene order are also frequently conserved. Phage also tends to conserve genes that are active against other phage (i.e., DNA modification, lambda RexA, T4 rII). With the sequencing of numerous phage genomes, however, a large number of novel genes have been identified. Currently, 350 full genomes of tailed phage and 400 prophage from bacterial genomes have been sequenced. In general, large DNA viruses are tenfold overrepresented in small single-domain genes (~100 aa). Comparative genomics, especially of lactobacterial phages, suggest that most phage genomes evolve as mosaics, with sharp boundaries between genes as well as at protein domains within genes (see **Figure 5**). Recombination between lytic, temperate, and cryptic prophages appears to account for this gene and subgene domain variation. Some specific phages have mechanisms to generate specific gene diversity (such as bordetella phage using RT for surface receptor diversity), but most diversity is the product of recombination. Two broad patterns of phage variation have been observed corresponding to host-unassociated lytic and host-associated (congruent) temperate phage. In most bacterial genomes (ECOR *Escherichia coli* collection, cyanobacteria, *B. subtilis*), patterns of prophage colonization account for significant genetic distinctions between closely related host strains. The general picture for tailed phage of bacteria is that they are not the products of reduction of host genomes.

Large Eukaryotic DNA Viruses

As noted, evolutionary links between tailed phage and large DNA viruses of eukaryotes are apparent. The phycodnaviruses of unicellular green algae clearly have many phage-like characteristics, including the presence of

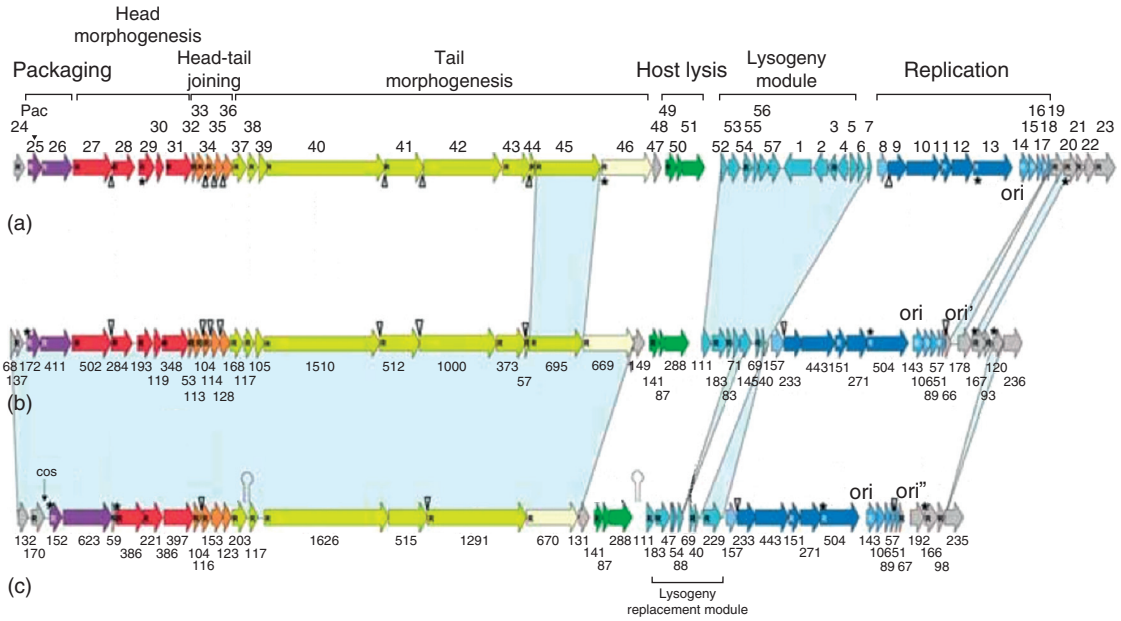

Figure 5 Genome comparison of temperate *S. thermophilus* phage 01205, virulent *S. thermophilus* Sfi11, and the virulent *S. thermophilus* Sfi19. Probable gene functions are indicated and genomes have been divided into functional units. Genes belonging to the same module are indicated with the same color. Areas of shading indicate regions of major difference. From Desiere F, Lucchini S, Canchaya C, Ventura M, and Brüssow H (2002) Comparative genomics of phages and prophages in lactic acid bacteria. *Antonie van Leeuwenhoek* 82: 73–91.

restriction/modification enzymes, homing endonucleases, the injection of viral DNA, and the external localization of the viral capsid. They also have many characteristics of eukaryotic DNA viruses, such as a clearly herpes virus-related DNA polymerase, PCNA proteins, nonintegrating DNA, and numerous signal-transduction proteins. Thus, phycodnaviruses show hybrid characteristics of prokaryotic and eukaryotic viruses.

The evolutionary pattern of the large DNA viruses of eukaryotes is generally best traced by comparing their respective DNA-dependent DNA polymerases (DdDp). These exist in distinct classes that are typically specific for each viral lineage and are usually the most highly conserved of the set of core genes within a viral lineage. However, some viruses, such as the white spot syndrome virus (WSSV) infecting shrimps, have almost no genes in common with other DNA viruses. Generally, the specific set of core genes is clade specific. The first fully sequenced viral genome tree was that of the baculoviruses (see **Figure 6**). The overall pattern of evolution shows the conservation of the core set in which most clades can be differentiated from one another mainly by acquisition of several novel viral genes (although some lineage-specific gene loss is also apparent). In another example, coccolithoviruses differ from related phycodnaviruses by the acquisition of 100 kbp gene set, including six subunits of DdDp core genes. Similar patterns of divergence can be seen with the herpesvirus family members. In addition, most herpesvirus clades also show coevolution with their host. However, the poxviruses (orthopoxviruses), show a different overall evolutionary pattern and are not congruent with host. The more ancestral orthopoxvirus members, such as cowpox virus and mousepox virus, have greater gene numbers that appear to have been lost in the human-specific and virulent smallpox virus. Avipoxviruses have even greater gene diversity but the entomopoxviruses are the most complex and diverse of all. The complexity and brick shape of the poxviruses originally inspired the view that these viruses might evolve from bacterial cells following the reduction of complexity. However, DNA sequencing makes it clear that viral core genes have no bacterial analogs. In some instances, viral lineages have clearly fused with other viral and host lineages. For example, the baculovirus Autographa californica MNP virus (AcMNPV) has acquired a gypsy-like retrovirus (e.g., TED), an endogenous retrovirus associated with moth development. The polydnaviruses (circular DNA viruses) are fused into their host genomes (as endogenous DNA viruses) of some parasitoid wasps, essential for survival of the wasp larvae.

Small DNA Viruses

The small, double-stranded, circular DNA viruses (*Papillomaviridae* and *Polyomaviridae*) show evolutionary patterns that are highly host linked. Virus and host evolution are mostly congruent, and virus evolution tends to be slow.

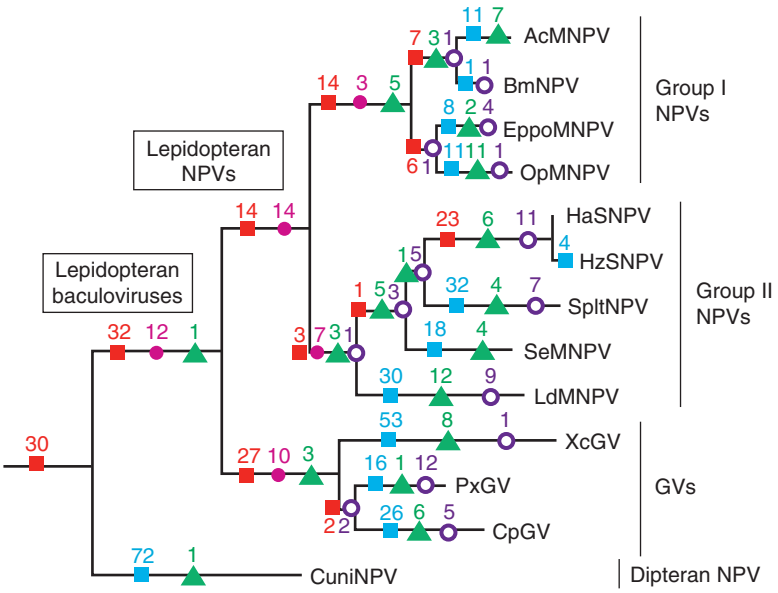

Figure 6 Gene content map of 13 complete sequences of baculoviruses, including the genus *Granulovirus*. The tree shows the most parsimonious hypothesis of changes in gene content during baculovirus evolution. Colors and shapes indicate gene conservation, acquisition, and loss. Reproduced from Herniou EA, Olszewski JA, Cory JS, O'Reilly DR (2003) The genome sequence and evolution of baculoviruses. *Annual Review of Entomology* 48: 211–234, with permission from Annual Reviews.

For example, approximately 100 human papillomaviruses show congruent evolution with human (and primate) host. This seems to be due to both a highly species- and tissue-specific virus replication, as well as a tendency to establish persistent infections. However, the rolling circular replicon (RCR) viruses, such as parvoviruses, can have distinct evolution patterns. Both mouse minute virus (MMV) and canine parvoviruses can have quasispecies-like populations, which can show evolutionary rates at 10^{-4} substitutions per site per year. Such rates are at the lower end of those seen with RNA viruses. In bacteria, RCR viruses and RCR plasmids appear to represent a common gene pool. Other poorly characterized small eukaryotic DNA viruses, such as human torque teno virus, are asymptomatic but show high variation during persistence for unknown reasons.

Endogenous and Autonomous Retroviruses

Retroviruses present a special problem in understanding patterns of eukaryotic virus evolution. Like prophage of bacteria, retroviruses both stably colonize their host as endogenous or genomic retroviruses (ERVs) that are often defective, but may also sometimes emerge from their host (especially rodents) to produce autonomous virus. In addition, retroviruses are polyphyletic and prone to generating quasispecies due to high error rates as well as high rates of recombination. The most common conserved retrovirus genome elements are domains within the long terminal repeats (LTRs), RT, integrase, protease, gag protein, and env protein. Of these, env are the most often altered or deleted in host genomes. In addition, tRNA primer sites (such a lys [K] tRNA) are also often conserved and used for classification (i.e., human endogenous retrovirus, HERV-K family). However, each of these retroviral elements can potentially have distinct patterns of evolution and conservation, generating distinct dendrograms. Vertebrates, especially mammals, seem to host many retroviral elements within their genomes. Their autonomous retroviruses have a tendency to infect cells of the immune system. Murine leukemia virus (MLV) is the best-studied simple autonomous retrovirus, but many endogenous MLV relatives also exist. Retroviruses are present in genomes of early eukaryotes but significantly expanded in vertebrates. Gypsy-like retroviruses (aka chromoviruses, defined via RT and gag similarity) are often found conserved as full-length elements including env genes in most lower eukaryote genomes (e.g., *Caenorhabditis elegans*), but were mostly lost from tetrapods. Some lower eukaryotes clearly prevent colonization by ERVs, such as *Neurospora* fungi (via the RIP exclusion system). Many endogenous retroviruses are congruent with host evolution, whereas other ERVs are recently acquired and highly host specific. In terms of gene diversity, the retroviral *env* are the most diverse. There are five RT-based families recognized such as *Retroviridae, Hepadnaviridae, Caulimovoridae, Pseudoviridae,* and *Metaviridae*, the latter three being especially prevalent as genomic elements in flowering plants (especially Gypsy). Yet not all retroviruses seem able to colonize host germ line. For example, lentiviruses (such as simian

immunodeficiency virus (SIV) and HIV) show no examples of endogenization compared to the simpler MLV-related viruses that can be both autonomous (i.e., MLV, Gibbon ape leukemia virus) and endogenous (i.e., *Mus dunni* ERV, koala ERV). The converse can also be true, since no autonomous versions of HERV K, for example, are known.

Early views proposed that retroviruses evolved from nonviral retroposons (LTR RT elements, non-LTR LINE-like elements). These non-LTR elements, have distinct nonretroviral mechanistic features and core protein domains, but retain some virus-like domains of RT; thus, they appeared to predate retroviruses. However, we now know that gypsy-like retroviruses were present in the earliest eukaryotes. In addition, some LTR-containing elements, such as Gypsy, had initially been considered ancestral to retroviruses because all copies seemed to be defective. However, it is now established that complete gypsy retroviruses are conserved as ERVs in some yeast and *Drosophila* strains. Thus, although endogenous and exogenous retroviruses appear to evolve from each other, there is no evidence that exogenous retroviruses have emerged from non-LTR LINE-like elements.

The congruence between ERVs and host eukaryote evolution is sometimes striking. For example, all mammals have acquired their own peculiar versions of ERVs (and LINES). Recently, it has become clear that the placental mammals have conserved several families of ERV-derived *env* genes that provide an essential function for placental tissue (ERV W-syncytin 1, ERV FRD syncytin 2, enJSRV). Clearly, retrovirus evolution is highly intertwined with that of their hosts.

Never-Ending Emergence

A remaining concern of virus evolution is to understand the emergence of new viral pathogens. The unpredictable and stochastic nature of such virulent adaptations makes predictions difficult, as the link between virulence and evolution is vague. For example, the genetic changes that made the SARS virus (persisting in bats) into an acute human pathogen are still not predictable. Viral fitness and selection, and how they change from persistent states with acute species jumps, are not yet defined. However, some variables contribute to the likelihood of viral emergence, such as virus ecology. The population density and dynamics of the new host and the ecological interactions-between new and stable viral host are often crucial. In addition, virus–virus interactions can be important, allowing for recombination and/or reassortments or lowering immunological selective barriers via immunosuppression. The emergence of HIV-1 from different, persistent SIVs of African monkeys through chimpanzees into a new human disease, for example, includes the same issues. Also, the potential emergence of pandemic human influenza from avian (Anatiformes) sources, such as H5N1, remains a great concern. Thus, virus evolution will continue to interest us as we seek to predict, control, or eradicate viral agents of disease.

Feline Leukemia and Sarcoma Viruses

J C Neil, University of Glasgow, Glasgow, UK

© 2008 Elsevier Ltd. All rights reserved.

History

The description of murine leukemia viruses by Moloney and others stimulated an intensive search for similar viruses in other species. William Jarrett made the perceptive observation that lymphomas (lymphosarcomas) in cats often occurred at particularly high incidence in certain households, and in 1964 he showed that typical type C retroviruses could be demonstrated in the tumor cells by electron microscopy. He went on to show that these feline leukemia viruses (FeLVs) could be transmitted to cats where they induced lymphosarcomas and a range of degenerative diseases, including anemias and thymic atrophy.

Following these studies, Snyder and Theilen isolated a retrovirus from a feline fibrosarcoma that rapidly reproduced this tumor on inoculation into experimental cats. It is now recognized that feline sarcoma viruses (FeSVs) arise by recombination between FeLV and cellular proto-oncogenes and that, in contrast to FeLV, these viruses are not transmitted from cat to cat.

In clinical veterinary medicine, FeLV remains one of the most important viruses affecting the cat, despite advances in control of this infection. As a naturally occurring disease in an outbred host, FeLV has served as a paradigm for the natural history and molecular pathogenesis of the γ-retrovirus subfamily. It also played a foundational role in cancer genetics as a transducing agent which led to the discovery of novel cellular transforming genes.

Taxonomy and Classification

FeLVs are RNA viruses and belong to the family *Retroviridae*. They are further classified in the genus *Gammaretroviruses*.

Virion and Genome Structure

The virion particles are around 100 nm in diameter and consist of an outer membrane derived from the host cell surrounding a spherical core particle. The core encapsidates the viral genome which, as in other members of this viral family, is present as two linear single-stranded RNA molecules linked as a dimer. The virion RNA is positive-stranded and resembles cellular RNA having a 5′ cap and a 3′ poly(A) tract. As deduced from sequencing of proviral forms, the FeLV genome is around 8 kb long with a 67 base terminal redundancy and the gene order gag-pol-env.

The particles have surface spikes composed of multimers of the two env-coded proteins, the gp70 surface glycoprotein (SU), and the p15E transmembrane anchor protein (TM). Inside the envelope are the structural *gag* gene products which form a spherical core particle composed of p27, the major capsid protein (CA), with an outer layer formed by the p15 matrix protein (MA). Another gag product, the p10 nucleocapsid (NC), is associated with the virion RNA. Other minor virion proteins encoded by the *pol* gene comprise the protease (PR), reverse transcriptase (RT), and integrase (IN) enzymes.

Replication

Virus replication proceeds, following binding to specific host cell-surface receptors, internalization, and uncoating. The virion RNA is converted to a double-stranded DNA form by the virion RT which uses a proline tRNA primer and carries a ribonuclease H function that degrades the virion RNA. After nuclear translocation, viral integration is catalyzed by the IN protein and involves the creation of a staggered cut in cellular DNA with a consequent 4 bp duplication of host DNA at the insertion site.

As illustrated in **Figure 1**, the proviral form is flanked by long terminal repeats (LTRs) of 480–560 bp. These are generated during reverse transcription by duplication of unique sequences at the 3′ (U3) and 5′ (U5) ends of the RNA genome. The LTRs contain promoters and enhancers that drive transcription of viral RNA and also processing signals for cleavage and polyadenylation of the

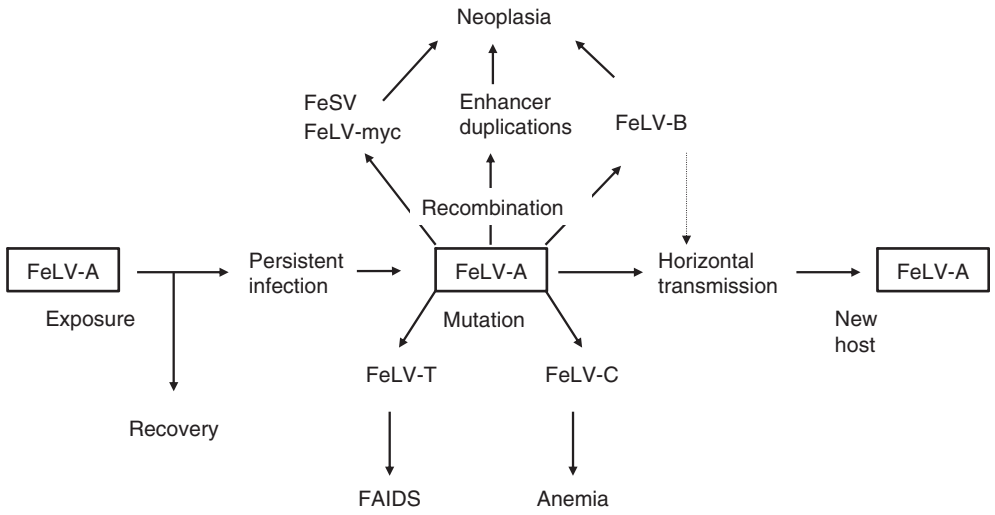

Figure 1 Life cycle of FeLV in its host, the domestic cat. FeLV-A is the most readily transmitted form and is found in 100% of isolates. In cats which become persistently viremic, this prototypic virus may evolve by recombination or point mutations to generate pathogenic variants that can lead to the rapid demise of the infected host animal. Multiple variants can arise in a single host. Few of these variants show any capacity for horizontal transmission to new hosts with the exception of FeLV-B. In this way, FeLV inflicts a substantial disease burden without significant reducing host numbers.

RNA transcripts. The 5′ LTR functions to initiate transcription while the 3′ LTR acts primarily as an RNA processing signal.

The virion RNA can function as a messenger RNA for Gag and Pol products, while a spliced subgenomic mRNA of around 3 kb encodes the Env products. Most full-length RNA translation products terminate at the 3′ end of *gag* to produce the Pr65gag precursor, while a small percentage read through into *pol* by misreading of an UAG termination codon, generating the Pr180Gag-pol precursor. During and after the budding process, the virion aspartyl PR catalyzes the cleavage of both precursor proteins to their mature forms. The envelope gene products are synthesized as a Pr80env precursor and processed by cellular PRs to the mature, disulfide-linked gp70 and p15E envelope proteins. The *gag* gene is also abundantly expressed in an alternative, glycosylated form via an upstream AUG codon. This product is expressed on the cell surface and shed after cleavage by cellular PRs. It is dispensable for *in vitro* virus replication but is highly conserved and may play a role *in vivo*.

Assembly of virus particles occurs at the cell surface by extrusion of cores which form at the budding site, concomitantly acquiring a host cell-derived outer membrane with virus-coded surface spikes. Virus replication and release is often noncytopathic.

Geographic Distribution

FeLV occurs worldwide in domestic cat populations although prevalence varies significantly and has declined in pet cats in areas where active control measures have been instigated. FeLV has also been isolated from the European wild cat (*Felis sylvestris*). Endogenous retroviral sequences closely matched to FeLV are found in the same species and in related small felids such as the sand cat (*F. margarita*) and the jungle cat (*F. chaus*). Although not a direct source of disease, these endogenous sequences can participate in recombination with exogenous FeLV to generate variant viruses with altered host range.

Epidemiology

The outcomes of FeLV infection fall into several categories, which vary in likelihood according to the age and immune status of the exposed host. The majority of cats undergo a transient infection lasting up to 3 months, during which they are viremic and shed virus. They then develop neutralizing antibody and concomitantly clear infectious virus and a little later, virus antigen from the blood stream. Some cats appear to clear virus infection successfully, while others may harbor latent virus in the bone marrow for some years. A recent study based on analysis of virus loads by polymerase chain reaction (PCR) suggests that animals that control viremia may be further subdivided into abortive, regressive, or latent infection. Even where latent infection persists, reactivation is not a frequent event and the vast majority of these cats do not develop an FeLV-related disease. However, at this stage virus can be reactivated by immunosuppression. The final group (persistent or progressive infection) remains actively infected, shedding virus from epithelial surfaces and displaying high titer plasma viremia. Such cats may remain apparently healthy for 2–3 years before succumbing to an FeLV-related disease.

The proportion of cases falling into these groups differs between multicat households and those households containing one or two free-ranging cats. In the former case, the introduction of an FeLV carrier results in repeated exposure of susceptible cats, often at a young age so that up to 30–40% become persistently viremic and at risk of disease. Approximately 50% of free-ranging urban and suburban cats have serological evidence of exposure to FeLV but only 1–5% of these cats are actively infected and the disease incidence is correspondingly lower.

Dual infection with FeLV and feline immunodeficiency virus (FIV) occurs and is associated with rapid disease onset, particularly if cats with preexisting FeLV infection encounter FIV. Rapid death of dually infected animals may reduce the apparent overlap of these agents in the field, but the populations at risk of infection also differ. FIV infection rates increase directly with age while persistent FeLV infection has a peak incidence in young cats.

FeLV Subgroups and Host Range

FeLV isolates were initially classified as subgroup A, B, C according to their viral interference properties in feline fibroblast cells *in vitro*. Viruses of a given subgroup prevent superinfection (interfere) with other viruses of the same subgroup (**Table 1**). This property is based on the use of three different host cell-surface receptors by FeLV-A, B, and C, and the blockade of these receptors in persistently infected cells by viral Env glycoproteins. The lymphotropic variant FeLV-T has more complex entry requirements, and does not replicate well in fibroblast cells. It appears that this isolate requires the FeLV-A receptor and an auxiliary mechanism in which a truncated *env* gene product encoded by endogenous FeLV sequences (FeLIX) is used as a co-receptor through binding to the FeLV-B receptor. Primary receptors for subgroups A, B, and C have been identified and shown to be transmembrane transporter molecules which the virus has subverted to gain entry to the host cell.

Natural isolates contain either subgroup A alone, or mixtures of subgroups A + B, A + C, or A + B + C. FeLV isolates of subgroup A are generally restricted to growth in feline cells, whereas subgroups B and C have a greatly expanded host range, infecting cat, human, mink, and canine cells. FeLV infection is generally noncytopathic and persistent and the virus is commonly propagated in long-term cultures of embryo-derived fibroblasts. Some strains such as FeLV-T or FeLV-C are cytopathic or induce apoptosis in lymphoid cells *in vitro*, reflecting their *in vivo* pathogenic properties.

Clinical Features and Pathology

Of those cats which become persistently viremic following FeLV exposure, over 80% die within 3.5 years. Most young cats infected with FeLV die from degenerative diseases rather than from tumors. Profound immunosuppression associated with thymic atrophy is a common finding in kittens. Other diseases seen in FeLV-infected cats include enteritis, immune complex glomerulonephritis, pancytopenia, and hemolytic anemia. Erythroid hypoplasia, an acute disease involving failure of red cell development past the burst-forming unit (BFU) stage, is specifically associated with FeLV subgroup C.

The most common neoplasm induced by FeLV is lymphosarcoma of T-cell origin, usually restricted to the thymus or sometimes occurring as a multicentric tumor in lymph nodes. The tumors often develop between 1 and 3 years after infection and the first signs may be chronic wasting and anemia. At presentation, the normal architecture of the lymphoid organ has usually been destroyed by a monomorphic infiltrate of lymphoblastic cells. The thymic tumors frequently display a rearrangement of the T-cell antigen receptor β-chain gene and may also express the co-receptor molecules CD4+ and/or CD8+. FeLV is also commonly associated with myeloid leukemias and a myelodysplastic syndrome-like disease, as well as with other forms of hematopoietic malignancy. Multicentric fibrosarcoma is a rare sequel to FeLV infection but these tumors are

Table 1 Properties of feline leukemia virus subgroups

Subgroup	*Origin*	*Receptor*	*Function*	*Pathogenesis*
A	Exogenous	feTHTR1?	Thiamine transport?	Minimally pathogenic to acute immunosuppression
B	Recombination FeLV-A × endogenous FeLV	Pit-1 (Pit-2)	Phosphate transport	More common in leukemic cats Some isolate-specific diseases, e.g., FeLV-GM1 myeloid leukemia
C	Mutation of FeLV-A (Env vrA)	FLVCR	Heme export	Erythroid hypoplasia
T	Mutation of FeLV-A (outside RBD)	? FeLV-A receptor +FeLIX, Pit-1		Acute immunosuppression

often associated with the *de novo* generation of a FeSV. FeLV is also found in association with 35% of alimentary tumors, primarily of B cell origin, but the virus is not always clonally integrated in these tumors and the role of the virus is, therefore, unclear. FIV can also increase the frequency of malignant diseases in cats, and some rare cases arise on a background of dual infection.

Envelope Gene Variation and Pathogenicity

The common infectious form of FeLV is FeLV-A which is a remarkably highly conserved virus as shown by sequence analysis of several strains and serotypic analysis of a much larger number. FeLV variants frequently arise from FeLV-A by mutation and recombination, and such variants are often implicated in the acute diseases which develop in persistently infected cats. The variant viruses generated from FeLV-A are generally dependent on the continued presence of the prototype for their propagation *in vivo*. However, as the variants are less efficiently transmitted and are in some cases rapidly fatal, they tend to die out with the host while the prototypic FeLV-A continues to colonize new hosts (**Figure 1**).

The most commonly isolated FeLV recombinants are subgroup B viruses (**Table 1**). These are derived by recombination between FeLV-A and endogenous FeLV-related proviruses which are found in the genome of the domestic cat and related small feline species. Although the endogenous FeLV-related proviruses all appear to be replication defective, their envelope genes can be rescued by the recombination process leading to the generation of FeLV-B viruses. FeLV-B can infect cells refractory to, or already containing, FeLV-A by virtue of their distinctive receptor specificity.

The anemia-inducing FeLV-C isolates are rarer and appear to be derived from FeLV-A by mutation of a single variable domain (VRA) of the *env* gene. The acute disease properties of these variants appear to be due to compromised viability of erythroid progenitor cells due to downregulation of the FeLV-C receptor, a vital heme exporter.

Minor *env* mutations also appear to give rise to the acutely immunosuppressive FeLV-FAIDS variants. The prevalence of acutely immunosuppressive viruses in nature is unknown, but immunosuppressive disease is a common manifestation of FeLV infection.

The relationship of subgroup variation to oncogenesis is complex. FeLV-B recombinants are more common in tumor bearing than in infected asymptomatic cats. This higher frequency might reflect merely longer-standing infection, but some FeLV-B-containing isolates have an altered spectrum of neoplastic disease. For example, FeLV-GM1, which contains a replication-defective FeLV-B component, induces mainly myeloid leukemia.

FeLV Oncogenesis: Virus Evolution and Mutagenesis of Cellular Oncogenes

Two modes of virus-induced host gene mutation have been described in FeLV-associated cancers. The first is 'transduction', where recombination leads to the generation of an acutely oncogenic variant in which viral gene sequences are replaced by a host-derived insert. Such viruses are replication defective and are found in nature in association with a replication-component FeLV helper virus.

Multicentric fibrosarcomas of young cats are relatively rare, but are generally FeLV positive and frequently involve a novel sarcoma virus. Similarly, transduction of c-*myc* has been observed in up to 20% of naturally occurring thymic lymphosarcomas in FeLV positive cats. In all, nine different host cell genes have been shown to be transduced by FeLV (**Table 2a**). The transducing viruses induce tumors with short latency in cats and in the case of FeSVs may transform cells in tissue culture.

Alternatively, host genes can be affected by proviral 'insertional mutagenesis' (*cis*-activation). Four known oncogenes and an uncharacterized novel integration locus have been identified as common tumor-specific insertion

Table 2a FeLV gene transduction in neoplasia

Gene	*Normal function of host gene product*	*Associated tumor*	*Examples*[a]
abl	Plasmamembrane protein kinase	Fibrosarcoma	FeSV-HZ2
fes	Plasmamembrane protein kinase	Fibrosarcoma	FeSV-GA,-HZ1,-ST
fgr	Plasmamembrane protein kinase	Fibrosarcoma	FeLV-GR,-TP1

fit-1	Transcription factor (c-*myb*)	T-cell lymphoma
flvi-1	Unknown	non-T, non-B lymphoma
flvi-2 (bmi-1)	Transcription factor	T-cell lymphoma
c-myc	Transcription factor	T-cell lymphoma
pim-1	Protein kinase	T-cell lymphoma

sites for FeLV in thymic lymphosarcomas (**Table 2b**). In this respect FeLV oncogenesis appears remarkably similar to that of the murine γ-retroviruses, and most studies of this process have been conducted recently in the laboratory mouse which has the advantages of complete genome sequence and the opportunity to manipulate the germline.

Changes within the LTR are also a feature of tumor-associated FeLV. In thymic lymphosarcomas, sequence duplications of the core enhancer domain are frequently found, and have been shown to arise *de novo* from infection with molecularly cloned FeLV isolate lacking such features. By analogy with the murine oncoretroviruses, the duplications are likely to increase the oncogenicity of the virus and reduce the latent period for tumor formation, possibly by increasing the potency of viral enhancer activity on nearby cellular promoters. There is evidence that these adaptive changes to the LTR operate tissue-specifically and proviruses carrying different duplications of LTR regions 5′ and 3′ to the core-enhancer region have been identified in myeloid leukemias and non-T, non-B splenic lymphomas, respectively. Chimeric murine retroviruses carrying the FeLV enhancer region have been generated, confirming that the tissue specificity is carried by this structure.

Immune Response

Unlike infection with the lentiviruses HIV and FIV, FeLV infection of cats may lead to recovery. There is evidence that both virus-specific cytotoxic T cells (CTLs) and neutralizing antibodies play a role in resistance as either can be used to prevent or limit infection by passive transfer. In natural infection, CTLs to virus structural protein epitopes can be detected as early as a week after infection and may be the primary means of control of infection as neutralizing antbodies are not detected until around 6 weeks post infection.

In the early literature on FeLV a distinction was made between antiviral immunity and antitumor immunity. Cats with antitumor (FOCMA) antibody were thought to be protected from tumor development. This antibody response is now believed to be directed to endogenous FeLV *env* proteins and its role in modulating tumor development is uncertain.

Transmission

Cats persistently infected with FeLV shed virus in their saliva, urine, and feces but, as the virus is fragile, close contact is required for transmission. The most frequent routes involve saliva and transplacental spread. Kittens infected *in utero* become persistently infected, but the consequences of infection in older cats depend on a number of factors. There is an age-related resistance to infection such that cats up to 12 weeks of age are highly susceptible, but above 16 weeks they are difficult to infect either naturally or experimentally.

FeLV subgroup A is always found in field isolates and about half also contain FeLV-B, whereas FeLV-C is present in only 1–2% of isolates. Although FeLV-B can arise *de novo* by recombination, it may also be transmitted between cats. This occurrence is dependent on pseudotype formation in which the genome of the B virus becomes enclosed in an envelope containing glycoproteins of the A subgroup.

Prevention and Control

Successful control measures can be adopted in multicat households by removing or isolating persistently infected animals. Productively infected cats are detected by virus isolation from plasma or more usually by enzyme-linked immunosorbent assay (ELISA) for virus antigen in the blood. A few cats remain persistently antigenemic but nonviremic. These cats do not usually transmit the virus unless they are shedding virus in the milk or saliva. Assays are conducted twice, 3 months apart to exclude cats that are transiently viremic.

Numerous vaccine strategies have been shown to offer protection against FeLV in laboratory conditions (**Table 3**) and FeLV was the first retrovirus for which commercial vaccines were developed. Vaccines in current use include whole inactivated virus preparations, subunit vaccines from recombinant viral Env protein expressed in bacterial cells, and a canarypox recombinant virus expressing Gag and Env. These vaccines offer a measure of protection against experimental challenge and are under evaluation for longer-term efficacy in the field. These vaccines do not generate sterilizing immunity but appear to prime the immune system to favor clearance of virus infection instead of persistent viremia.

Table 3 FeLV vaccines

Vaccine	*Protection*	*Commercial use*
Live attenuated FeLV	Yes	No (safety concerns)
Inactivated whole virus	Yes	Yes
Subunit vaccines		
SU from *E. coli*	Yes	Yes
ISCOM-Env (native)	Yes	No
Lymphoma cell extract	Yes (poor in some studies)	Withdrawn
Live vector vaccine		
Vaccinia-Env	No	No
Canarypox-Env-Gag	Yes	Yes
Feline herpesvirus-Env	Partial	No

Future Perspectives

There is continuing interest in control of FeLV infection due to its importance in veterinary medicine. In the future we can look forward to improvements in vaccine efficacy and further dissection of the host responses that confer protection. While the focus of attention of cancer genetics has moved on to more easily manipulated models, FeLV remains as a useful touchstone for our understanding of retroviral pathogenesis in an outbred, naturally infected host. Also, with the impetus of FIV as a model for human AIDS, the generation of reagents to probe the feline immune system offers new opportunities for comparative study of FeLV.

Glossary

Cloning vector The DNA molecule of a virus, plasmid, or cell into which a foreign DNA fragment can be integrated without loss of self-replicating activity. The vector introduces the foreign DNA fragment into an appropriate host cell for autonomous replication, usually in large quantity.

Phage library An ensemble of up to about 10^{10} phage clones, each harboring a different foreign coding sequence in-frame with either the N- or C-terminal region of a capsid protein gene. The clone thus allows display of a different 'guest' peptide on the virion surface.

Raman spectroscopy The branch of optical spectroscopy (named after its 1928 founder, C. V. Raman) concerned with measurements of the intensities of light scattered inelastically by molecules that have been excited by monochromatic radiation. The resulting spectrum, usually a plot of scattering intensity (in arbitrary units) versus energy (in wave number or cm^{-1} units), reflects the transfer of discrete energy quanta from the impingent photons to vibrational energy states of the molecules. The Raman spectrum, which is determined by both intramolecular bonding arrangements (covalency and conformation) and intermolecular interactions, provides a sensitive

signature of molecular structure and local environment.

Trans-envelope network A multiprotein complex that is located in the envelope of a bacterial cell and brings the inner and outer membranes in close proximity to one another.

Ultraviolet resonance Raman spectroscopy (**UVRR**) A type of Raman spectroscopy (see above) in which the wavelength of the exciting monochromatic radiation is in the ultraviolet region (i.e., wavelength $\lambda < 400$ nm, or wave number $\sigma > 25\,000$ cm^{-1}), so as to achieve resonance with electronic absorption processes of the molecules. In UVRR spectra, only the vibrational states of the chromophore are represented.

Introduction

The filamentous ssDNA viruses (genus *Inovirus*) are members of a genus of morphologically similar virions that infect different bacteria via molecular recognition of a host-specific pilin. The most well studied of these phages are the closely related M13, fd, and f1 virions, which infect *Escherichia coli* displaying a conjugative F-pilus. The genome sequences of these F-specific phages are sufficiently similar that they are collectively called Ff phage. Other filamentous phages that have been studied include IKe, which infects *E. coli* displaying a conjugative N-pilus, Pf1, which infects *Pseudomonas aeruginosa* strain PAK by binding to the bacterial type IV pilus, Pf3, which infects *P. aeruginosa* strain PAO by binding not to the inherent type IV pilus but to the conjugative RP4 pilus, and PH75, which infects *Thermus thermophilus*. These filamentous phages are nonlytic and nonlysogenic. On the other hand, the filamentous ssDNA bacteriophage CTXφ, which infects *Vibrio cholera* by recognition of a toxin-co-regulated pilus (TCP), is lysogenic.

Genetic, biochemical, and biophysical methods have been used to study the Ff bacteriophage life cycle, which is unique in its use of the bacterial cell envelope for virus assembly. Features of the nonlytic Ff assembly pathway are (1) the prolific production of phage particles, (2) the extrusion of progeny virions through the cell envelope, and (3) the requirement of stable transmembrane (TM) domains in virally encoded proteins that participate in the assembly process. Also noteworthy in Ff morphogenesis is that genomes of variable size can be packaged without deleterious consequences. For example, although the single-stranded DNA (ssDNA) genome of wild-type Ff (~6400 nt) is sheathed by 2750 copies of the major capsid protein, viable variants have been isolated containing as many as 12 000 nt and corresponding modifications in the filament length and number of subunits in the sheath. Biophysical studies have shown that the Ff phage particles are highly thermostable and highly flexible. Polymorphism of the viral capsid is also revealed by electron cryomicroscopy.

The life cycle of the filamentous ssDNA bacteriophage enables its use as a model for membrane-associated nucleoprotein assembly and as a valuable tool for molecular cloning, phage display, and pharmacotherapy. The filamentous ssDNA bacteriophage also serves as a vehicle for orientation of small molecules in solution spectroscopic (nuclear magnetic resonance, NMR) applications and as a model for nanowire self-assembly. Details of the molecular structure and life cycle of the filamentous ssDNA bacteriophage are considered in this article.

Taxonomy and Classification

The filamentous ssDNA bacterial viruses, which are visualized in electron micrographs as thin cylindrical filaments about 7 nm in diameter and ranging from 700 to 2000 nm in length, belong to the genus *Inovirus* of the family *Inoviridae*. They are distinguished from rod-shaped members of the genus *Plectrovirus* of the same family (typically 85–280 × 10–15 nm dimensions) by their greater contour length, smaller diameter, and lower flexural rigidity. The many species of the genus *Inovirus* so far identified have been categorized into four broad groups on the basis of the types of bacteria infected. The species encompassed by these four groups are listed in **Table 1**, in accordance with the classification of the International Committee on Taxonomy of Viruses (ICTV). The best characterized of the filamentous viruses with respect to both biological and structural properties is the coliphage M13, which serves as the prototype of the species *Enterobacteria phage M13*. This species also includes the closely related phages f1, fd, AE2, dA, Ec9, HR, and ZJ/2.

Physical Properties

Table 2 lists selected physical properties of several well-studied filamentous ssDNA bacterial viruses. Although each of the viruses included in **Table 2** exhibits a characteristic filamentous shape, significant differences occur in their contour lengths and in the mass ratio of capsid protein to DNA. Accordingly, differences are also anticipated in the packing arrangement of capsid subunits with respect to the encapsidated genome. The overall length of the viral filament is dictated by both the genome size and the number of subunits required to electrostatically balance the negatively charged DNA phosphates, which is accomplished by the distribution of basic side chains (Lys and Arg) near the subunit C-terminus. On the basis of fiber X-ray diffraction results, two distinct symmetry classes (I and II) have been

Table 1 Species of the genus *Inovirus*[a]

Host type	*Species*
Enterobacteriaceae	*Enterobacteria phage M13*,[b] *C-2, If1, IKe, I2–2, PR64FS, SF, tf-1, X,* and *X-2*

Symmetry class[b]	I	II	II	II	II

[a]The thermophilic filamentous ssDNA bacteriophage, PH75, which infects *Thermus thermophilus*, has not yet been assigned to a species, genus, or family by the International Committee on Taxonomy of Viruses.
[b]Class I phages have capsid subunits arranged with C_5S_2 symmetry (fivefold rotational symmetry and approximately twofold screw axes) and class II phages have capsid subunits arranged with $C_1S_{5.4}$ symmetry (no rotational symmetry and a single-start superhelical array of approximately 5.4 subunits per turn).

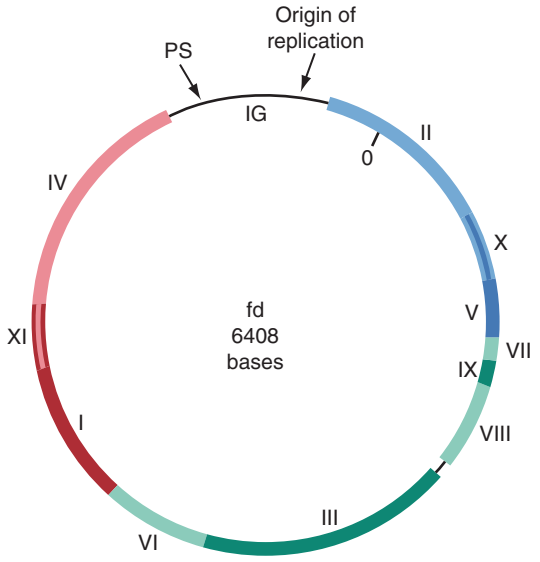

Figure 1 The genome organization of the Ff (fd) bacteriophage. All genes (I–XI) are labeled and color-coded by function of the gene product (blue, DNA synthesis; green, capsid; red, virus assembly). The single-stranded DNA genome of fd contains 6408 nt, which are numbered clockwise from the unique *Hin*dII site located in gene II. The intergenic region (IG) is located between genes II and IV and includes the packaging signal (PS) and the origin of replication. Adapted from Petrenko VA and Smith GP (2005) Vectors and modes of display. In: Sidhu S (ed.) *Phage Display in Biotechnology and Drug Discovery*, pp. 63–110. Boca Raton, FL: CRC Press.

defined to categorize subunit/DNA packing arrangements: subunits of the class I phages (e.g., M13, f1, and fd) are arranged with approximate C_5S_2 symmetry, while class II phages (e.g., Pf1, Pf3, and PH75) exhibit $C_1S_{5.4}$ symmetry. Further details of virion structure are discussed in the section titled 'Composition and structure'.

Genome Organization

The genomes of many filamentous viruses, including M13, f1, fd, IKe, Pf1, Pf3, PH75, and CTX, have been sequenced. Comparative analyses indicate that at least those of M13, f1, fd, IKe, and PH75 are similarly organized, as shown in **Figure 1** for fd.

Of the 11 virally encoded Ff genes, two (X and XI) overlap and are in-frame with larger genes (II and I, respectively). The Ff genome contains only one significant noncoding region (intergenic region, IG) consisting of about 500 nt. The IG contains the origin of replication, as well as a functionally and structurally distinct region called the packaging signal (PS), which is capable of forming a hairpin of 78 nt. During the phage life cycle, recognition of the genomic PS by virally encoded proteins initiates assembly of the viral particle. The viral genes are expressed from the origin of replication in a counterclockwise direction and are organized on the genome in functional groups, such that genes II, V, and X are grouped together and express proteins that facilitate DNA replication; genes III, VI, VII, VIII, and IX are grouped together and express structural proteins found in the mature infectious virion; and genes I, IV, and XI are grouped together and express proteins that direct virus assembly. The CTX genome lacks gene IV but contains genes that encode proteins specific to the CTX life cycle.

Composition and Structure

The typical filamentous virion consists of a covalently closed, ssDNA genome (5–10 kbp) sheathed by several thousand copies of the major capsid protein (pVIII, ~5 kDa) plus a few copies of minor proteins at the filament ends (**Figure 2**). The numbers of pVIII subunits and DNA nucleotides in several well-studied filamentous phages are given in **Table 2**. The pVIII subunits of the *Enterobacteria phage M13* species members (including phages M13, f1, and fd) have been studied extensively and can be discussed collectively. (Note that the amino acid sequence of the pVIII subunits in fd and f1 are identical and differ from that of M13 by a single amino acid change, namely Asp12 of fd (and f1) is replaced by Asn12 in M13; see **Table 3**.) It is evident from **Table 3** that the pVIII sequence in many filamentous viruses comprises three distinct components, an acidic N-terminal region, a hydrophobic central region, and a basic C-terminal region, suggesting that these fulfill distinct functions in phage morphogenesis.

Here, we consider in further detail the composition and structure of phage fd, which has served as the focus of many detailed and comprehensive biochemical and biophysical studies. The pVIII subunit is generally modeled as a gently curved α-helix that is tilted at a small average angle ($16 \pm 4^{\circ}$) relative to the filament axis. The N-terminus of pVIII is exposed on the exterior of the capsid and the C-terminus lines the core, where it is presumed capable of contacting phosphates of the packaged ssDNA. Fiber X-ray diffraction studies indicate that pVIII subunits of the capsid lattice are arranged in a right-handed slew with near-fivefold rotational symmetry and twofold screw symmetry (**Figure 2**). Five copies of each of four minor proteins form the ends of the fd filament. The initially assembled end ('head') contains minor proteins pVII (3.6 kDa) and pIX (3.6 kDa), while the ultimately assembled end ('tail') contains minor proteins pIII (42.6 kDa) and pVI (12.3 kDa). The packaged genome is oriented with its IG region (PS hairpin) at the head, gene III region near the tail, and the intervening non-base-paired antiparallel strands of the DNA loop spanning the length of the filament core (**Figure 2**). Phage display and genetic studies suggest further that the minor proteins pVII and pVI at the head and tail, respectively,

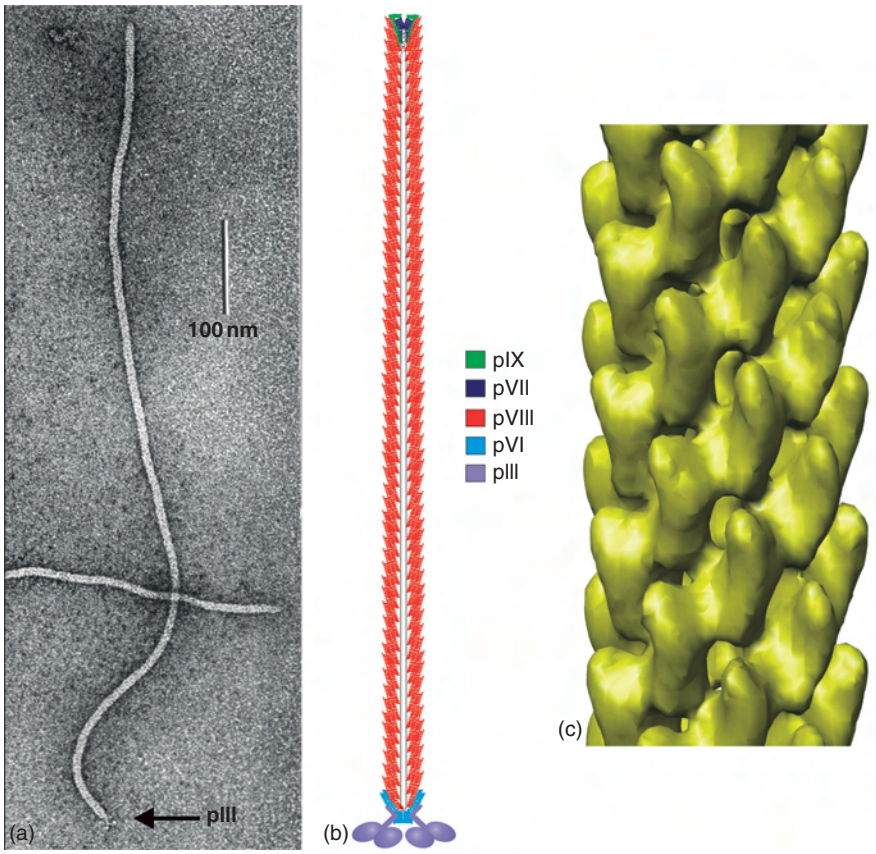

Figure 2 The fd filamentous ssDNA bacteriophage. (a) A negatively stained electron micrograph showing one complete virion (top to bottom) oriented with the pIII tail (arrow) at the bottom. The flexibility of the virion, which is apparent, is consistent with the experimentally determined equilibrium persistence length of 1.0 μm. form contacts with the neighboring pVIII subunits, while pIX and pIII decorate the surfaces of the filament tips. Each pIII subunit is known to contain a globular N-terminal domain that is visible in electron micrographs (**Figure 2**).

In the mature fd virion, pVIII is predominantly α-helical and the C-terminal end of the α-helix (residues 40–50) consists of 'basic' and nonpolar side chains along opposite faces. Although direct experimental evidence is lacking, model-building exercises have revealed that it is possible to position the positively charged side chains of this amphipathic helix proximal to the surface of the capsid core, where interaction with packaged DNA would be facilitated. The net positive charge of the C-terminal region apparently functions to neutralize the negatively charged DNA phosphates. This is supported by the fact that mutating Lys 48 of pVIII to an uncharged side chain results in the assembly of an appropriately elongated (∼35%) fd virion; that is, additional pVIII subunits are required to package the genomic complement. The opposite nonpolar (hydrophobic) face of the C-terminal helix provides a suitable surface for intersubunit contacts.

The N-terminal region of pVIII (residues 1–20) also forms an amphipathic helix, in this case with 'acidic' and nonpolar faces. The former is exposed on the capsid surface, while the latter is presumably engaged in inter-subunit contacts. In aqueous environments of low or moderate ionic strength, electron micrographs reveal extensive intervirion clustering, which may be mediated by the acidic (and/or polar) residues of the capsid surface. In some micrographs, liquid-crystalline phase formation is evident. Although high ionic strength conditions tend to disfavor such intervirion clustering, the bundles once formed are not readily dissociated.

The highly hydrophobic central region of the pVIII α-helix (residues 21–39) appears to serve as the pillar of capsid stability. This α-helical segment also appears to function as a distinct domain in the assembly process, as is discussed in the next section. Studies based upon site-directed and random mutations of residues throughout the central α-helix region have contributed significantly to an understanding of inter-subunit contacts in both the mature virion and its assembly precursors. As implied above, hydrophobic contacts between subunits involve not only the central region of the α-helix but also the nonpolar faces of the N- and C-terminal segments. The periodicity of small nonpolar side chains (Gly, Ala) along specific faces of the α-helix facilitates close packing of subunits. For example, small side chains appear to be required at pVIII positions 25, 34, 35, and 38 for fd capsid stability. A similar requirement applies to the capsid subunits of other filamentous bacteriophages.

Genetic and biophysical studies of proteins show that the pentapeptide motif Gly/Ala-X-X-X-Gly/Ala (where X is any residue) increases the thermostability of packed α-helices. Of the sequences listed in **Table 3**, all contain at least one Gly/Ala-X-X-X-Gly/Ala motif within the central hydrophobic region (residues 21–39). Interestingly, the corresponding segment of the pVIII subunit of the thermophilic *T. thermophilus* phage PH75 contains four Gly/Ala-X-X-X-Gly/Ala motifs among 11 small side chains (residues Ala and Gly). Conversely, the mesophile infecting fd phage contains two Gly/Ala-X-X-X-Gly/Ala motifs among six small side chains of the 19-peptide region. In summary, hydrophobic interactions lead to close packing of pVIII helices, which is likely the principal source of capsid stability.

The multifunctional minor capsid protein pIII, which directs host infection, progeny virus assembly termination, and virion tail stabilization, has been the subject of several structural studies. The 406-amino-acid protein comprises three domains, namely two closely associated and globular N-terminal domains (N1 and N2, consisting of residues 1–67 and 88–218, respectively) that protrude from the capsid, and a stalk-like C-terminal domain (residues 253–406) that is anchored to the capsid. The domains are linked by flexible, glycine-rich sequences. The crystal structure of the N1–N2 fragment indicates a largely β-stranded structure.

The conformation of the packaged genome is not known for fd or any other filamentous phage. Because DNA typically represents a very small percentage of the virion mass (6–16%, **Table 2**), most biophysical probes do not yield definitive structural information regarding the packaged genome. Methods that selectively probe the ssDNA bases, such as ultraviolet resonance Raman (UVRR) spectroscopy, reveal strong hypochromic effects in the fd genome, which implies close contact between the purine and pyrimidine bases. Conversely, UVRR studies of Pf1 suggest unstacked bases in its packaged genome.

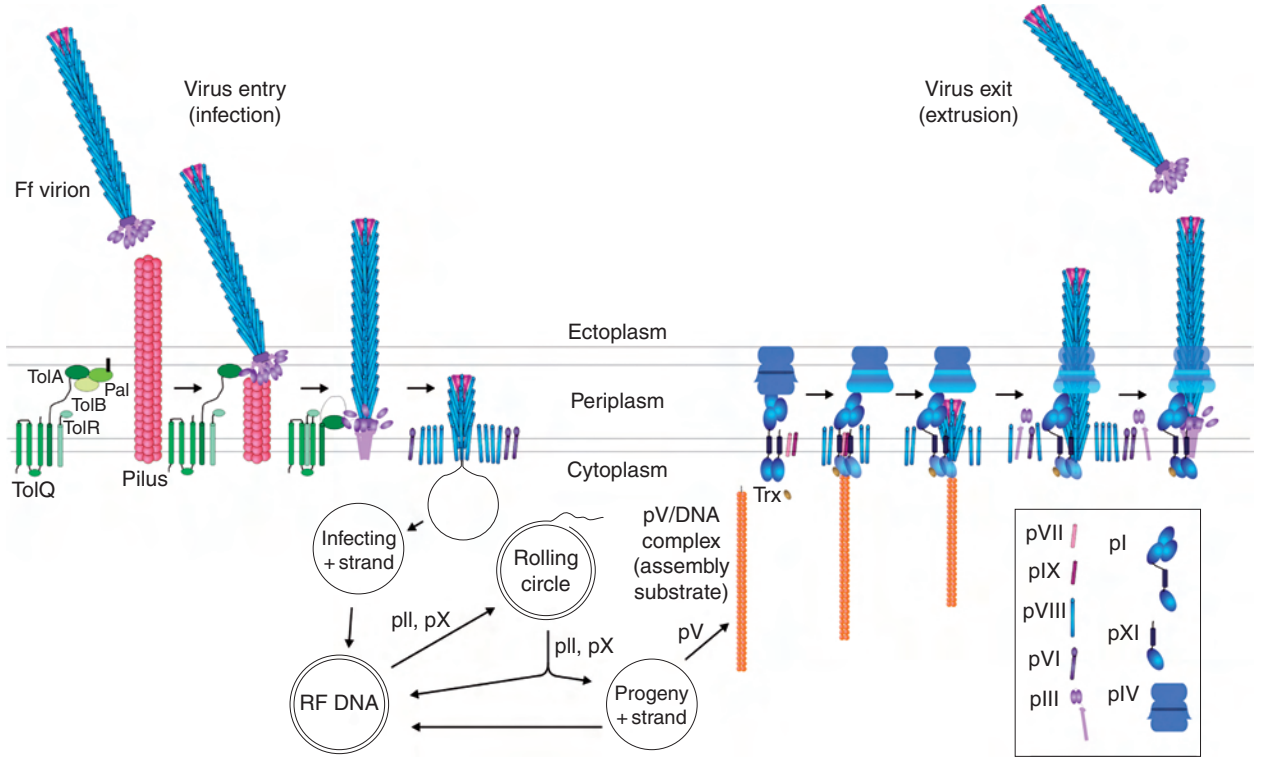

Figure 3 Schematic representation of the Ff life cycle. In the periplasmic space, the arrows show progressive stages of disassembly (left) and assembly (right) as discussed in the text. Viral and bacterial components are not drawn to scale (e.g., the actual dimensions of the Ff virion are 6.5 × 880 nm). Pilin biogenesis proteins are not shown.

Raman spectroscopy also indicates very different local deoxynucleoside conformations in the packaged ssDNA molecules of phages fd and Pf1.

Life Cycle

Infection

The mechanism of host cell infection by a filamentous bacteriophage has been studied in detail only for the bacteriophage Ff, which recognizes the conjugative F pilus of *E. coli* cells harboring the F plasmid. The process involves a trans-envelope network of host proteins – the Tol–Pal system – that is located in the *E. coli* cell envelope and serves to maintain the stability of the outer membrane. The Tol–Pal system includes the cytoplasmic membrane proteins TolA, TolR, and TolQ, which are anchored to the inner membrane, and the proteins TolB and Pal, which are associated with the outer membrane. TolA consists of an N-terminal TM domain, a periplasmic spanning α-helix, and a C-terminal globular domain also located in the periplasmic space. These domains are linked by glycine-rich segments. Like TolA, TolR has TM and periplasmic domains, whereas TolQ lacks a periplasmic domain and is located predominantly in the cytoplasm. TolA, TolR, and TolQ are associated with one another via their TM domains and all are necessary for viral infectivity. TolB is a periplasmic protein and Pal is a lipoprotein that is anchored to the outer membrane. Interaction of TolA with both TolB and Pal connects the outer and inner membranes of the *E. coli* cell. In the initial step of infection (**Figure 3**), the N2 domain of pIII binds the F-pilus, inducing a conformational change in N1–N2 that exposes a site of the N1 domain specific for TolA binding. The conformational change in N1–N2 allows a fast *cis*–*trans*-isomerization of the peptide bond between Gln212 and Pro213. When the peptide bond is in the more stable *trans*-form, the TolA binding site is exposed. Isomerization to the initial *cis*-form is a slow reaction, the rate of which is determined by the sequence of amino acids flanking Pro213. The rapid isomerization of the Gln212–Pro213 bond to the *trans*-form is a molecular switch controlled by the slower reverse reaction, which acts as a molecular timer. During the time that the N1 TolA binding site is exposed, the F-pilus is believed to retract through a secretin channel in the outer membrane of the host cell, by depolymerization of pilin, thus translocating pIII into the periplasm. The N1 domain of pIII binds the periplasmic C-terminal domain of TolA, the second phage receptor, forming a bridge between the adsorbed phage particle and the bacterial inner membrane. Subsequently, the C-terminal domain of pIII directs continuation of the infection process. Genetic studies suggest that the TolA–N1 interaction causes a conformational

change in the pIII C-terminal domain, which 'unlocks' the capsid. Once unlocked, a TM region of the pIII C-terminal domain likely interacts with the inner membrane to initiate dissociation of the capsid proteins, pVIII, pVII, and pIX, into the inner membrane with concomitant release of the viral genome into the cytoplasm. The capsid proteins of the infecting virion are retained in the membrane for use in the assembly of progeny virions.

DNA and Protein Synthesis

Upon entry into the cytoplasm, the ssDNA viral genome is converted into a replicative double-stranded form (RF) by the activity of host-encoded polymerases (RNA Pol and DNA Pol III) and a host-encoded single-stranded DNA-binding protein (SSB). To initiate this event, Pol synthesizes a short RNA primer beginning at nucleotide 5753. Pol III extends this primer the length of the viral strand, and Pol I and ligase close the complementary strand to produce a circular, dsDNA molecule. Gyrase supercoils the circle, thus resulting in the RF DNA, which serves as the template for transcription of viral genes.

Synthesis of ssDNA viral molecules requires the virally encoded protein pII, which specifically nicks the viral strand ((+)-strand) of RF DNA. The resultant 3′ hydroxyl group is used by the host DNA synthesizing apparatus (Pol III, SSB, and Rep helicase) to generate a new (+)-strand by the rolling-circle mode of replication, thus displacing the parent (+)-strand, which is subsequently circularized by pII. The newly synthesized RF DNA is closed and supercoiled for additional rounds of replication. The displaced and circularized (+)-strand can serve as either a substrate for additional RF DNA formation (template for (−)-strand synthesis) or a virus genome (encapsidation). At early stages of infection, the former path is more likely; at later stages, as the concentrations of virally encoded proteins become large, encapsidation is favored.

The (−)-strand serves as the template for transcription of viral genes, beginning at gene II. The presence of two strong terminators, one of which is rho-independent between genes VIII and III and the other rho-dependent in the IG, divides the genome into regions that are relatively frequently (genes II–VIII) and infrequently (gene III–IG) transcribed. The former has three strong promoters that lead to three primary transcripts. Post-transcriptional modification of these primary transcripts results in a set of six smaller and more stable mRNA molecules, all of which encode pVIII and a subset (four) of which encode pV. Multiple transcripts facilitate synthesis of the large amounts of pV and pVIII required to coat the prolifically produced (+)-strands (up to 200–300 progenies per cell). The frequently transcribed region also includes genes for the minor capsid proteins pVII and pIX. However, the translational initiation sites for synthesis of these proteins are weak. Accordingly, pVII and pIX are not produced in abundance. Proteins pII and pX, which likewise are encoded in the frequently transcribed region but not required in abundance, are regulated at the translational level via pV binding to the mRNA transcripts. This inhibition is evident at high cellular concentrations of pV, when amounts of the protein exceed the threshold required to sequester (+)-strands targeted for viral assembly.

Transcription of the genome and translation of the mRNA transcripts produces 11 viral proteins, of which pII, pX, and pV are required for (+)-strand synthesis, pIII, pVI, pVII, pVIII, and pIX are incorporated into the capsid, and pI, pIV, and pXI facilitate membrane-associated assembly. pII (409 residues) is a strand-specific endonuclease required for (+)-strand and RF syntheses; pX (111 residues) is synthesized from an AUG site within and in-frame with the C-terminal coding region of pII; pV (87 residues) forms a stable homodimer, the crystal structure of which has been solved to 1.8 Å and gives insight into the mechanism of binding of antiparallel ssDNA strands.

Each of the five capsid proteins of Ff exhibits a sequence consistent with an α-helical TM domain. All reside in the cytoplasmic membrane prior to assembly into the virion. Nascent pVIII contains a 23-residue signal sequence, which is removed from the N-terminus by a periplasmic signal peptidase, yielding the 50-residue subunit of the mature capsid. The N-terminal segment (1–19) of the mature subunit resides on the periplasmic face of the inner membrane, the middle 20 or so residues span the membrane, and the C-terminal segment (40–50) is situated in the cytoplasm. Although Sec proteins of *E. coli* ordinarily facilitate membrane insertion and translocation, these processes for pVIII are Sec-independent and mediated instead by the host-encoded protein YidC. Maturation of the pIII precursor, which contains an 18-residue N-terminal signal, is also accomplished following membrane translocation. A C-terminal sequence of 23 hydrophobic residues anchors pIII to the inner membrane, while most of the protein is located in the periplasmic space. The three remaining minor capsid proteins, pVI (112 residues), pVII (33 residues), and pIX (32 residues), are membrane-inserted without the aid of a signal sequence.

The three morphogenetic proteins of Ff are also located in the bacterial cell envelope. pI (348 residues) contains an internal TM region and spans the inner membrane with residues 1–253 in the cytoplasm and 273–348 in the periplasm. pXI (108 residues), which is synthesized from within the pI coding region, shares the sequence of the pI C-terminal segment. Accordingly, pXI is anchored to the membrane by a short N-terminal TM region, while most of the protein resides in the periplasm. The only viral protein located in the outer membrane is pIV. The 426-residue precursor is translocated into the periplasm where a 21-residue signal sequence is removed. The resulting 405-residue protein is integrated into the

outer membrane as an oligomer of 14 subunits, each with its N-terminus in the periplasm. A cryoelectron microscopy-based image reconstruction of detergent solubilized pIV at 22 Å resolution reveals a barrel-like cylindrical complex of three domains – an N-terminal ring (N-ring) of inner diameter 6.0 nm, a middle ring (M-ring) blocked by protein density, and a C-terminal ring (C-ring) of inner diameter 8.8 nm. In a recent model of the pIV multimer, it has been proposed that the C-ring is embedded in the outer membrane and the M- and N-rings are located in the periplasmic space, where a virus assembly-induced conformational change would allow opening of the gated M-ring and widening of the narrow N-ring.

Virus Assembly

Virus assembly occurs in the bacterial envelope at sites where the inner and outer membranes are associated by a trans-envelope network of proteins comprising the virally encoded pI, pIV, and pXI. This network is not transient and exists even in the absence of virus assembly. In addition to pI, pIV, and pXI, virus assembly is also dependent on host-encoded thioredoxin, ATP hydrolysis and the proton motive force across the cytoplasmic membrane. Thioredoxin must be in the reduced state; however, redox capability of the protein is unnecessary. pI likely catalyzes ATP hydrolysis, since its cytoplasmic domain contains an ATP-binding Walker motif, which is necessary for phage assembly.

The substrate for assembly is the pV-coated viral genome, in which the PS is exposed at one end. The PS likely forms an initiation complex with the cytoplasmic domains of pI, pVII, and pIX. pV is stripped from the genome concurrent with association of the positively charged C-terminal pVIII domain to the ssDNA molecule. The viral genome is translocated across the inner membrane as pVIII subunits assemble to it. A proposed hinge region between the TM and N-terminal amphipathic domains of pVIII may facilitate the transition of the capsid subunit from the inner membrane to the viral coat, although direct experimental evidence is lacking. Concurrent with assembly of the capsid, the progeny virion exits the bacterial cell through the pIV channel. The periplasmic N-terminal and middle domains of the pIV channel must undergo large conformational changes to allow passage of the 7 nm virus particle. The narrow N-terminal ring of the channel (6 nm i.d.) must expand and the gated middle ring must open. Since pI binds to both the initiation complex and the pIV channel, the initiation of virus assembly may be coupled to pIV conformational change by way of pI, which would avoid unintended channel opening. Additionally, if energy is necessary to widen the pIV channel or open its gate, pI may provide this energy via ATP hydrolysis.

Elongation of the progeny phage continues until the end of the viral genome is reached, at which time pVI and pIII associate with the tip of the viral capsid to terminate assembly and release the virion into the extracellular milieu. Without pVI and pIII, virus assembly continues by packaging additional genomes, one after the other, until the resultant polyphage is removed from the cell by mechanical shearing. Genetic studies have shown that separate regions of the C-terminal domain of pIII are important for termination of virus assembly, release of the viral filament from the host cell, and stabilization of the virion particle. An 83-residue C-terminal segment (residues 324–406) allows incorporation of pVI, but not release of the progeny phage. Ten additional residues (313–322) within the 313–406 segment confer the ability to release progeny phage from the bacterial cell envelope. A pIII C-terminal fragment of at least 121 residues is needed to release stable filamentous ssDNA bacteriophage progeny from an *E. coli* cell.

Biotechnology

Several aspects of the unique life cycle and morphology of the Ff bacteriophage have been exploited for biotechnological applications. (1) The size of the packaged genome is variable, such that it can easily tolerate an insertion of up to 6 kbp, which is compensated by the additional assembly of the proportionate number of pVIII subunits, as noted earlier. (2) The orientations of pVIII within the capsid lattice and pIII at the virion tail allow fusion of non-native peptides and proteins to exposed sites of the viral particle without significant disruption of phage viability or capsid stability. (3) The mature virion is very stable to changes in pH, temperature, and ionic strength. (4) Phage preparations yield high titers resulting in efficient and inexpensive large-scale phage production. (5) The phages are distinct from animal and plant viruses, and are generally not toxic to mammalian cells.

The filamentous ssDNA bacteriophage M13 has been used as a cloning vector for decades. The foreign gene to be cloned is usually inserted between functional sequences of the IG region of the genome. The virus assembly process allows up to 12 kbp of DNA to be packaged without adverse effects on phage viability. Inserts greater than 6 kbp, which result in a genome larger than 12 kbp, are possible with compensatory mutations elsewhere in the genome. One advantage of cloning with M13 is that both single-stranded and double-stranded products can be isolated from progeny phage and intracellular RF DNA, respectively.

Most biotechnological applications of M13 are byproducts of the revolutionary exploitation of the phage as a platform from which peptides (or proteins) can be displayed. To produce a phage that displays a foreign peptide, the coding sequence is inserted in-frame with that of a capsid protein, usually pVIII or pIII, so that the fused

peptide is exposed on the surface of the virion. Minor capsid proteins pVI, pVII, and pIX have also been successfully used for phage display, although to a lesser extent than pIII and pVIII. The display of the peptide must not interfere with capsid protein function. In the case of pVIII tethering, the peptide must be compatible with translocation of the capsid subunit across the inner membrane and with capsid assembly. Accordingly, peptides are usually fused to the pVIII N-terminus. For pIII, the peptide must not occlude the pilin binding site. Interference of the displayed peptide with the life cycle and/or stability of the phage can often be overcome by using a helper phage to facilitate production of hybrid virions containing both wild-type and fused capsid proteins, thus minimizing the adverse effect of the display. When sequences from a DNA library are inserted into the genome for display, a phage library containing up to 10^{10} different displayed peptides is produced.

The applications of phage display for biotechnological progress range from identification of molecular recognition elements between interacting proteins and ligands to targeted drug delivery for treatment of diseased mammalian cells. Biomedical applications include (1) antibody selection using a phage-displayed epitope library to facilitate the design of vaccines with optimal binding affinity for target epitopes; (2) immunopharmacotherapy for cocaine addiction, in which cocaine-sequestering antibodies displayed on a filamentous ssDNA bacteriophage are delivered to the central nervous system intranasally; (3) *in vivo* visualization of β-amyloid plaques by delivery of phage-displayed anti-β-amyloid antibodies to the brain with subsequent staining with fluorescent-labeled anti-phage antibody; and (4) cell-targeted gene and drug delivery, in which the phage is essentially a therapeutic nanocourier. Filamentous ssDNA bacteriophage display systems have also been successfully applied for nonmedical biotechnological purposes, for example, in the synthesis and assembly of nanowires for lithium ion battery electrodes. In this case, the tetrapeptide Glu-Glu-Glu-Glu is fused to the N-terminus of pVIII and treated to bind cobalt oxide forming a Co_3O_4 nanowire. These Co_3O_4 viral nanowires electrostatically self-assemble to form a nanostructured monolayer, which is used as the negative electrode in the construction of a Li-ion battery.

Glossary

D-dimers Fibrinolysis is mediated by plasmin, which degrades fibrin clots into D-dimers. Clinically, D-dimers can be used to diagnose DIC.

Disseminated intravascular coagulation (DIC) An acquired syndrome characterized by inappropriate accelerated systemic activation of coagulation with fibrin deposition in the microvasculature and consumption of procoagulants and platelets.

Fibrin degradation products (FDPs) The protein fragments produced after digestion of fibrinogen or fibrin by plasmin. Typically, a hallmark of disseminated intravascular coagulation. Also, referred to as fibrin-split products.
RNAi The silencing of the expression of a selected gene by a homologous portion of double-stranded RNA. Also, referred to as RNA interference.
Tissue factor (TF) A procoagulant protein responsible for activation of the extrinsic coagulation pathways.

Introduction

In 1967, the first filovirus outbreak occurred in Germany and Yugoslavia among laboratory workers handling African green monkeys and/or tissues from contaminated monkeys imported from Uganda. The causative agent was identified as a new virus called Marburg virus (MARV). MARV re-emerged in 1975 in Johannesburg, South Africa, when a man who had recently returned from Zimbabwe became ill. The infection was spread to the man's traveling companion and a nurse at the hospital. While the man died of the disease, the other two cases recovered from the illness after receiving supportive care. The following year in 1976, a mysterious outbreak swept through several remote villages in Africa. The disease was rapidly fatal (318 cases; mortality rate 88%). Examination of samples revealed a previously unknown virus similar to that of the MARV. This virus was named Ebola after a local river in central Africa and became the second member of the family *Filoviridae*. Since 1976, there have been a number of outbreaks of both types of filoviruses. Isolation and characterization of the causative agents of the Ebola outbreaks resulted in the identification of a number of related viruses. Today *Filoviridae* forms a separate family within the order *Mononegavirales* and can be divided into two genera: *Marburgvirus* and *Ebolavirus*. The latter is composed of four distinct species with varying degrees of lethality in man, *Zaire ebolavirus* (~90% lethal), *Sudan ebolavirus* (~50 %), *Reston ebolavirus* (unknown lethality), and *Ivory Coast ebolavirus* (unknown lethality). In contrast, the MARV genus is composed of a single species, *Lake Victoria marburgvirus*. However, there have been a number of isolates of MARV identified with varying degrees of morbidity and mortality. The case–fatality (CF) rate from the most recent isolate, MARV-Angola, has been reported to be ~90%. Although there has been a tremendous amount of work performed on filoviruses, the source of these outbreaks remains undetermined and there remains no approved vaccine or therapeutic intervention.

Background

Ebola Virus History

Ebola virus (EBOV) was first discovered during near-simultaneous outbreaks in the former Zaire and Sudan. These outbreaks were due to serologically distinct viral species that would be designated ZEBOV and SEBOV, respectively. The CF was ~88% in the initial ZEBOV outbreak and ~53% in the SEBOV outbreak. The source of these outbreaks was never determined. These outbreaks were followed by several smaller outbreaks in the late 1970s. After an almost 20-year absence, a new EBOV outbreak was reported in 1989 in a colony of cynomolgus monkeys (*Macaca fascicularis*), imported from the Philippines to a holding facility in Reston (VA, USA). Although the Reston species appeared to be highly lethal in nonhuman primates (NHPs), no disease was reported in any of the documented human exposures. Although there have been a number of subsequent outbreaks of REBOV in NHP facilities both in and outside of the US, to date there have been no cases of human infections reported. Investigations traced the source of all REBOV outbreaks to a single export facility in the Philippines (Laguna Province); however, the original source and mechanism of entry into this facility remain unknown. In 1994, EBOV reemerged in Africa with the identification of a fourth species, ICEBOV, as well as the detection of ZEBOV for the first time in Gabon. The fourth species of EBOV, ICEBOV, was identified in Côte d'Ivoire following the exposure of a researcher during a necropsy to determine the cause of death of local chimpanzee populations. The source for the infection of the chimpanzees was undetermined. The outbreak in Gabon occurred in the Ogooue-Ivindo Province; a total of 51 cases and 31 deaths were documented (CF = 61%) in this outbreak.

The largest outbreak of EBOV occurred in 1995 in Kikwit, Democratic Republic of the Congo (DRC) (formerly Zaire). A total of 310 cases with 250 deaths (CF = 81%) were reported. Approximately one-fourth of all cases were reported among healthcare workers. This outbreak was quickly followed by two additional outbreaks that occurred in DRC and Gabon. Only one of the three primary cases identified could be linked to contact with a dead chimpanzee. A total of 31 cases with 21 deaths (CF = 68%) were documented. The second outbreak occurred as a series of unrelated cases in hunters during July and August 1996. Reminiscent of previous outbreaks (Gabon and Côte d'Ivoire), there were reports of several dead great apes (gorillas and chimpanzees) in the same area. A total of 60 cases with 45 deaths (CF = 75%) were reported. Interestingly, sequence analysis of the isolates from 1994 and 1996 differed by less than 0.1% in the glycoprotein and polymerase genes.

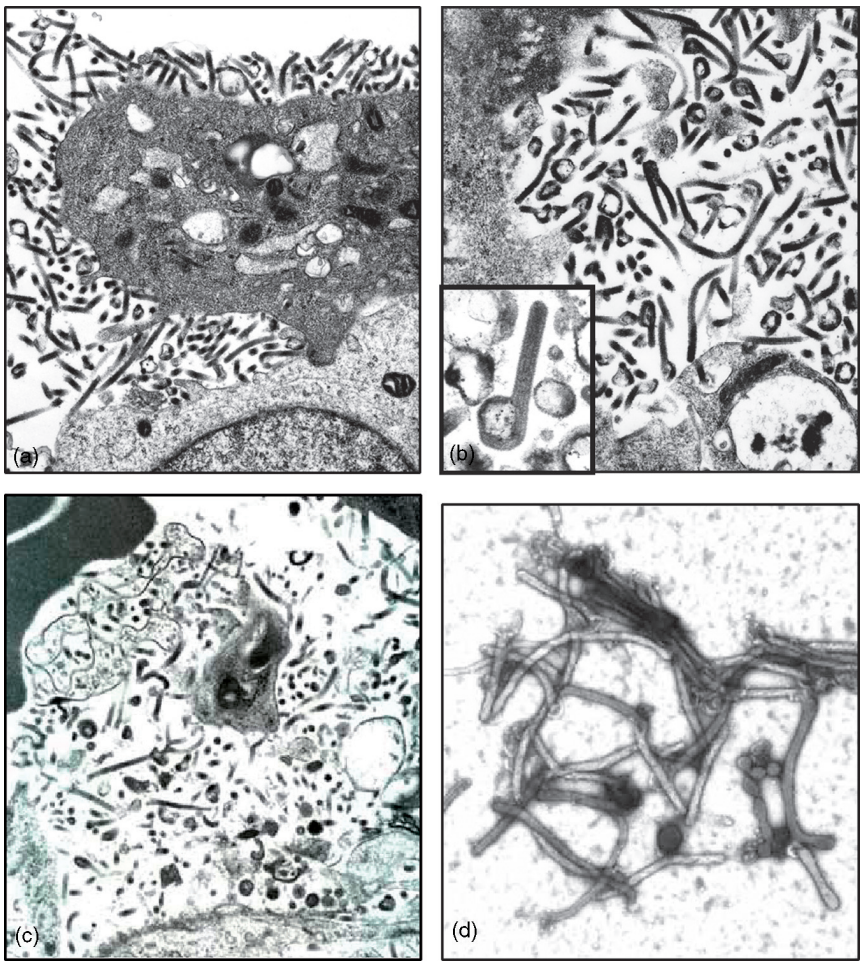
Ongoing, sporadic outbreaks of EBOV continue to be reported in central Africa. Most often, these outbreaks

have been associated with infection of the great ape population. It is believed that these outbreaks are to blame for the widespread loss of these animals. It has been reported that the population of Western lowland gorillas has dropped by 50% and as much as 90% in some areas. Conservationists have stated that it will take decades for the populations of these animals to recover.

Marburg Virus History

MARV was first identified in 1967 during simultaneous outbreaks in Germany and Yugoslavia among laboratory workers handling African green monkeys and/or tissues from contaminated monkeys imported from Uganda. Secondary cases were reported among healthcare workers and family members. All secondary cases had direct contact with a primary case. A total of 32 cases and 7 deaths (CF = 21%) occurred during this outbreak. Over the next several decades MARV was associated with multiple sporadic and isolated cases among travelers and residents in southeast Africa.

From 1998 to 2000 a number of MARV cases were reported among young male workers at a gold mine in Durba, DRC. Cases were subsequently detected in the neighboring village. Although a few cases were detected among family members, secondary transmission appeared to be rare. Subsequent virological investigation revealed that these cases were due to multiple introductions of different strains from an as-of-yet unidentified source. In total there were 154 cases with 128 deaths (CF = 83%) reported.



The largest and most deadly outbreak of MARV occurred in 2004–05 in the Uige Province of Angola. A total of 252 cases and 227 deaths (CF = 90%) were reported. Unlike previous outbreaks, a large number of the victims were children under the age of five. Virological analyses suggest that this isolate is very close to the strain from the original cases in 1967 in Europe. The reason for the increased virulence of the Angola isolate remains unclear.

Transmission

Both EBOV and MARV are transmitted by direct contact with the blood, secretions, organs, or other bodily fluids from infected persons, or infected animals. Many of the initial cases in outbreaks can be traced to the handling of infected animals, particularly chimpanzees and gorillas. Amplification has most often been associated with hospitals, where the virus is spread through nosocomial routes, or through burial ceremonies, where it is not uncommon for mourners to have direct contact with the deceased. While the modes of transmission have been well documented, the true source of these outbreaks and the reservoir for these viruses remain unclear. Although NHPs have been a source of infection for humans, the highly virulent nature of filoviruses in these animals suggests that they are not the reservoir. Different hypotheses have been developed to try to explain the origin of EBOV outbreaks. The presence of bats or contact with bat guano is often a common theme during outbreaks of both MARV and EBOV. Laboratory observation has shown that fruit and insectivorous bats experimentally infected with ZEBOV can support viral replication without apparent signs of illness. In a recent survey of small animals in Africa near areas of human or great ape EBOV outbreaks, asymptomatic infection of three species of fruit bats, *Hypsignathus monstrosus*, *Epomops franqueti*, and *Myonycteris torquata*, was reported. The exact ecology of EBOV and MARV remains to be determined and may include multiple natural reservoirs.

Virion Structure and Composition

Filoviruses are enveloped, nonsegmented, negative-strand RNA viruses. The virus envelope is derived from the lipid membrane envelope from the host cellular plasma membrane and therefore the lipid and protein composition reflect that of the infected cell. Filovirus virions have a characteristic thread-like, filamentous morphology (**Figure 1**). Pleomorphic virus structures ranging from straight tube-like structures, branched structures, and curved filaments shaped like a 6 (shepherd's crook), a U, or a circle. The diameter of filovirus virions are typically 80 nm, while the length can vary between 130 and 14 000 nm. The average length of a virus particle ranges from about 800 to 1000 nm with MARV being closer to 800 nm and EBOV closer to 1000 nm. Structurally, the virus particle is composed of seven viral proteins. The glycoprotein (GP), a type I transmembrane protein complex composed of two proteins, a ~140 kDa GP_1 and ~26 kDa GP_2. Normally, the two GP subunits are disulfide linked; however, when GP_1 is not disulfide-linked with GP_2, the GP_1 can be released in a soluble form from infected cells. Glycosylation, both N- and O-linked, provides approximately 50% of the GP mass. Complex cellular processing including glycosylation and proteolytic cleavage of the GP_1–GP_2 precursor protein leads to the generation of the GP_1–GP_2 heterotrimeric spikes in the virus envelope. GP_1 allows for receptor binding while GP_2 contains the fusion domain necessary for viral entry into the host cell. Surface projections of GP are dispersed evenly over the entire surface at 10 nm intervals. Functionally, the virus GP allows for attachment, receptor-mediated endocytosis, fusion with endocytotic vesicles, and release of the virion core into the host cell cytoplasm. To date, no specific host cell receptor has been identified. A variety of putative receptors and cofactors have been identified including the asialoglycoprotein receptor, folate receptor-α, and C-type lectins. Given the wide cell tropism of the virus, or the receptors are likely either constitutively expressed proteins, that involve multiple proteins with conserved binding domains, or

involve cofactors that facilitate virus entry. Viral particles may gain entry into the cell by co-opting common phagocytic pathways leading to a nonspecific entry mechanism.

The remaining six viral proteins are found within the virion, underlying the host-derived membrane. The viral protein 40 (VP40) functions as a matrix protein, and is essential for efficient viral assembly and budding. VP24 has been demonstrated to participate in the spontaneous formation of the nucleoprotein complex. Similar to VP40, studies indicate that VP24 behaves as a minor matrix protein. The nucleoprotein (NP) and VP30, VP35, polymerase (L) proteins, and the viral genomic RNA form the ribonucleoprotein complex. The nucleocapsids form a symmetrically helical filamentous structure underlying the viral envelope and the core structure has a striated appearance similar to that of rhabdoviruses. The L protein, the largest protein, functions as the virus-associated RNA-dependent RNA polymerase. VP30 functions as an EBOV-specific heterologous transcription activation factor that recognizes a secondary stem–loop structure during transcription. Similar to other transactivator factor proteins, VP30 exists in both phosphorylated and unphosphorylated forms within virions. In addition to their function as structural proteins, VP35 and VP24 have been shown to act as interferon antagonists.

Genome Organization and Expression

The linear genome is approximately 19 000 nt in length and consists of a single-stranded, negative-sense RNA (**Figure 2**). The genomic nucleic acid is not infectious. The genome contains highly conserved, transcription initiation and termination sites. Genomes contain intergenic sequence regions that vary in length, nucleotide sequences, and contain regions of gene overlap. While EBOV and MARV have a substantial degree of structural similarity in their respective genome organization, limited nucleotide sequence, homology is observed. Similar to the majority of other mononegaviruses, filovirus replication and transcription occurs in the cytoplasm of the infected

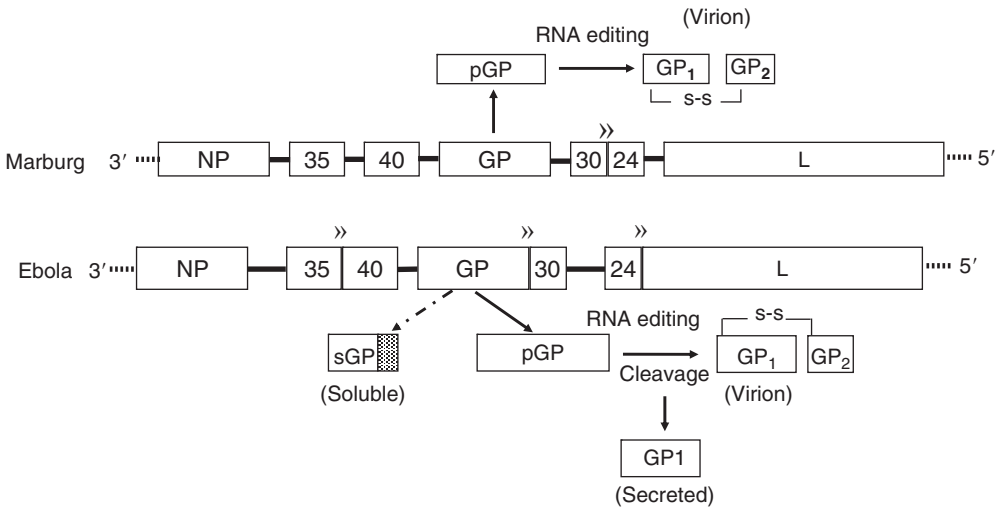


Figure 2 Filovirus genome organization and generation of glycoproteins. Linear, negative-sense, single-stranded, RNA monopartite genome, ~19 000 nt. Relative positions of the encoding regions for viral proteins depicted as boxes; NP, nucleoprotein; 35, VP35; 40, VP40; GP, glycoprotein; 30, VP30; 24, VP24; L, viral polymerase. Leader and trailer and intergenic regions (nontranscribed regions) shown as lines. Overlapping regions indicated by ≫ symbol. For Ebola, glycoprotein gene generates a soluble GP (sGP) and precursor GP (pGP). pGPs for Ebola and Marburg are cleaved by host-derived enzymes to generate a GP_1 and GP_2 subunit that are disulfide linked.

cell. The viral-encoded RNA-dependent RNA polymerase generates full-length positive-sense antigenomes that serve as templates for the synthesis of the progeny negative-sense genomes. Filoviral subgenomic mRNAs are monocistronic and polyadenylated. A single genome contains seven genes that are arranged linearly. Monocistronic subgenomic mRNAs complementary to the viral RNA lead to the generation of seven filovirus proteins found within the virion. For both MARV and EBOV, each gene encodes a single polypeptide, except for the GP. The structural glycoprotein GP_1 and GP_2 are generated as a single precursor polypeptide that is cleaved by host cell pro-protein convertases to generate the two subunits of the final protein. EBOV is different from MARV in that an additional viral protein is generated; a nonstructural, soluble form of GP, referred to as secreted GP (sGP). sGP is translated from an mRNA that has undergone RNA editing. Interestingly, the majority of GP mRNA encodes for the sGP which has been detected in cell culture and serum from EBOV-infected patients. Both soluble GP_1 and sGP have been implicated in the pathogenesis of EBOV by acting as decoy proteins that sequester neutralizing antibodies during infection; however, the exact role of the soluble forms of GP remains to be elucidated.

Pathogenesis

Clinical Features/Presentation

The clinical manifestations of EBOV and MARV are often compared to that of severe sepsis or septic shock. Following a 2–21 day incubation period, cases often present with a variety of nonspecific symptoms including high fever, chills, malaise, and myalgia. As the disease progresses, there is evidence of multisystemic involvement, and manifestations include prostration, anorexia, vomiting, nausea, abdominal pain, diarrhea, shortness of breath, hypotension, edema, confusion, maculopapular rash, and eventually coma. Patients normally progress rapidly with death occurring 6–9 days after the onset of symptoms. The development of petechiae, ecchymoses, mucosal hemorrhages, and uncontrolled bleeding at venipuncture sites are indicative of development of abnormalities in coagulation and fibrinolysis. Massive loss of blood is atypical and, when present, is largely restricted to the gastrointestinal tract. Fulminant infection typically evolves to shock, convulsions, and, in most cases, diffuse coagulopathy.

Animal Models

While only limited information is available for pathophysiology of human cases of EBOV or MARV, a lot has been learned from studies employing experimentally infected NHPs. Although the majority of studies in humans and NHPs to date have focused on ZEBOV, limited studies suggest that MARV may behave in a similar manner. EBOV and MARV are most often characterized by three common factors: development of lymphocyte apoptosis, aberrant production of pro-inflammatory cytokines, and the development of coagulation abnormalities. Sequential analysis of samples collected from ZEBOV-infected NHP shows early and prominent infection of monocyte/macrophages (MO/Φ) and dendritic cells (DCs). The importance of this selective targeting has been well documented.

Infection of the MO/Φ not only facilitates distribution of virus to the spleen and lymph nodes but also triggers a cascade of events including the upregulation and production of the procoagulant protein tissue factor (TF) as well as a number of pro-inflammatory cytokines/chemokines and oxygen free radicals. *In vitro* studies of human MO/Φ have confirmed these observations. Similar to septic shock caused by bacterial pathogens, disease triggered by EBOV or MARV infection is thought to involve inappropriate or maladaptive host responses. It is likely that these responses are more important to the development of the observed pathology than any structural damage directly induced by viral replication. Infection of DC likely facilitates disease progression by hindering the ability of the host to orchestrate an effective immune response to clear the virus.

Although lymphocytes do not appear to be productively infected by filoviruses, the importance of their role in the development of the disease pathology cannot be understated. The loss of lymphocytes through apoptosis has been well documented. Flow cytometry demonstrated a striking loss of circulating CD8+ T cells and natural killer (NK) cells prior to or corresponding with the onset of symptoms. The exact mechanism(s) responsible for triggering this widespread loss of lymphocytes remains unclear. RNA analysis of peripheral blood mononuclear cells (PBMCs) collected from NHPs has demonstrated the upregulation of a number of pro-apoptotic genes and anti-apoptotic genes.

Infection of MO/Φ also appears to be critical in the triggering and propagation of the coagulation abnormalities observed in filovirus infections. Recently, it was demonstrated that infection of MO/Φ *in vitro* or *in vivo* resulted in the upregulation of TF. Interestingly, this expression was observed only in infected cells, suggesting a direct correlation with the virus. Analysis of sera from infected animals revealed the presence of microparticles or small membrane vesicles with procoagulant and pro-inflammatory properties. Analysis of these microparticles showed that many of these expressed TF and may therefore have been derived from filovirus-infected MO/Φ.

The contribution of the endothelium as well as the infection of endothelium remains controversial. *In vitro* studies have demonstrated that endothelial cells are easily infected by either MARV or EBOV. However, analysis of tissues collected from human cases has produced conflicting results. Analysis of sequential tissues from NHP suggests that endothelial cells are not targeted until the later stages of disease. Electron microscopy examination of tissues showed activation of endothelial cells but no widespread damage to the vasculature. Analyses of clinical chemistries support this observation, with a drop in small molecular weight proteins but not total proteins. The cause for this vascular leakage is unclear and is likely multifactorial. Fibrin degradation products (FDPs), thrombin, reactive oxygen species, pro-inflammatory cytokines, as well as activation of the complement and kinin systems can all contribute to increased vascular permeability. Rapid increases in levels of D-dimers were observed in sera of EBOV-infected NHP with initial increases being detected before the onset of clinical symptoms. While the contributions of the complement and kinin systems in the development of EBOV and MARV pathogenesis are yet to be evaluated, the production of pro-inflammatory cytokines and oxygen free radicals has been well documented. In EBOV-infected NHP, IFN-α, interleukin-6 (IL-6), monocyte chemoattractant protein 1 (MCP-1), macrophage inflammatory protein (MIP)-1α, and MIP-1β were detected in sera at the early to mid-stages of disease. IFN-β, IFN-γ, IL-18, and TNF-α were also detected in sera but not until the later stages of disease.

In recent years, the importance of the interaction between coagulation and inflammation as a response to severe infection has become increasingly appreciated. In addition to driving upregulation of procoagulant proteins, inflammatory mediator, may inhibit fibrinolytic activity, and downregulate natural anticoagulant pathways, in particular, the protein C anticoagulant pathway. Uncontrolled activation of coagulation systems may lead to disseminated intravascular coagulation (DIC). DIC is a syndrome with both bleeding and thrombotic abnormalities characterized in part by the presence of histologically visible microthrombi in the microvasculature. These microthrombi may hamper tissue perfusion and thereby contribute to multiple organ dysfunction and high mortality rates. Before acute DIC can become apparent, there must be a sufficient stimulus to deplete or overwhelm the natural anticoagulant systems. During activation of the clotting system, the host regulates the process through the production and activation of a variety of inhibitors of the clotting system. In this process, however, the inhibitors are consumed, and if the rate of consumption exceeds the rate synthesized by liver parenchymal cells, plasma levels of inhibitors will decline. Analysis of tissue and sera from ZEBO-infected NHPs shows widespread fibrin deposition and marked decreases in plasma levels of protein C. The drops in protein C correlate with increase in D-dimers and disease progression.

Host Responses

The low sporadic disease incidence and remote locations of most outbreaks have led to limited careful study of the host responses to virus infection. Perturbations of the innate and acquired immune responses are consistent with fatal disease outcome. In a few studies patients that survived Ebola infections were reported to have generated a virus-specific immunoglobulin M (IgM) response and to have transient expression of pro-inflammatory cytokines. In sharp contrast, fatal EBOV cases have dysregulated cytokine expression levels, coagulation abnormalities, fibrin deposition, DIC, and evidence of cell death and the lack of an effective adaptive immune response. Through direct and

indirect mechanisms, and pathways that are not clearly understood, the fatal cases are associated with the lack of B- or T-lymphocyte responses. Altered innate responses, both cellular and soluble, combined with early infection of MO/Φ and DC, likely impair the host's ability to initiate an appropriate adaptive immune response to clear filovirus-infected cells. Simultaneously, virus-induced or inappropriate host defenses lead to dysregulated innate immune responses. Filovirus proteins VP35 and VP24 interfere with and modulate these key immune pathways by inhibiting cellular antiviral defenses. Ultimately, these events result in immune dysregulation and uncontrolled explosive virus replication.

Animal models have offered some insight into protective immune responses. In EBOV infection in mice, early interferon responses are vital to controlling virus replication. In concert, EBOV-specific antibody and cellular responses help eliminate virus infection in this animal model. Protective filovirus vaccines have been shown to induce antibody and/or cellular responses that offer protection in rodents and NHPs. Therefore, an appropriate innate and adaptive immune response can offer immunity to both MARV and EBOV.

Treatment and Prevention

Currently, there are no approved therapies or vaccines for the treatment and/or prevention of EBOV and MARV. Control and treatment are limited to containment and basic supportive care. Suspected cases should be isolated from other patients and strict-barrier-nursing techniques implemented. Contact tracing and follow-up of people who may have been exposed through close contact with cases are essential. If not already implemented proper disinfection and handling of materials from infected patients must be initiated. Education of the community as to the presentation of the disease, the nature by which it is transmitted, and the sources by which patients are likely to come into contact with the virus are critical to preventing and containing future outbreaks.

Although there are no approved vaccines there has been considerable progress in the identification and successful testing of candidate vaccines in animal models. These platforms can be separated into several categories: replication-deficient platforms, replication-competent platforms, and virus-like particles (VLPs). The replication-deficient platforms are viral vectors such as adenovirus or Venezuelan equine encephalitis virus (VEEV) expressing filoviral proteins. The first successful strategy to protect NHP from EBOV employed a replication-deficient adenovirus expressing EBOV GP and NP. In this strategy, a DNA prime of GP and NP genes was followed by an adenovirus-expressing GP boost. Subsequent studies demonstrated protection using a single adenovirus GP vaccination 28 days before EBOV challenge. Questions have been raised about the durability of the replication-deficient strategies as well as the ability of these strategies to overcome any pre-existing immunity to the vaccine platform. Efficacy has also recently been demonstrated using a live-attenuated (replication-competent) vesicular stomatitis virus (VSV) expressing the GP of EBOV. Additional work demonstrated that by simply swapping out the EBOV GP for either the MARV or Lassa fever virus GP, this platform could provide full protection against lethal MARV or Lassa fever virus challenge, respectively. The VSV platform has the additional benefit in that it has been demonstrated to provide 100% protection against MARV when administered 30 min after MARV exposure and ~50% protection for EBOV when rapidly administered in an EBOV post-exposure setting. While it is likely that the replication-competent platforms may provide increased durability there is some concern about the safety of administration of any live vaccine. Therefore, additional studies are needed to fully evaluate the safety profile of this platform. Finally, filovirus-like particles generated by the co-expression of viral membrane proteins (GP and VP40) are currently being evaluated in NHPs. This strategy may be beneficial in that it will likely overcome the safety concern associated with the use of live-attenuated platforms and/or the issues of preexisting immunity. Consistent with other protein vaccines, there are concerns about the durability of the immunity, adjuvant choice, as well as the necessary dosing regimen to achieve long-lasting immunity.

In addition to the wealth of candidate vaccine platforms developed and tested over the last few years, there have also been a number of candidate therapeutics that been evaluated in animal models. These strategies have met with varying degrees of success and can be divided into two basic categories, those that directly target the virus and those that target the host and/or the disease manifestations in the host. Recently, investigators reported success using either antisense oligonucleotides or RNA interference (RNAi) corresponding to sequences in the viral genomic or mRNA *in vivo*. Additional studies will be needed to evaluate whether the antisense technology can provide any therapeutic value when used after exposure and whether the success of the RNAi strategies in guinea pig models will translate into the more stringent NHP models. Reduction in morbidity and mortality has also been observed using therapeutics targeting the clinical manifestations in the NHP models. Treatment of ZEBOV-infected NHP with a recombinant protein, recombinant nematode anticoagulant protein c2 (rNAPc2) that blocks the TF-mediated activation of the extrinsic pathway of blood coagulation, resulted in ~33% survival as well a substantial increase in the mean time to death. Interestingly, substantial reductions in plasma levels of IL-6, MCP-1, and viral load were noted in rNAPc2-treated animals. It is unknown if treatment with other anticoagulant strategies that block the

intrinsic and/or common pathways may also offer comparable and/or improved therapeutic benefit.

Finally, it is important to mention therapeutic strategies that are yet to provide any survival benefit when tested in NHP models. Although type I IFNs have shown promise in the mouse model of EBOV infection, testing of IFN-α2 failed to protect NHPs against EBOV or MARV. In addition, *S*-adenosylhomocysteine, which had been hypothesized to protect mice against EBOV, at least in part through induction of a type I IFN response, also failed to protect NHP. Currently, alternative IFN therapies and formulations are under evaluation. It is unclear if these approaches will have any improved efficacy in NHPs. In addition, heparin, convalescent serum, and equine anti-EBOV immunoglobulin have been used to treat infections in humans and/or NHPs, but were inconsistent and appeared to be of little therapeutic value. While passive antibody treatment has been successful in mice, the benefit of antibody immunotherapy remains controversial. Although results in rodent models have been encouraging, initial studies in NHPs have not been as successful. Additional studies are needed to fully evaluate the utility of this therapeutic avenue.

Glossary

Fingerling Young fish between the fry and adult stages.

Fry Newly hatched or very young fish.

Tegument The layer of proteins situated between the capsid and the envelope in herpesvirus particles; equivalent to the matrix in other viruses.

Classification and History

Most currently recognized fish herpesviruses infect species that are farmed or harvested from the wild for human consumption. The conditions used in aquaculture may enhance the disease potential of these pathogens and increase their likelihood of detection. It is probable, therefore, that many more fish herpesviruses await discovery. A similar prospect applies to amphibian herpesviruses, since the two known examples originated from a single host species. Herpesviruses of fish and amphibians, like those of higher vertebrates, are usually highly species specific in the natural setting. This indicates that they have evolved in close association with their hosts over long periods of time. Many of these viruses cause mortality only in young fish, and some are also agents of epidermal hyperplasia or neoplasia. Some have been studied to such a limited extent that causal links with the disease whose occurrence led to their identification have not yet been established adequately.

Several fish and amphibian herpesviruses have been classified as members of the family *Herpesviridae*. These include viruses that infect white sturgeon, *Acipenser transmontanus* (acipenserid herpesviruses 1 and 2), Japanese eel, *Anguilla japonica* (anguillid herpesvirus 1), carp, *Cyprinus carpio* (cyprinid herpesvirus 1), goldfish, *Carassius auratus* (cyprinid herpesvirus 2), northern pike, *Esox lucius* (esocid herpesvirus 1), rainbow trout, *Oncorhynchus mykiss* (salmonid herpesvirus 1), channel catfish, *Ictalurus punctatus* (ictalurid herpesvirus 1), Pacific salmon, *Oncorhynchus* species (salmonid herpesvirus 2), walleye, *Stizostedion vitreum* (percid herpesvirus 1), and turbot, *Psetta maxima* (pleuronectid herpesvirus 1). Only one of these viruses (ictalurid herpesvirus 1) has been classified further into a species (*Ictalurid herpesvirus 1*) and a genus (*Ictalurivirus*). Candidate herpesviruses have also been reported in black bullhead (*Ictalurus melas*), Japanese flounder (*Paralichthys olivaceus*), pilchard (*Sardinops sagax*), and redstriped rockfish (*Sebastes proriger*). The viruses representing the classified amphibian herpesviruses (ranid herpesviruses 1 and 2) originated from the leopard frog, *Rana pipiens*. The tenuous genetic relationships between herpesviruses of fish and amphibians and those of higher vertebrates have prompted the proposal that the former group be separated into a new family (*Alloherpesviridae*) and grouped with other herpesviruses into an order (*Herpesvirales*). Elucidation of the genetic relationships among these viruses, upon which detailed subclassification will depend, is at an early stage.

This article focuses on three principal viruses, one infecting an amphibian and two infecting fish. These are Lucké tumor herpesvirus (LTHV; ranid herpesvirus 1), channel catfish virus (CCV; ictalurid herpesvirus 1), and koi herpesvirus (KHV; proposed cyprinid herpesvirus 3). Comments are made on other viruses where appropriate.

In 1934, Lucké reported that intranuclear acidophilic inclusion bodies typical of certain virus infections were present in renal adenocarcinomas of the leopard frog. He concluded 4 years later that the tumor was caused by a virus. Almost two decades elapsed before herpesvirus particles were observed in frog kidney tumor cells by electron microscopy (**Figure 1**), and another decade followed before a causative relationship was established between LTHV and the tumor. The complete genome sequence of the McKinnell strain of LTHV was published in 2006 along with that of the other amphibian herpesvirus, the Rafferty strain of frog virus 4 (FV4; ranid herpesvirus 2).

In 1968, Fijan reported the first isolation of CCV from young channel catfish, in which it causes an acute disease of high mortality. The first detailed characterization of the virus was published 3 years later, and showed that capsids with the typical herpesvirus morphology are assembled in infected cell nuclei. Three-dimensional reconstructions

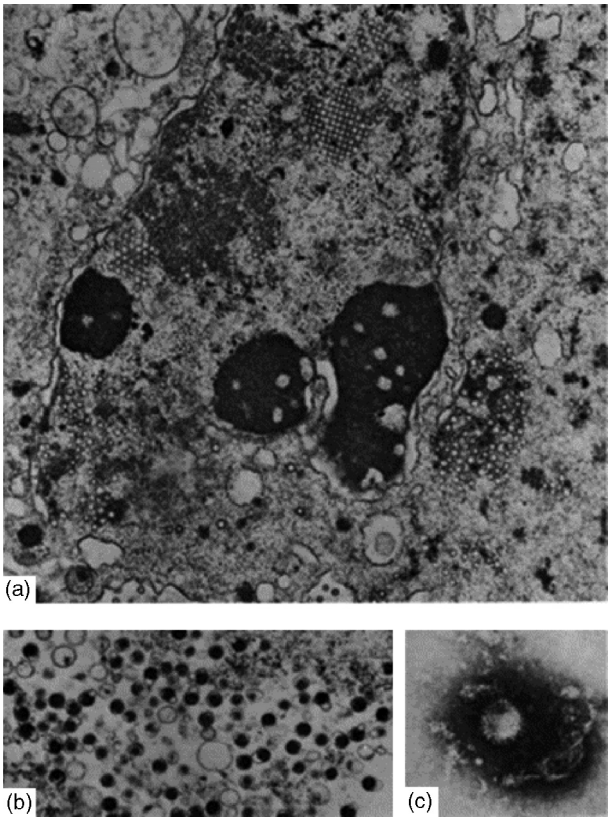

Figure 1 (a) Thin section of an inclusion-bearing Lucké tumor cell with typical herpesvirus particles in various stages of development in the nucleus. Magnification ×19 400. (b) Enveloped extracellular virions. Magnification ×24 000. (c) Negatively stained nonenveloped particles showing typical herpesvirus morphology. Magnification ×110 000. Reproduced from Granoff A (1972) Lucké tumor-associated viruses – a review. In: Biggs PM, de-The G, and Payne LN (eds.) *Oncogenesis and Herpesviruses*, pp. 171–182. Lyons: International Agency for Research on Cancer, with permission from WHO.

derived by cryoelectron microscopy have shown that, apart from minor dimensional differences, the CCV capsid is strikingly similar to that of herpes simplex virus type 1 (HSV-1) (**Figure 2**). The complete genome sequence of the Auburn strain of CCV was published in 1992.

In 1998, a herpesvirus-like agent was identified as the cause of high mortality among carp, including expensive ornamental fish known as koi. The first outbreaks of this new disease may have occurred as early as 1996. In initial studies, this agent (KHV) was also known as carp interstitial nephritis and gill necrosis virus. Consideration of developmental, morphological, and, most recently, genetic attributes have led to the virus being proposed formally as a member of the proposed family *Alloherpesviridae*. The complete genome sequences of three strains of KHV (from Japan, USA, and Israel) were published in 2007.

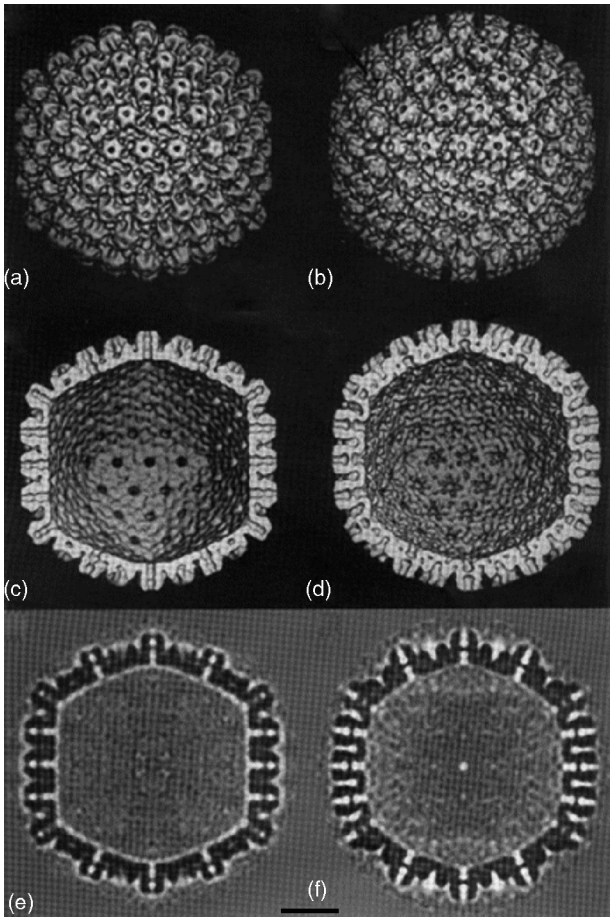

Figure 2 Comparison of the three-dimensional capsid structures of CCV (a, c, e) and HSV-1 (b, d, f). The capsids are viewed along a twofold symmetry axis. Outer surfaces (a and b); inner surfaces (c and d); central thin sections (e and f). The distribution of capsomers (a and b) is distinctive for the triangulation number, $T = 16$, with lines of three hexons connecting pentons along each edge of the icosahedral surface lattice. Scale = 25 nm. Reproduced from Booy FP, Trus BL, Davison AJ, and Steven AC (1996) The capsid architecture of channel catfish virus, an evolutionarily distant herpesvirus, is largely conserved in the absence of discernible sequence homology with herpes simplex virus. *Virology* 215: 134–141, with permission from Elsevier.

Geographic and Seasonal Distribution

The Lucké tumor occurs in north-central and northeastern parts of the USA and southern Canada. In the 1960s, the frequency of affected frogs reached 9% in some collections. However, leopard frog populations have since declined drastically, and the tumor has also become very rare. Production of LTHV within tumors is temperature dependent and therefore seasonal. Tumor cells contain acidophilic intranuclear inclusions and virus particles at temperatures below 11.5 °C but not at higher temperatures, and transition between these states can be induced by temperature shift. The mechanisms by which temperature regulates virus growth have not been elucidated, and their operation *in vivo* and *in vitro* (explanted tumors) indicates that the immune system is not a primary factor. Despite the absence of virus particles at higher temperatures, there is some evidence that tumors express virus-specific proteins.

The occurrence of CCV disease has paralleled the intensification of channel catfish farming in the southern USA and other warmer temperate regions. The lack of reported CCV isolations from wild channel catfish indicates that factors such as dense stocking and poor environmental conditions may predispose farmed fish stocks to outbreaks of disease. A key factor is water temperature, since epizootics occur in the summer months and the incubation period has been shown to be considerably shorter at higher temperatures up to 30 °C.

KHV has spread to many countries worldwide, presumably as a result of intensive aquaculture and unregulated transport of live fish in the absence of diagnostic assessment. Water temperature is an important seasonal factor influencing disease, with losses tending to occur during periods at 18–25 °C (spring and autumn). In one study, experimental infections of koi resulted in a cumulative mortality of 95% at 23 °C, with marginally fewer deaths occurring more rapidly at 28 °C and more slowly at 18 °C. Mortalities did not occur at 13 °C, but shifting virus-exposed fish from 13 to 23 °C resulted in rapid onset of mortality.

Pathology, Clinical Features, and Pathogenesis

Little information is available on the natural transmission of LTHV and the factors that influence the occurrence of tumors. It is possible that virus is transmitted by contact with urine or by infection of oocytes in tumor-bearing frogs. Although FV4 infects the embryos and larvae of *R. pipiens*, surviving animals do not develop tumors. Examinations of

the gene complements of the two viruses have not provided a ready explanation of this biological difference.

CCV causes an acute hemorrhagic disease in juvenile channel catfish. It is readily transmitted from fish to fish, probably entering through the gills. In artificial settings, it can also be transmitted by injection or orally by ingestion of contaminated food. After experimental infection, CCV can be isolated from the kidneys and then from other organs, in some of which impressively high titers of virus may be attained. The primary route for virus shedding is probably via the urine.

CCV can be remarkably virulent in susceptible populations of channel catfish. Under optimal conditions the incubation period can be as short as 3 days, and mortality can rise rapidly to 100%. Signs of distress may be accompanied by convulsive swimming, including a 'head-up' posture, and lethargy and death follow. Externally, affected fish may display protruding eyes, a distended abdomen and hemorrhages, largely on the ventral surface. Internally, viscera may be enlarged and hemorrhagic, but certain organs, such as kidneys, liver, and spleen, may be pale. The digestive tract is empty of food, instead containing a mucoid secretion, and a fluid accumulation is present in the peritoneal cavity. Histopathological examination reveals widespread and profound changes. Initially, the kidneys show edema, hemorrhage, and necrosis, and then these features develop in the liver and digestive tract. Electron microscopic studies reveal virus particles in affected organs.

Given the virulence of CCV in young catfish, it is reasonable to suppose that the virus might persist in an inapparent or latent form in adult fish, as do higher vertebrate herpesviruses in their hosts. There is evidence in support of this. Viral mRNA and antigens have been detected in adult fish and, in more recent studies, virus was recovered by co-cultivation of tissues from wintering adult fish and virus DNA was detected by polymerase chain reaction (PCR) in various tissues of surviving fish many months after infection. There is evidence that the CCV genome may exist in circular or concatemeric form in surviving fish. However, the site of latency has not been identified. Reactivated CCV from adult fish could be transmitted horizontally, and there is circumstantial evidence that vertical transmission may also occur.

KHV is highly contagious, has an incubation period of 2–3 days, and exhibits mortality rates of 80–100%. Clinical signs include increased mucus production, pale patches on the skin and gills, labored breathing, and swelling and then necrosis of the gill filaments. Pathological lesions are evident primarily in the gills but may be present in the kidney, skin, liver, spleen, brain, and gastrointestinal tract. Gill disease is characterized by hyperplasia and then fusion of secondary lamellae, inflammation of the gill rakers, and subsequent necrosis. Kidney disease, if present, is characterized by a peritubular and interstitial nephritis. Virus particles are present in affected organs. The routes of infection and shedding are not known, though the gills and skin are obvious candidates, and cohabitation is an effective means of transmitting the disease. Depending on water temperature, virus may survive for periods of days to weeks. Immunohistochemistry and PCR analyses have demonstrated large amounts of the virus in the gills, skin, kidneys, and spleen with smaller amounts in liver, brain, and intestinal tract, mirroring the pathological involvement of these organs. Given its identity as a herpesvirus, it is likely that KHV has a latent aspect to its life cycle. There is some evidence for this, in that temperature-dependent reactivation of KHV has been shown to occur experimentally in surviving carp several months after initial exposure.

Two other carp herpesviruses have been characterized. From limited DNA sequence data, both appear to be closely related to, though distinct from, KHV. Carp pox herpesvirus (cyprinid herpesvirus 1) has been implicated as the cause of a localized epithelial hyperplasia, which manifests itself as benign smooth nodules on the skin and may be transferred by applying material from the lesions to the abraded skin of other fish or following bath exposures of young carp or koi to virus from cell culture. The agent is difficult to grow successfully in cell culture, and thus is isolated infrequently from clinical cases. Hematopoietic necrosis herpesvirus of goldfish (cyprinid herpesvirus 2) was first observed in Japan in 1992, and since then severe outbreaks of the associated disease have occurred in several countries. The virus affects goldfish and not carp, and the disease shares some pathological manifestations similar to that caused in carp by KHV, although the hematopoietic tissue in the kidney rather than the gills is the principal virus target. Similar to cyprinid herpesvirus 1, the goldfish virus is difficult to isolate, although it has been successfully cultured on occasion, with the experimental demonstration that upon bath exposure goldfish will succumb to typical signs of the disease and death.

Two salmonid herpesviruses have been shown to cause virulent disease either naturally or experimentally. Herpesvirus salmonis (salmonid herpesvirus 1; SalHV-1) was isolated on several occasions from a rainbow trout hatchery in the state of Washington. Oncorhynchus masou virus (salmonid herpesvirus 2; SalHV-2) was isolated from Japanese land-locked salmon, and has the property of causing epithelial tumors in survivors of experimental infection. Two additional herpesviruses, the NeVTA and Yamame tumor viruses, have been isolated from *Oncorhynchus* species. They appear to be related to each other, but it is not known whether they represent distinct salmonid herpesviruses or whether they are isolates of SalHV-2 or, as seems less likely, SalHV-1.

Diseases ostensibly due to several other fish herpesviruses have been described. Walleye herpesvirus is

associated with epidermal hyperplasia, but causality has not been demonstrated. Similarly, the role of turbot herpesvirus has not been proven in episodes of substantial mortality among farmed fry.

Growth Properties

The Lucké tumor occurs naturally in *R. pipiens*. Tumors can be induced readily in *R. pipiens* embryos or larvae inoculated with LTHV-containing extracts of Lucké tumors or virus purified by density gradient centrifugation. The ascites frequently produced by tumor-bearing frogs contains virus that can induce tumors when inoculated into embryos. Tumors have also been induced experimentally in other species of the host genus. Despite attempts employing cell lines from a wide range of hosts, it has not proved possible to culture LTHV *in vitro* from homogenates of Lucké tumors or the urine of tumor-bearing frogs. Therefore, it has not been possible to investigate the replication cycle. In contrast, FV4 can be grown in cell culture, and produces cytopathic effects typical of herpesviruses within 10–21 days after infection of *R. pipiens* embryo or adult kidney cells at 25 °C. These include cell rounding and vacuolization, enlargement of nuclei and development of intranuclear inclusions, and formation of syncytia.

CCV causes acute infection only in young channel catfish up to about 6 months old, the degree of mortality depending on the strain of fish. Certain other closely related species, such as the blue catfish (*Ictalurus furcatus*), may be infected experimentally by injection, but other species are refractory even by this route. Host cell requirements are a little less stringent in cell culture, but virus growth still only occurs in ictalurid and clariid fish cell lines. Among commonly used cell lines BB (*Ictalurus nebulosus* or brown bullhead) and CCO (channel catfish ovary), the latter is more susceptible. Optimal virus yield is obtained at 25–30 °C, and about 50% of progeny virus is released into the culture medium. Virus infection causes the formation of syncytia, particularly at lower multiplicities of infection, followed eventually by disaggregation and lysis. Under optimal conditions, peak virus yield may be attained only 12 h after infection. Thus, CCV is one of the fastest growing herpesviruses *in vitro*.

Experimental determinations have shown that about 50 CCV proteins are expressed or induced in infected cell culture. As with other herpesviruses, expression appears to be coordinately regulated. The major immediate early protein, which is likely to regulate the expression of other virus genes, has an apparent molecular mass of 117 000 Da. The capsid contains an abundant constituent (the major capsid protein) with a molecular mass of 128 000 Da and at least two smaller proteins. The major capsid protein of higher vertebrate herpesviruses is invariably larger, having a molecular mass of about 150 000 Da. Different isolates of CCV may be differentiated by restriction endonuclease digestion of their DNAs, but are recognizably similar. CCV DNA replicates in the nuclei of infected cells via head-to-tail concatemers made up of a unit comprising the unique region linked to a single copy of the direct repeat.

KHV disease is restricted to koi and common carp, and other fish tested have been shown to be resistant even after extensive exposure to infected carp at permissive temperatures. A cell line derived from koi fin has been used to culture KHV, with optimal growth occurring at 15–25 °C and no growth at 10 or 30 °C. The highest virus yields are generated 7 days after infection at 20 °C, with most infectivity released into the culture medium. KHV strains are highly similar to each other as assessed by restriction endonuclease and sequence analyses. A total of 31 virion proteins have been detected. Studies of KHV gene expression are in their infancy.

SalHV-1 causes disease when injected into young rainbow trout maintained at 6–9 °C, but not in other salmonid species. A similar temperature optimum is characteristic of growth in the rainbow trout cell line RTG-2. SalHV-2 has a slightly wider host range, causing virulent disease in the young of several members of the genus *Oncorhynchus* and the rainbow trout. It has a higher temperature optimum for growth in RTG-2 cells than SalHV-1 (15 °C).

Genetics and Evolution

The complete genome sequences of two fish and two amphibian herpesviruses have been determined: those of CCV, KHV, LTHV, and FV4. Partial data are available for other viruses in this group. **Table 1** shows some of the basic characteristics of the sequenced genomes. All have a type A genome structure, consisting of a unique region (U) flanked by a direct repeat at the termini (TR). However, this structure is not universal among fish and amphibian herpesviruses, as the SalHV-1 genome has a type D structure. All of the sequenced genomes contain a number of families of genes that are related (usually distantly) to each other and have presumably arisen by gene duplication. KHV has the largest genome thus far reported for any herpesvirus.

Figure 3 shows the predicted gene layout in CCV, which has the smallest sequenced genome among the fish and amphibian herpesviruses. Analysis of the sequence indicates the presence of 62 genes in U (two spliced) and 14 genes in TR. Several gene functions have been predicted from computer-aided comparisons of predicted CCV proteins with proteins from other organisms. Ten genes belong to four gene families: two encoding related sets of protein kinases (PK1 with ORF14, ORF15, and ORF16; PK2 with ORF73 and ORF74), one encoding proteins similar to a

Table 1 Characteristics of sequenced fish and amphibian herpesvirus genomes

Virus	*Genome size*[a] *(bp)*	*G + C composition (mol.%)*	*Genes*[b]	*Gene families*
CCV	134 226 [18 556]	56.2	76	4
KHV	295 146 [22 469]	59.2	156	5
LTHV	220 859 [636]	54.6	132	15
FV4	231 801 [912]	52.8	147	15

[a]The total size of the DNA sequence is given, with the size of TR in square brackets.
[b]Genes that are duplicated by virtue of their presence in the terminal repeat are counted only once.

bacteriophage deoxynucleoside monophosphate kinase (dNMPK; ORF76 and ORF77), and one encoding proteins containing a potential zinc-binding domain (RING; ORF9, ORF11, and ORF12). Other genes encode a potential zinc-binding protein (ORF78), a protein containing a myosin-like domain (ORF22), a helicase (ORF25), a DNA polymerase (ORF57, composed of two exons), a deoxyuridine triphosphatase (ORF49), a thymidine kinase (ORF5), a subtilisin-like proprotein convertase (ORF47), the ATPase subunit of the putative terminase (ORF62, composed of three exons), a putative primase (ORF63), a protein containing an ovarian tumor (OTU)-like cysteine protease domain (ORF65), an envelope glycoprotein (ORF46), and seven other membrane-associated proteins (ORF6, ORF7, ORF8, ORF10, ORF19, ORF51, and ORF59). The principal constituent proteins of CCV virions have been identified by proteomic analysis. The capsid includes the major capsid protein (ORF39), a potential scaffold protein

(ORF28), and two other proteins that possibly constitute the intercapsomeric triplex (ORF27 and ORF53). Several virus proteins in the tegument have been identified, in addition to actin. The major envelope protein is specified by ORF59.

LTHV, FV4, and KHV have substantially more genes than CCV, and many of these are members of gene families or genes apparently captured from the cell or other viruses. For example, the frog herpesviruses, unlike the fish herpesviruses, encode a DNA (cytosine-5-)-methyltransferase and, presumably as a result, have extensively methylated genomes. Overall, the two frog herpesvirus genomes are the most closely related of the four, sharing 40 genes (when genes with marginal similarity are excluded). CCV shares 19 genes with the frog herpesviruses and only 15 with KHV. The modest number of conserved genes indicates that the evolutionary distance among lower vertebrate herpesviruses is substantially greater than that among higher vertebrate herpesviruses.

Where functions may be predicted for the conserved genes, they are central to herpesvirus replication, being involved in capsid morphogenesis, nucleotide metabolism, DNA replication, and DNA packaging. The arrangement of homologous genes in LTHV and FV4 is collinear, except for one block of genes that is in a different position and orientation in the two genomes. In contrast, homologous genes in the frog herpesviruses are situated in several rearranged blocks in the more distantly related fish herpesviruses. This parallels the situation among members of different subfamilies of higher vertebrate herpesviruses. As with higher vertebrate herpesviruses, homologous genes tend to be located centrally in the genomes.

The salmonid viruses SalHV-1 and SalHV-2 have been shown to be distinct viruses on the base of serological comparisons, DNA hybridization studies, and limited DNA sequencing. The SalHV-1 genome is approximately 174 kbp in size and has homologues of at least 18 CCV genes in several rearranged blocks. Sequence data indicate that these two viruses are related to each other and, more distantly, to CCV.

No proteins encoded by fish and amphibian herpesviruses are detectably related in their primary sequences to proteins that are specific to higher vertebrate herpesviruses (e.g., those that make up the capsid, of which the structure is conserved). This observation suggests that the two groups diverged from their common ancestor a long time ago. The best (and perhaps only) sequence-based evidence for a common evolutionary origin of the two groups depends on conservation of the putative ATPase subunit of the terminase, which is encoded by a spliced gene containing three exons (**Figure 3**). This protein is thought to be involved in packaging replicated DNA into the capsid and is also distantly conserved in T4-like bacteriophages, thus contributing to the notion that herpesviruses may share an ancient origin with bacteriophages.

Immune Response

Understanding of the immune responses to amphibian and fish herpesviruses is not well developed, and data obtained under relatively normal conditions of infection are limited largely to CCV. Adult channel catfish produce peak neutralization titers on average 8 or 9 weeks after primary immunization with CCV, and a further moderate increase in titer of short duration is apparent after boosting. The importance of virus growth in eliciting the immune response is indicated by the observation that heat-inactivated virus is poorly immunogenic. Serum neutralization indexes have been used to document a link between outbreaks of CCV disease and potential carriers of the virus. These studies, though not extensive, have given some indication that seroconverted adult fish are able to transmit CCV.

Control and Prevention

The devastating economic losses occasioned by certain of the fish herpesviruses prompt the need for intervention protocols. Avoidance and containment of outbreaks presently involve the use of ostensibly virus-free or partially resistant breeding stock, as clean environmental conditions as practicable, destruction of affected populations, and disinfection of ponds. The use of temperature variation regimes to aid the survival of infected fish has also been mooted. It is clear from the KHV situation, where individual fish may be very valuable, that effective diagnosis and monitoring of stock movements should be considered in order to avoid the spread of highly virulent diseases.

CCV is sensitive to nucleoside analogs that inhibit the growth of higher vertebrate herpesviruses. In general, these compounds are phosphorylated by the virus, but not the cellular, thymidine kinase. Further steps in phosphorylation probably involve cellular enzymes. The triphosphate form then inhibits DNA replication by direct interaction with the DNA polymerase or by incorporation into nascent DNA. These compounds include the widely used antiherpetic drug acyclovir. Phosphonoacetate, which inhibits the DNA polymerase by mimicking pyrophosphate, is also inhibitory. Against considerations of cost and administration, however, it is doubtful whether antiviral therapy will ever be generally practicable for the treatment of fish herpesvirus diseases.

The poor immunogenicity of inactivated CCV and KHV preparations suggests that the use of live, attenuated viruses is likely to be more effective in vaccination strategies. However, given the potential for latent vaccine virus to revert to wild type, thorough characterization of vaccine candidates and development of assays to differentiate vaccine from wild-type virus are essential (for a precedent

in higher vertebrate herpesviruses, consider pseudorabies virus). The use of avirulent strains of virus in which virulence genes are replaced by detection markers may lead in the long term to safe, efficacious vaccines.

CCV attenuated by passage in a clariid fish cell line was able to provide substantial protection against the lethal effect of infection by virulent virus, particularly when the initial immunization was boosted. This virus exhibits several genomic differences from wild type, most notably a substantial deletion in ORF50, which potentially encodes a secreted glycoprotein. In this context, deletion of ORF5, which encodes thymidine kinase, has been shown to cause attenuation of virulence in channel catfish fingerlings. Attenuated versions of KHV produced by serial passage in koi fin cell culture and subjecting clones to further mutation *in vitro* did not induce lethal disease and protected immunized fish against challenge. This protection correlated with antibody production.

DNA vaccines also hold promise in combating fish herpesvirus diseases, particularly in their avoidance of utilizing intact virus. From seven CCV genes tested, ORF59 (encoding the major envelope glycoprotein) and ORF6 (encoding a predicted membrane protein) produced significant resistance to challenge, with combined vaccination even more effective.

Acknowledgment

The author is grateful to Ronald Hedrick for comments on the pathological features of KHV in light of his unpublished data.

Glossary

Cytopathic effect Morphologic changes in cells resulting from virus replication.
Dysplasia An abnormality in the appearance of cells and indicative of a preneoplastic change.
Hyperplasia An increase in the number of cells of an organ or tissue.
Leiomyosarcoma Neoplasia of smooth muscle cells.
Malpighian cells Cells of the deepest layer of the epidermis.
Neoplasia An abnormal growth of cells.

Oncogene Cellular or viral gene whose products are capable of inducing a neoplastic phenotype.
Proto-oncogene A normal cellular gene which when inappropriately expressed or mutated becomes an oncogene.

Introduction

Retroviruses have been documented in a wide range of vertebrate species including lower vertebrates such as frogs, snakes, sharks, fish, birds, and turtles. To date, however, the majority of these reported sequences represent only partial fragments of the retrovirus. In recent years, the complete genomic sequence of exogenous fish retroviruses from Atlantic salmon (*Salmo salar*), walleye (*Sander vitreus*), and snakehead (*Ophicephalus striatus*), and an endogenous retrovirus of zebrafish (*Danio rerio*) have been determined. Analysis of these viral genomes indicates a high degree of diversity among the fish retroviruses as well as several unique features compared to mammalian and avian retroviruses.

The etiological relationship between retroviruses and cancer is well established in mammalian and avian systems. Simple retroviruses can promote cell proliferation by inducing the ectopic expression of captured cellular oncogenes (viral transduction for acutely transforming viruses) in which an oncogene recombines into the viral genome, or by integration near or within the coding sequence of cellular proto-oncogenes (nonacute transforming viruses). Transcription factors encoded by some complex retroviruses, like human T-cell leukemia virus-1 (HTLV-1), also have nonacute oncogenic potential by deregulating cellular pathways controlling cell proliferation.

Like their mammalian and avian counterparts, many fish neoplastic/proliferative diseases are suspected of having a retroviral etiology. Retroviruses are reported to be associated with 13 spontaneous proliferative diseases of fish based on the observation of retrovirus-like particles and, in some cases, reverse transcriptase activity in neoplastic lesions. Seven of these diseases with putative viral etiologies display a seasonal cycle, that is, they develop and regress annually. Retrovirus-associated tumors of the skin have received the most attention, since they are most visible and easily sampled. Skin tumors with suspected viral etiologies have been found in white sucker (*Castostomus commersoni*), walleye, yellow perch (*Perca flavescens*), and European smelt (*Osmerus eperlanus*). Retroviruses have also been linked to lymphoma in northern pike (*Esox lucius*), leukemia in chinook salmon (*Oncorhynchus tshawytscha*), and leiomyosarcoma of the swimbladder in Atlantic salmon. One noteworthy piscine retrovirus, the snakehead fish retrovirus (SnRV), has not been associated with tumor induction. In most of these systems, the etiologic relationship of retroviral infections and neoplasms rests on circumstantial evidence such as observations of viral particles by electron microscopy and the presence of reverse transcriptase activity. However, sequencing of fish retroviruses has facilitated use of molecular-based diagnostic reagents and, in some cases, shed light on potential modes of pathogenesis. In particular, the walleye retroviruses, walleye dermal sarcoma virus (WDSV) and walleye epidermal hyperplasia virus type 1 (WEHV-1) and type 2 (WEHV-2), express a subset of accessory genes exclusively during oncogenesis, specifically implicating the encoded proteins in the process of tumorigenesis.

Retroviruses and their Life Cycle

Retrovirus particles are composed of viral structural and enzymatic proteins and two copies of the positive-sense single-stranded RNA genome. The proteins are surrounded by a lipid bilayer, acquired from the host cell, in which viral envelope glycoproteins are embedded. Retroviral infection is initiated when the surface glycoprotein binds to its cognate receptor on the surface of a susceptible cell. Upon fusion of the viral and cellular membranes, the viral core enters the cytoplasm where the virally encoded enzyme, reverse transcriptase, copies the RNA genome into DNA. The viral integrase protein binds reverse transcribed DNA and mediates its integration into the genomic DNA of the host. In rare cases, retroviral infection of host germ-line cells and subsequent integration into the chromosomes can establish retroviral sequences as heritable genetic elements, known as endogenous retroviruses.

Based on the complexity of the viral genome, retroviruses can be divided into two broad categories: simple and complex. Simple retroviruses, including members of the *Gammaretroviruses* and *Alpharetroviruses*, contain three genes: *gag*, *pol*, and *env*. Expression of a full-length unspliced messenger RNA (mRNA) and a spliced mRNA serve as the templates for translation of the retroviral structural and enzymatic proteins. These proteins are first translated as polyproteins from *gag* and *pol*, respectively, and are processed by a virally encoded protease. The viral envelope glycoprotein is encoded from a singly spliced viral transcript containing the *env* gene.

Complex retroviruses are distinguished from simple retroviruses on the basis of their additional coding capacity and pattern of viral gene expression. This category of retroviruses includes *Lentiviruses* such as human immunodeficiency virus type 1 (HIV-1), *Spumaviruses*, and the *Deltaretroviruses*, human T-cell leukemia virus (HTLV-1), and bovine leukemia virus (BLV). Complex retroviruses produce multiply spliced transcripts that encode two classes

of accessory/regulatory proteins. One class includes transcriptional regulatory proteins such as HTLV-1 Tax and HIV-1 Tat, which act *in trans* to directly regulate the activity of the viral promoter. A second class, including HTLV-1 Rex and HIV-1 Rev, act post transcriptionally, to facilitate transport of unspliced and singly spliced viral transcripts to the cytoplasm. The combined action of these proteins divides the replication cycle into two temporal phases: an early, regulatory phase, and a later, structural phase. During the regulatory phase, low levels of fully spliced transcripts encoding *trans*-activators increase levels of transcription leading to the accumulation of post-transcriptional regulatory proteins. These proteins allow production of unspliced and singly spliced mRNAs that encode the viral structural proteins.

Both simple and complex retroviruses have been identified in fish species. Retroviruses isolated from walleye and snakehead fish resemble complex retroviruses based upon their genome structure and transcriptional profile, while simple retroviruses have been identified in Atlantic salmon and zebrafish.

Skin Tumors in Walleye and Their Associated Retroviruses

Walleye dermal sarcoma (WDS) and walleye discrete epidermal hyperplasia (WEH) are neoplastic and hyperplastic skin lesions in walleye that have been etiologically associated with infection by three distinct retroviruses (**Figure 1**). WDS and WEH were first reported in 1969 on fish from Oneida Lake in New York. Since then, WDS and WEH have been reported on walleyes throughout North America. These diseases have a seasonal cycle; tumor incidence is highest in the late fall and early spring months at frequencies of 27% and 5% for WDS and WEH, respectively. Lower tumor prevalence in summer months is associated with regression on individual adult fish.

WDS appears as a cutaneous mesenchymal neoplasm arising multicentrically within the superficial dermis and overlaid with epidermis. Fall tumors appear highly vascularized due to a network of capillaries, while spring tumors are frequently white with ulcerated surfaces. Invasive tumors are rarely observed in feral fish. WEH lesions are benign mucoid-like plaques with distinct boundaries. They can range from 2 to 3 mm in diameter to large lesions with irregular borders that may be as large as 50 mm across. Histologically, this disease appears as an epidermal proliferation consisting primarily of Malpighian cells.

Experimental transmission of WDS and WEH has been achieved with cell-free filtrates. Interestingly, only cell-free filtrates prepared from the spring, regressing WDS, not fall, developing WDS, are able to transmit disease. Infection of walleye fingerlings less than 9 weeks of age results in the frequent development of invasive tumors.

Electron microscopic observation of retrovirus particles and cell-free transmission of both diseases suggest a retroviral etiology for WDS and WEH. WDSV was isolated from WDS tissue, and two independent retroviruses, WEHV1, WEHV2, were isolated from WEH lesions. Similar hyperplastic lesions on yellow perch in Oneida Lake are associated with two new retroviruses, perch epidermal hyperplasia virus types 1 and 2 (PEHV1, PEHV2).

Isolation and Sequencing of Retroviruses from WDS and WEH Lesions

WDSV, WEHV1, and WEHV2 have been molecularly cloned and sequenced (**Figure 2**). The genome structures of WDSV, WEHV1, and WEHV2 indicate large and complex viral genomes (12.7, 12.9, and 13.1 kbp, respectively).

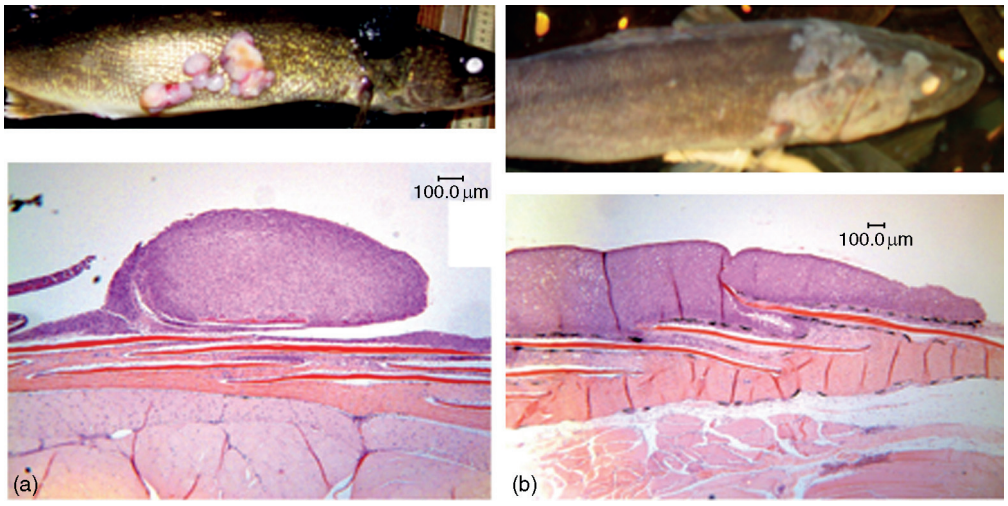

Figure 1 (a) Gross and histological images of walleye dermal sarcoma and (b) walleye epidermal hyperplasia.

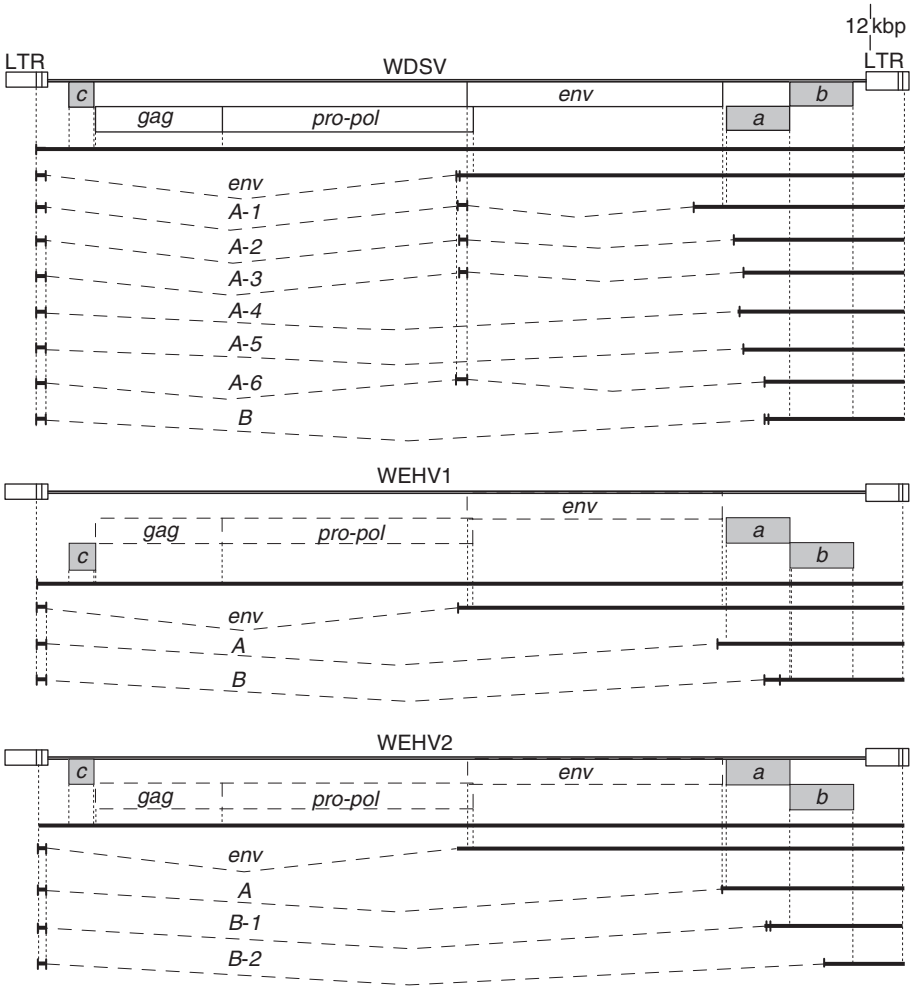

Figure 2 Genomic and transcriptional maps of WDSV, WEHV1, and WEHV2. Genomic organization of viral DNA with retroviral genes and accessory genes *orfa*, *orfb,* and *orfc* is depicted under each virus heading. The envelope-spliced transcript (*env*) and additional spliced transcripts (*A* and *B*), which are capable of expressing accessory genes, are illustrated. The vertical dashed lines indicate the boundaries of the exons, introns, and open reading frames.

All three viruses have intact open reading frames (ORFs) capable of encoding the structural and enzymatic genes *gag*, *pol*, and *env*. *gag* (viral capsid) and *pol* (reverse transcriptase) are in the same reading frame and synthesized as a polyprotein through a termination suppression mechanism. *pro* (viral protease), responsible for cleaving the polyprotein, is located in the same reading frame as *pol*. A unique feature of all three viruses is the presence of additional orfs that have tentatively been called *orfa*, *orfb*, and *orfc*. The *orfa* and *orfb* genes are located between *env* and the 3′ long terminal repeat (LTR), while *orfc* is located between the 5′ LTR and the start of *gag*. Database searches with OrfA protein amino acid sequences suggest limited homology with D-type cellular cyclins within the cyclin-box motif, and are referred to as rv-cyclins. WEHV1 rv-cyclin has a 20% amino acid identity and 35% similarity with human cyclin D-3, whereas WEHV2 and WDSV rv-cyclin are most similar to human cyclin D-1 (22%/35% and 19%/29% amino acid identity/similarity). Similarities with known walleye and other piscine cyclins are not significantly greater. The WEHV cyclin homologs are 37% identical within the cyclin box motif and 21–28% identical with the WDSV cyclin. Sequence homologies between rv-cyclin and OrfB in the walleye retroviruses suggest they arose by a gene duplication event.

Roles of the WDSV Accessory Proteins in Pathogenesis

Transcriptional mapping by RT-PCR and Northern blot analyses of developing and regressing WDS and WEH have demonstrated temporal gene expression profiles and complex splicing patterns analogous to those seen in the complex retroviruses of mammals. In developing WDS tumors, only low levels of multiply spliced subgenomic transcripts are detected. These transcripts predominantly contain the coding sequences for rv-cyclin and OrfB. Regressing spring tumors contain high levels of full-length and subgenomic

transcripts as well as unintegrated viral DNA and transmissible virus. OrfC is likely encoded by the full-length transcript coincident with tumor regression.

A detailed transcriptional analysis of WDSV showed an alternative splicing pattern of the *orfa* transcript (**Figure 2**). In developing tumors, the *orfa* transcript contains the coding sequence for a full-length rv-cyclin protein that localizes to the nucleus of mammalian and walleye cells. Alternatively spliced forms of this transcript encode amino-terminal truncated forms of the rv-cyclin protein, which localize in the cytoplasm of cells. The different forms of rv-cyclin may play functionally different roles in developing and regressing tumors. A single, spliced transcript encodes the OrfB protein, which is predominantly localized in the cytoplasm in tumor explant cells, but is capable of shuttling into and out of the nucleus when expressed in piscine and mammalian cells.

The OrfC protein from WDSV has been shown to localize to mitochondria and to disrupt mitochondrial function, which results in apoptosis. Only the full-length viral transcript found in regressing tumors is capable of encoding OrfC. Apoptotic cells are present in regressing, but not developing, WDS tumor sections. Therefore, the OrfC protein may be responsible for a direct viral mechanism of tumor regression.

WDSV *orfa* and *orfb* are the only virus transcripts found in developing tumors, suggesting direct roles for rv-cyclin and OrfB in the process of tumorigenesis, and their oncogenic potential has been demonstrated by several experimental approaches. WDSV *orfa* supported growth of a yeast (*Saccharomyces cerevisiae*) strain conditionally deficient for the synthesis of the G1 to S cyclins that are necessary for cell cycle progression. WEHV *orfa* did not support yeast growth in this model. Transgenic expression of WDSV *orfa* in mice from a skin-specific promoter caused a moderate to severe squamous epithelial hyperplasia and dysplasia dependant on skin injury. This suggests that rv-cyclin is not oncogenic as a result of a 'single-hit' mechanism, but rather, that secondary genetic or epigenetic events (possibly wound repair) are necessary for tumor development and progression. A similar phenotype has been described in transgenic mice expressing *v-jun* oncogene from the H-2K^k major histocompatibility complex (MHC) class I antigen gene promoter. When expressed in mammalian or piscine cell culture, WDSV rv-cyclin localized in the nucleus and was found by co-immunoprecipitation to be associated with cyclin dependent kinase 8 and cyclin C, general transcription initiation factors, and RNA polymerase II transcription complexes. In piscine cells, rv-cyclin inhibited transcription from the WDSV promoter independent of *cis*-acting DNA sequences. However, rv-cyclin can activate other viral promoters in fish cells, and can activate the WDSV promoter in select mammalian cells; thus rv-cyclin activation and inhibition of transcription are dependent on both the promoter and the cell type. WDSV rv-cyclin contains a defined transcription activation domain in the carboxy end of the protein, and the isolated activation domain is capable of interacting with co-activators of transcription. WEHV rv-cyclins do not have a corresponding carboxy-region activation domain. WDSV rv-cyclin may exhibit oncogenic potential by differential regulation of host gene expression such as proto-oncogenes or tumor suppressors.

Less is known about the capabilities of the OrfB protein, but initial studies indicate its direct association with the regulation of signal transduction pathways. It is concentrated, in tumor explant cells, at focal adhesions, and along actin stress fibers. Established OrfB-expressing lines are resistant to the chemical induction of apoptosis, suggesting a role in oncogenesis.

The origins of the accessory genes of complex retroviruses are unclear. This includes the origins of the WDSV accessory genes encoding rv-cyclin, OrfB, and OrfC. In the case of rv-cyclin and OrfB, their extreme divergence from host cyclin sequences indicates that any transduction event was ancient and led, ultimately, to an exclusive, complex viral species. The OrfC protein, like the accessory proteins of other complex retroviruses, has no clear homology to host proteins.

Control of the Seasonal Cycle of Disease

An interesting aspect of WDS is the control of the seasonal switch in viral gene expression and associated tumor regression. Potential modulators of viral gene expression include host immunity and endocrine activity (accompanying spawning) and environmental factors such as water temperature, physical trauma, and sunlight. A number of *cis*-acting elements important for transcription activation have been identified in the WDSV promoter. There is differential binding of proteins from developing and regressing tumor nuclear extracts to a 15 bp repeat region in the WDSV promoter. This element may be critical to the induction of high levels of virus expression. The WDSV rv-cyclin protein negatively regulates the WDSV promoter in tissue culture cells. Presumably, it is advantageous for the virus to have lower levels of gene expression during tumor development to avoid immune surveillance as well as the cytopathic effects associated with virus production. While rv-cyclin may function in the repression of virus expression during tumor growth, the host, environmental, or viral signals that switch on full virus expression are yet to be determined.

Snakehead Retrovirus

The SnRV was isolated from a productively infected cell line derived from a Southeast Asian striped snakehead

fish. Cell culture supernatant from these infected cells demonstrated high levels of RT activity and the presence of type C-like retrovirus particles. Additionally, supernatant from the infected cell line induced cytopathic effects in cultures of a bluegill cell line (BF-2).

Molecular approaches were utilized to identify and sequence the SnRV from infected cells. The large 11.2 kbp genome of SnRV contains intact coding regions for *gag*, *pol*, and *env* (**Figure 3**). An arginine tRNA primer binding site used for reverse transcription initiation distinguishes SnRV from other retroviruses. The structure and transcriptional profile of SnRV suggests a complex expression pattern capable of encoding an ORF located between *env* and the 3′ LTR and two very small ORFs termed ORF1 and ORF2. Within the leader sequence of SnRV resides a start codon located just upstream of the major splice donor site that could potentially encode a 14 amino acid peptide (LP). Expression of Env from a singly spliced transcript is predicted to utilize the LP initiation codon and fuses this 14 amino acid peptide in frame to downstream *env* sequences. A transcript with four exons and two initiator codons would encode ORF1 and ORF2 proteins. The 3′ ORF would be expressed from a transcript containing three exons and would encode a protein of 24 kDa. Finally, the fourth spliced transcript may encode 3′ ORF or possibly a LP-Env cytoplasmic domain (CD) fusion protein. The 3′ ORF contains an N terminal acidic domain, cysteine residues, and a basic region, motifs commonly found in transcriptional activators. These small ORFs have no significant homology to any known proteins in the databases, and their role in the viral life cycle is unknown. No endogenous copies of SnRV have been identified in the snakehead genome and an uninfected cell line has been established.

Although the presence of SnRV in wild populations has not been thoroughly examined, the virus has been independently isolated from two separate snakehead cell lines derived from whole fry tissue and from caudal peduncle tissue from juvenile fish. In all cases, fish from which these cell lines were derived appeared healthy.

Salmon Swimbladder Sarcoma-Associated Retrovirus

An outbreak of neoplastic disease of the swimbladder of Atlantic salmon was first reported at a Scottish commercial marine fish farm in 1975. Affected salmon were sluggish and in poor condition. A viral etiology was suspected, and electron microscopic evaluation of tumors revealed the presence of budding viral particles with retroviral morphology. A second outbreak occurred between 1995 and 1997 in brood stock salmon held at the North Attleboro National Fish Hatchery in Massachusetts. The fish exhibited skin discoloration and hemorrhages on the fins and body and showed a general debilitation and lack of vigor. In May of 1997, significant mortality was noted at the facility such that 35% of the population was affected by late spring of 1998. All of the affected fish displayed swollen abdomens due to multinodular masses on internal and external surfaces of the swimbladder. In several cases, these multinodular masses occupied the entire swimbladder (**Figure 4**). Histologic examination revealed that the tumors were composed of well-differentiated fibroblastic cells that were arranged in interlacing bundles, which were classified as leiomyosarcomas.

Isolation of a Retrovirus from Salmon Swimbladder Sarcoma

An exogenous retrovirus, termed Atlantic salmon swimbladder sarcoma virus (SSSV), was initially identified in tumors by degenerate RT-PCR of tumor RNA, and the entire viral sequence completed by DNA sequencing of

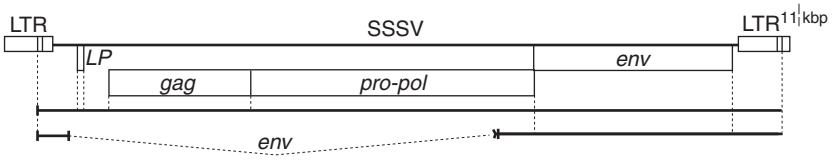

Figure 5 Genomic and transcriptional map of SSSV. Predicted coding regions are shown as open boxes. The envelope-spliced transcript (*env*) is illustrated. LP indicates the location of a predicted leader peptide. The vertical dashed lines indicate the boundaries of the exons, introns, and open reading frame.

proviral DNA. In contrast to the complex walleye retroviruses, SSSV is a simple retrovirus. The viral genome contains ORFs capable of expressing *gag*, *pol*, and *env* (**Figure 5**). Additionally, a short 25 amino acid leader peptide of unknown function is located upstream of the Gag-Pol polyprotein ORF. SSSV differs from other simple retroviruses by not having related endogenous sequences in the host genome, and SSSV is the only retrovirus to use a methionine-tRNA as a plus-strand primer. Additionally, sequences in *pol* display homology to central polypurine tract regions identified in complex retroviruses. Central polypurine tracts facilitate the formation of a single-stranded DNA region called a central DNA flap as a result of reverse transcription priming from this internal site. In HIV-1, this feature plays a major role in complex retroviral replication and allows efficient infection of nondividing cells. It is intriguing that SSSV displays a high proviral copy number (greater than 30 copies per cell) with a polyclonal integration pattern in swimbladder tumors. SSSV must be capable of initiating multiple rounds of infection within the same cell. The specific mechanisms leading to the high copy number and its implications in the pathogenesis of disease are of significant interest for future research.

Sequence Comparisons of SSSV with Other Retroviruses

A comparison of the sequence of SSSV viral proteins with other retroviruses indicates large regions of homology with mammalian type C and type D viruses in Pol and Env. Additionally, a 179 amino acid region in the C terminus of Gag and a 1064 amino acid region of Pro–Pol displays 23% and 33% identity to the related WDSV proteins, respectively. SSSV has striking homology to the sequence of the zebrafish endogenous retrovirus (ZFERV). BLAST analysis of the Gag, Pol, and Env ORFs of SSSV reveals a 25% identity with ZFERV over 533 amino acids within Gag, a 40% identity over 533 amino acids of Pol, and a 39% identity over 429 amino acids of Env.

Prevalence, Seasonality, and Transmission of SSSV

A PCR diagnostic assay was developed using sequences within the *pol* gene of SSSV. Prevalence at the North Attleboro fish facility has been found to be 52% and 5% of a natural stock of Pleasant River salmon were found to harbor SSSV.

Like other retroviral diseases of fish, observations suggest that salmon swimbladder sarcoma is seasonal. First, of the 34% fish mortality at the North Attleboro facility between 1997 and 1998, 57% occurred in June. Second, in the following year, the surviving salmon had an SSSV incidence (measured by PCR) that cycled with a peak in late summer to early winter and then diminished in late winter to early spring. The period of highest SSSV incidence correlated with salmon spawning runs in late fall. Interestingly, WDSV prevalence, which peaks during late spring, also correlates with the time of spawning. This suggests that endocrine changes during spawning runs may be a critical factor in the observed seasonal variation in disease incidence.

Pathogenesis of SSSV

The existence of SSSV sequences in association with an outbreak of the swimbladder sarcoma suggests a role for the retrovirus in pathogenesis of the disease. As a simple retrovirus with no transduced cellular oncogenes, one possible mechanism of tumorigenesis is the insertional activation of a cellular proto-oncogene. The high copy number of proviruses in tumors has made the analysis of insertional activation events difficult, but multiple insertions increase the likelihood of such a mechanism. It is also feasible that SSSV may express an oncogenic viral gene product. This mechanism of oncogenesis has been proposed for the Jaagsiekte sheep retrovirus (JSRV) in the induction of ovine pulmonary adenocarcinoma and in Friend spleen focus-forming virus (SFFV)-associated erythroid hyperplasia in mice. Additionally, the presence of common integration sites within JSRV-associated tumors suggests that insertional mutagenesis may act in concert with the envelope in tumor development. Thus, a multifactorial mechanism for the development of salmon swimbladder sarcoma must also be considered.

In addition to sarcoma, a number of other distinct pathologies are associated with SSSV infection. These diseases are frequently debilitating and are, therefore, of significance to the aquaculture industry. Atlantic salmon at the North Attleboro hatchery, during the SSSV outbreak, presented with multifocal hemorrhages, sloughing of the epidermis, lethargy, wasting, and failure to mature sexually in addition to swimbladder tumors.

Zebrafish Endogenous Retrovirus

Endogenous retroviruses have been identified in almost all vertebrate genomes, and most are defective due to mutations and deletions. An endogenous retrovirus, ZFERY with a genome of 11.2 kbp has been identified in the Tubingen stock of zebrafish, and contains intact coding regions for *gag*, *pol*, and *env*. The *gag* and *pol* genes are in the same reading frame. While the majority of endogenous retroviruses are transcriptionally silent because of mutation or methylation, ZFERV remains transcriptionally active. In addition to genomic transcripts that encode Gag and Pol proteins, an unusual multiply spliced *env* transcript is produced. Expression appears highest in the larval and adult zebrafish thymus, and no expression was detected in 2-day old embryos, suggesting that ZFERV expression may be tied to thymic development.

Phylogeny of Fish Retroviruses

Retroviruses have been classified into seven genera based largely on highly conserved amino acid sequences in the retroviral reverse transcriptase gene. While the majority of the viral sequences employed in this classification represent mammalian and avian retroviruses, a new genus termed *Epsilonretroviruses*, representing the fish retroviruses WDSV, WEHV-1, WEHV-2, has been added to the most recent classification. As more retroviral sequences from lower vertebrates have been identified, it has become apparent that this classification scheme may be inadequate to represent the apparent diversity.

Based on the unique characteristics of SnRV, including its genomic organization, tRNA primer, and complex transcriptional profile, the virus is yet to be definitively placed in the current classification. The large size of the genome, genetic organization, and presence of additional ORFs suggest that SnRV is closest to the spumaviruses and walleye retroviruses, but its limited sequence homology suggests SnRV is divergent from these groups.

Phylogenetic analysis indicates that, while the walleye retroviruses cluster in a group representing the *Epsilonretroviruses*, SSSV and ZFERV appear to represent a new branch of piscine retroviruses between the walleye retroviruses and the *Gammaretroviruses*, a genera that includes the murine leukemia virus (MLV)-related retroviruses (**Figure 6**). The SnRV appears quite divergent from the other fish retroviruses by its placement in a distinct branch near the *Spumaviruses*. This would suggest that SnRV is quite divergent from the genus *Epsilonretrovirus* and may represent yet another group of retroviruses. Interestingly, a more encompassing phylogenetic analysis using all known retroviral sequences from lower vertebrates, including partial endogenous retroviral *pol* fragments from Stickleback (*Gasterosteus aculeatus*), brook trout (*Salvelinus fontinalis*), Brown trout (*Salmo trutta*), freshwater whiting (*Corogonus lavaretus*), and puffer fish (*Fugu rubripes*), indicates that the majority of the fish viruses, excluding SnRV, cluster together with MLV-related viruses in a group

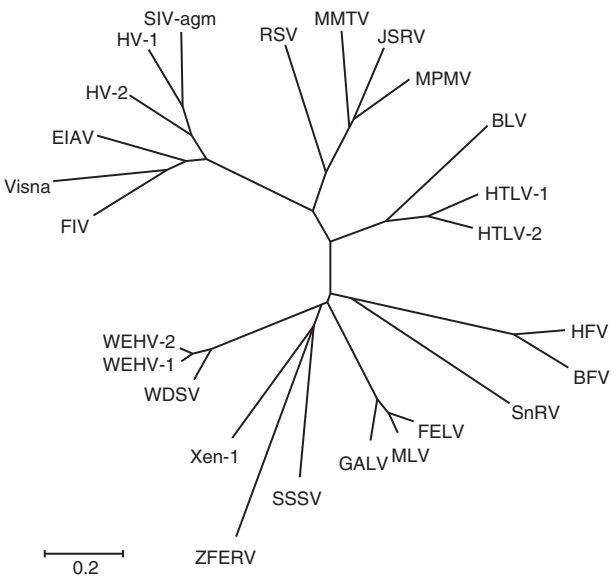

Figure 6 Unrooted phylogenetic tree of representative retroviruses based on an amino acid alignment of seven conserved domains in reverse transcriptase. Retroviruses are designated as follows: MPMV (Mason–Pfizer monkey virus), JSRV (Jaagsiekte sheep retrovirus), MMTV (mouse mammary tumor virus), RSV (Rous sarcoma virus), EIAV (equine infectious anemia virus), FIV (feline immunodeficiency virus), Visna (visna virus), HIV-2 (human immunodeficiency virus-2), HIV-1 (human immunodeficiency virus-1), SIV-agm (simian immunodeficiency virus-agm), HTLV-1 (human T-cell leukemia virus type 1), HTLV-2 (human T-cell leukemia virus 2), BLV (bovine leukemia virus), SSSV (salmon swimbladder sarcoma virus), SnRV (snakehead retrovirus), BFV (bovine foamy virus), HFV (human foamy virus), FeLV (feline leukemia virus), MLV (murine leukemia virus), GALV (gibbon ape leukemia virus), WDSV (walleye dermal sarcoma virus), WEHV-1 (walleye epidermal hyperplasia virus type 1), WEHV-2 (walleye epidermal hyperplasia virus type 2), ZFERV (zebrafish endogenous retrovirus), Xen-1 (Xenopus endogenous retrovirus-1).

separate from most non-MLV related mammalian retroviruses. This raises the possibility that some retroviral groups maybe restricted to particular vertebrate classes. However, it is evident from the diversity among the fish retroviruses, that there is a high degree of heterogeneity within this group.

Fish Rhabdoviruses

G Kurath and J Winton, Western Fisheries Research Center, Seattle, WA, USA

Published by Elsevier Ltd.

Glossary

Cytopathic effect (CPE) Damage caused in cultured cells due to insult such as infection with virus.
Genogroup Grouping of virus isolates within a species based on genetic data, such as nucleotide sequences and phylogenetic analyses.
Novirhabdovirus A member of the taxonomic genus *Novirhabdovirus*, within the family *Rhabdoviridae*. This genus contains many important fish rhabdoviruses.
Nucleocapsid For a rhabdovirus, the inner structure of the virion comprised of the viral genomic RNA wrapped in nucleocapsid (N) protein with associated phosphoprotein (P) and polymerase (L) proteins.
Spill-over and spill-back events Transmission of pathogens, and consequently disease, between wild and cultured populations of animals (in this case, fish).
Vesiculovirus A member of the taxonomic genus *Vesiculovirus*, within the family *Rhabdoviridae*. This genus currently contains only mammalian rhabdoviruses but several fish rhabdoviruses are very closely related to this genus.

Introduction

Some of the most significant viral pathogens of fish are members of the family *Rhabdoviridae*. The viruses in this large and important group cause losses in populations of wild fish as well as among fish reared in aquaculture. While many of the best known fish rhabdoviruses produce acute disease and high mortality, others have been isolated from chronic or asymptomatic infections. Fish rhabdoviruses often have a wide host and geographic range, and infect aquatic animals in both freshwater and seawater.

The diseases caused by fish rhabdoviruses are generally characterized as acute, hemorrhagic septicemias affecting multiple organs. Death is usually due to organ failure and subsequent loss of osmoregulation. In addition to petechial hemorrhages, gross signs include accumulation of ascites, darkening, and exopthalmia. Internally, necrosis of multiple organs is evident upon histological examination. Mortality is frequently highest in younger fish and can be explosive in aquaculture settings, resulting in losses approaching 100% in some cases. Fish that survive infection typically develop protective immunity. Transmission of fish rhabdoviruses occurs both horizontally between fish, and vertically through egg-associated transmission from an infected adult to its progeny. The role of long-term carriers and reservoirs is an area requiring further research.

Understanding of fish rhabdovirus infections improved significantly following the establishment of a variety of fish cell lines, beginning in the 1960s. Infection of cultured cell lines produces typical cytopathic effects (CPEs) consisting of cell rounding and necrosis following the release of mature virions by budding. The rate of the appearance of CPE is related to the incubation temperature, which is typically set to mirror the temperature optimum for the fish host (e.g., 10–25 °C). Highly reproducible laboratory challenge models have been developed for several important fish rhabdoviruses and their principal hosts. These tools have been used extensively to further our understanding of host–pathogen relationships and the role of environmental factors such as temperature on the virus replication cycle and the disease process.

The rhabdoviruses recovered from fish and described in the literature comprise a diverse collection of isolates (**Table 1**). Those studied in detail have been assigned to one of two quite different groups: isolates that are members, or likely members, of the established genus, *Novirhabdovirus*, and those fish rhabdovirus isolates that are most similar to members of the genus *Vesiculovirus* (**Figure 1**). Formal species names have been assigned to only four fish rhabdoviruses, all within the genus *Novirhabdovirus*, while several others are recognized as tentative members of a genus. There are also several partially characterized or unusual isolates that have been reported as rhabdoviruses based largely on their characteristic bullet-shaped morphology in electron micrographs. Upon further study, some of the fish rhabdoviruses listed in **Table 1** may be shown to be the same virus species.

Novirhabdoviruses of Fish

The genus *Novirhabdovirus* was established in 1998, and includes four official species as shown in **Table 1**. Infectious hematopoietic necrosis virus (IHNV) and viral hemorrhagic septicemia virus (VHSV) are economically significant viruses that cause epidemics in salmonid fish. IHNV is endemic in salmonids of northwestern North America and has become established in Europe and Asia through historical aquaculture-related activities. VHSV

Table 1 Fish rhabdoviruses from the published literature and their status in the *Eighth Report of the International Committee on Taxonomy of Viruses* (ICTV). Virus names shown as indented are isolates described in the literature that are either now considered to be indistinguishable from a recognized species (indicated in parentheses), or those that appear to be similar to the virus directly above but require further characterization

Named virus	*Abbreviation*	*Status in 8th ICTV*
I. Species and tentative species in the genus *Novirhabdovirus*		
Infectious hematopoietic necrosis virus	IHNV	Type species of the genus
Oregon sockeye virus (IHNV)	OSV	
Sacramento River Chinook virus (IHNV)	SRCV	
Viral hemorrhagic septicemia virus	VHSV	Formal species in genus
Egtved virus (VHSV)		
Brown trout rhabdovirus (VHSV)		
Cod ulcus syndrome rhabdovirus (VHSV)		
Carpione brown trout rhabdovirus (VHSV)	583	
Hirame rhabdovirus	HIRRV	Formal species in genus
Snakehead virus	SHRV	Formal species in genus
Eel virus B12	EEV-B12	Tentative species in genus
Eel virus C26	EEV-C26	Tentative species in genus
II. Vesiculovirus-like viruses from fishes		
Spring viremia of carp virus	SVCV	Tentative species in genus
Swim bladder inflammation virus (SVCV)	SBI

Scophthalmus maximus rhabdovirus	SMRV	None

was originally known as a major pathogen of trout in Western Europe, but in recent years it has also been revealed as a relatively ubiquitous pathogen of numerous species of marine fish in both the Pacific and Atlantic Oceans. Hirame rhabdovirus (HIRRV) and snakehead rhabdovirus (SHRV) are important pathogens of cultured fish in Asia. Hirame rhabdovirus has been isolated from several species of wild and cultured marine fish suffering from a hemorrhagic septicemia. In Japan and Korea, HIRRV causes economically significant disease, especially in cultured Japanese flounder (hirame). Snakehead rhabdovirus has been isolated from both wild and cultured snakehead in Southeast Asia where it causes a severe ulcerative disease. These four viruses have all been well studied, and each one has been developed as an important research model for studies of various aspects of fish rhabdovirus molecular biology. In addition to these formal species in the genus, there are two tentative members that have been isolated from eel, but these and several other fish rhabdoviruses reported in the literature are less well characterized.

The virions of novirhabdoviruses have the typical bullet-shaped morphology of rhabdoviruses and are *c.* 150–190 nm in length and 65–75 nm in diameter (**Figure 2(a)**). Virions are comprised of five viral proteins. The single glycoprotein (G) on the surface of enveloped virus particles has been shown to be a major antigenic protein that is, by itself, capable of eliciting a protective immune response. The matrix protein (M) is an inner component of the virions that binds both the cytoplasmic domain of the G protein and the viral nucleocapsid and, for IHNV, has been shown to downregulate host transcription. The major structural component of the nucleocapsid is the viral nucleocapsid (N) protein that associates with

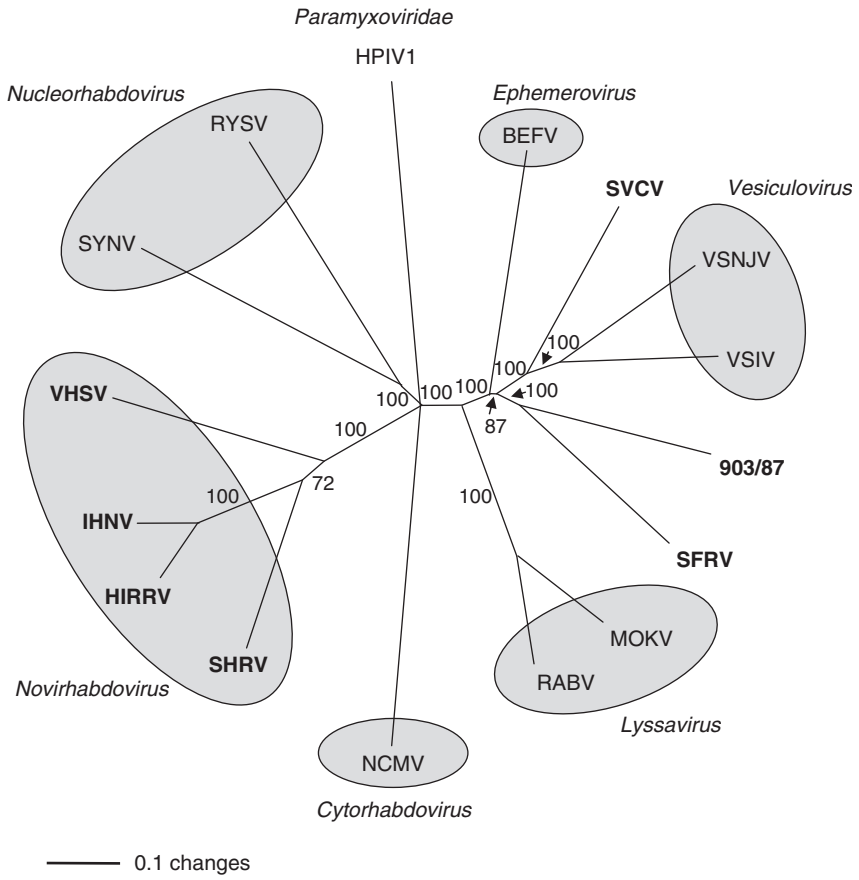

Figure 1 Phylogenetic tree showing the relationship of fish rhabdoviruses (in bold) with other representative members of the family *Rhabdoviridae*. Partial polymerase protein sequences comprising ~460 amino acids at the N-terminus of the L protein were used in a neighbor-joining distance program. Two groups of fish rhabdoviruses are shown either as members of the genus *Novirhabdovirus* or as vesiculovirus-like isolates. Abbreviations used are: BEFV, bovine ephemeral fever virus; SVCV, spring viremia of carp virus; VSNJV, vesicular stomatitis New Jersey virus; VSIV, vesicular stomatitis Indiana virus; 903/87, European lake trout rhabdovirus; SFRV, starry flounder rhabdovirus; MOKV, Mokola virus; RABV, rabies virus; NCMV, northern cereal mosaic virus; SHRV, snakehead virus; HIRRV, hirame rhabdovirus; IHNV, infectious hematopoietic necrosis virus; VHSV, viral hemorrhagic septicemia virus; SYNV, sonchus yellow net virus; RYSV, rice yellow stunt virus. The paramyxovirus human parainfluenza virus 1 (HPIV-1) was used as the outgroup. Phylogenetic analysis used 1000 bootstrapped data sets, and nodes with bootstrap values less than 70% were collapsed to polytomies.

full-length viral genomic RNA and facilitates its interaction with the viral polymerase. The large polymerase protein (L) is a complex protein that carries out most of the enzymatic functions of genome replication and transcription. The phosphoprotein (P) is an essential cofactor that is required for polymerase function. These five virion proteins are found in all known rhabdoviruses and, to date, it appears that their roles are conserved across genera. In addition to these familiar rhabdovirus proteins, the hallmark of the novirhabdoviruses is the presence of a sixth protein, the nonvirion (NV) protein, which has not yet been identified in any rhabdovirus of another genus. The NV protein is not found in virus particles, but it is synthesized, often in only trace amounts, within infected cells. The presence of an apparently functional NV gene is conserved in all novirhabdovirus isolates examined to date, but the role of this protein is not well defined. Through the use of reverse genetics, it has been shown that the NV gene and its encoded protein product are not essential for replication in cultured cells or in fish, but in some cases it enhances replication and pathogenicity.

Fish rhabdovirus replication occurs in the cytoplasm of infected cells by processes common to all rhabdoviruses. During the replication cycle the viral RNA-dependent RNA polymerase (L) transcribes individual mRNAs for each viral gene, and also copies the RNA genome to produce progeny genomes. Viral mRNAs are translated into viral proteins that traffic to the outer cell membrane where assembly with viral genomic RNA occurs and budding through the cell membrane releases new enveloped virus particles. All novirhabdovirus genomes are single-stranded minus-sense RNA molecules *c.* 11 000 nt in length. The genome organization is conserved across the genus, and is shown for the type species *Infections hematopoietic necrosis*

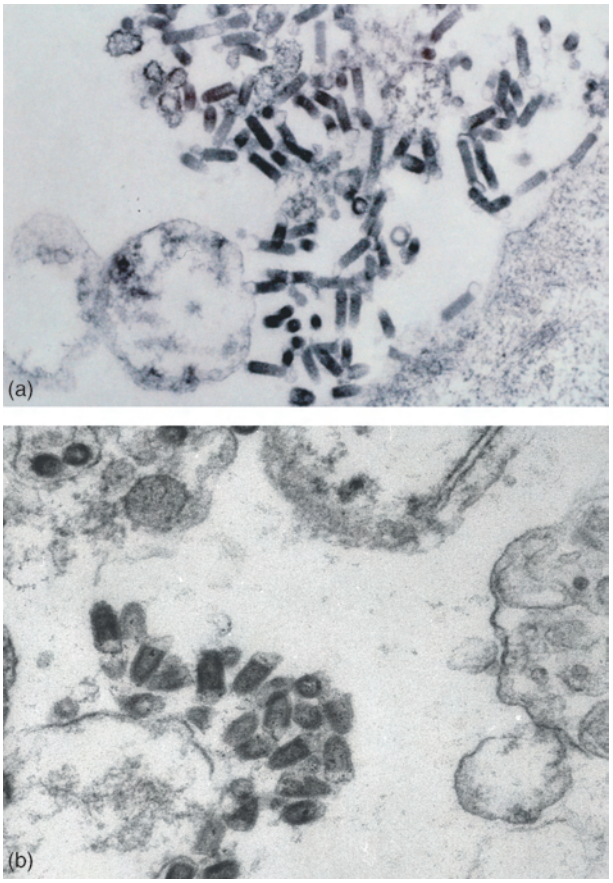

Figure 2 Electron micrograph showing a representative member of each of the two groups of fish rhabdoviruses. (a) *Viral hemorrhagic septicemia virus*, a species in the genus, *Novirhabdovirus*. (b) Starry flounder rhabdovirus, a vesiculovirus-like rhabdovirus of fish. Scale = 200 nm (a, b).

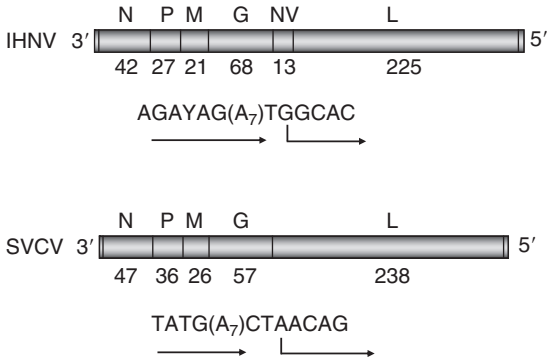

Figure 3 Genome organization of representatives of the two major subgroups of fish rhabdoviruses. IHNV represents the genus *Novirhabdovirus* and spring viremia of carp virus (SVCV) represents the vesiculovirus-like rhabdoviruses of fish. Both have negative-sense single-stranded RNA genomes of *c.* 11 000 nt containing nucleocapsid (N), phosphoprotein (P), matrix (M), glycoprotein (G), and polymerase (L) genes as shown. Species in the genus *Novirhabdovirus* have an additional gene encoding an NV protein. Approximate sizes (in kDa) of the encoded proteins are shown below each gene. Conserved gene junction sequences for each virus are shown in positive-sense (mRNA) orientation below the genome with arrows indicating putative transcription stop (ending with seven A's) and start signals.

virus in **Figure 3**. The six viral genes occur in the order 3′-N–P–M–G–NV–L-5′. This is identical to the genome organization of members of the genera *Vesiculovirus* and *Lyssavirus*, with the exception of the additional NV gene at the G–L junction. The genome termini have complementary leader and trailer regions of approximately 50–60 and 40–115 nt, respectively. The untranscribed, intergenic regions are single nucleotides, typically A or T, at all gene junctions except for the G–NV junction, which is slightly more variable. Putative transcription start and stop signals for each gene, shown in **Figure 3**, are highly conserved among individual genes. They are also conserved among novirhabdovirus species and differ from the conserved regulatory sequences of rhabdoviruses in other genera.

Genetic diversity within novirhabdovirus species has been well characterized for IHNV and VHSV. Genetic typing of hundreds of IHNV field isolates from North America, as well as from Europe, Russia, and Asia, has shown surprisingly low diversity, with a maximum of 9% nucleotide sequence diversity in a relatively variable region of the G gene. Despite this overall low diversity, genetic typing clearly resolves IHNV isolates into three major genogroups that correlate with their geographic origin in North America. Similar typing of extensive global collections of VHSV isolates has revealed much greater diversity, with up to 16% nucleotide diversity in full-length G gene sequences, and four phylogenetic subgroups that also correlate with geographic range. For both the IHNV and VHSV subphylogenies, additional studies with partial nucleocapsid (N) gene sequences have confirmed the genogroups defined by partial G gene analyses. Diversity between species of novirhabdoviruses can be illustrated with full G protein amino acid sequences. Within the genus, IHNV and HIRRV are most closely related with 74% identity (83% similarity) in their G proteins. Within the entire genus, the G proteins of the four member species are more divergent, with as little as 37% identity (54% similarity). Comparisons outside the genus reveal 13–23% identity (27–48% similarity) between the G proteins of novirhabdoviruses and the fish vesiculovirus-like isolates or members of other rhabdovirus genera.

Vesiculovirus-Like Viruses of Fish

At present, no fish rhabdoviruses are accepted as formal species within the genus *Vesiculovirus*, but many rhabdoviruses isolated from fish are clearly closely related to members of this genus, and distinct from the members of

the genus *Novirhabdovirus*. Some vesiculovirus-like fish rhabdoviruses are considered tentative species in the genus *Vesiculovirus* (**Table 1**). The best studied vesiculo-like fish rhabdovirus is spring viremia of carp virus (SVCV), which has a long history of causing severe epidemics among cultured carp in Europe. SVCV is well characterized at both the biological and molecular levels, and it is considered the representative of the vesiculovirus-like fish rhabdoviruses. Full-length genome sequences are available for several strains of SVCV, and numerous other isolates are partially sequenced, facilitating phylogenetic analyses that confirm its close relationship to the mammalian vesiculoviruses. Many isolates of a similar virus, pike fry rhabdovirus, have also been described, and several other fish rhabdoviruses have been isolated from various cold- and warm-water hosts including various species of eel, snakehead, trout, and perch. By serological assays and phylogenetic analyses, at least some of these isolates appear to be distinct vesiculo-like viral species. Phylogenetic trees of partial G or L gene sequences indicate that these isolates form an emerging cluster of tentative species around the mammalian genus *Vesiculovirus*, as illustrated in **Figure 1**. Future work by the ICTV will likely establish some formal species among the vesiculo-like fish rhabdoviruses and clarify whether they should be accepted as members of the genus *Vesiculovirus*.

Virions of the fish vesiculo-like rhabdoviruses are typically shorter and wider than novirhabdoviruses, with bullet-shaped particles measuring *c.* 80–150 nm in length and 60–90 nm in diameter (**Figure 2(b)**). Particles are composed of five viral proteins that correspond to the five major virion proteins found in all rhabdoviruses. The virus replication cycle roles of the N, P, M, G, and L proteins are as described above for novirhabdoviruses. Among fish rhabdoviruses, the distinguishing feature of the fish vesiculo-like viruses is the absence of an NV gene at the G–L junction, indicating that, whatever the role of the NV protein in novirhabdoviruses, it is not essential for rhabdovirus replication in fish *per se*.

The negative-sense RNA genome of SVCV is just over 11 000 nt in length, and it has genes encoding the five major viral proteins in the same order found in all rhabdovirus genomes (**Figure 3**). The upstream untranslated region of each gene is a conserved 10 nt sequence and the downstream untranslated regions are more variable. The 3′ and 5′ termini of the genome have complementary leader and trailer regions of *c.* 20–60 and 12–20 nt, respectively. The untranscribed, intergenic regions between genes are dinucleotides, which, for SVCV, are all CT with the exception of the G–L junction that has the tetranucleotide CTAT. Putative transcriptional start and stop signals, shown in **Figure 3**, are highly conserved among individual genes and among SVCV isolates. These regulatory signals at the SVCV gene junctions are nearly identical to those of mammalian virus members of the genus *Vesiculovirus*, and they differ from the regulatory sequences conserved among members of other rhabdovirus genera, including novirhabdoviruses. As an example of the levels of sequence similarity, the SVCV G protein has 31–33% amino acid sequence identity (52–53% similarity) with the G proteins of members of the genus *Vesiculovirus*, but only 19–24% identity (40–47% similarity) with G proteins of 11 rhabdoviruses from all other genera including *Novirhabdovirus*. Among several viruses reported as isolates of SVCV, partial G gene nucleotide sequences have 83–100% identity, and phylogenetic analyses resolved four genogroups that correlated with geographic origin in Eurasia. Among SVCV and other tentative species of fish vesiculo-like rhabdoviruses, partial G or L gene nucleotide sequences typically have 70–80% identity.

Fish Rhabdovirus Detection and Control

Because the diseases caused by fish rhabdoviruses are important to aquaculture, diagnostic methods for the detection and identification of the most significant pathogens are well established. Many cultured cell lines derived from finfish support the replication of a broad range of fish rhabdoviruses and are used routinely in cell culture-based assays to detect the presence of infections or to quantify infectious virus. Serological methods using polyclonal or monoclonal antibodies are used for both diagnostics and research, and molecular techniques such as DNA probes, polymerase chain reaction (PCR) assays, and quantitative polymerase chain reaction (qPCR) assays have been developed for confirmatory diagnosis, identification, and quantification of the most significant rhabdoviruses affecting fish. In many regions of North America, Europe, and Asia, the majority of all cultured fish stocks are surveyed on a regular basis for viral pathogens by fish health professionals.

Understanding the potential impacts of fish rhabdovirus infections on the health of native species and fish reared in aquaculture has led to increased attention to biosecurity and in measures to prevent the spread of aquatic animal diseases. During the mid-1900s, the inadvertent spread of several fish rhabdoviruses by movement of infected eggs or juvenile fish was responsible for several intercontinental introductions of pathogens with serious economic impacts. National and international standards now require health inspections for certain fish species prior to international or interstate transport. Several fish rhabdoviruses are on the list of pathogens for which inspections are required. The global trade in aquaculture species is reasonably well regulated. However, the huge global trade in ornamental fish is essentially unregulated and is a documented source of transboundary virus movement.

Considerable attention has also been given to improving methods for the control or prevention of aquatic animal diseases. These include sound management practices such as improved sanitation, the use of pathogen-free well water sources for early life-stage rearing, the installation of water treatment technologies for facilities using large volumes of water from open sources, and more frequent fish health inspections that make use of improved technologies. In aquaculture settings, the ability to break the cycle of vertical transmission between generations by the disinfection of eggs with an iodine solution has been an important control approach for fish rhabdoviruses.

Research on vaccines to protect fish from rhabdovirus infections has been conducted for more than 30 years. Initially, this work focused on traditional approaches including inactivated viruses or live-modified vaccines. Later, recombinant DNA technology produced experimental vaccines using bacterial or baculovirus expression systems as well as peptide immunogens. While some of these traditional and molecular vaccines were reported to be highly efficacious in both laboratory and field trials, prohibitive development and licensing costs, inconsistent efficacy, or safety concerns have prevented their use on a commercial scale. More recently, DNA vaccines have been engineered for protecting fish against the novirhabdoviruses, IHNV, VHSV, and HIRRV. These vaccines have been studied extensively and show exceptionally high efficacy against severe viral challenges under a wide range of conditions. An IHNV DNA vaccine was licensed for use in Canada in 2005. With regulatory concerns and vaccine delivery methods currently being addressed, it is possible that these will be among the first DNA vaccines to be used commercially for preventative veterinary care.

Current Aspects

The number of reported fish rhabdoviruses continues to grow as a result of the growth of aquaculture, the increase in global trade, the development of improved diagnostic methods, and the expansion of surveillance activities. The increase in nucleotide sequence information available for many fish rhabdoviruses has not only improved our understanding of the genetic diversity among members of the group, but also complicated our ability to form neat taxonomic categories. Upon further analysis, the creation of several new virus species and, possibly, genera may be needed to accommodate the range of fish rhabdoviruses, particularly the unassigned or less well characterized members of the family.

Due to their economic importance, the rhabdoviruses of finfish are among the best studied of all aquatic animal viruses, providing models for their function, movement, and persistence in the environment. There is an increasing understanding that rhabdoviruses are important pathogens of wild or free-ranging fish in both freshwater and marine ecosystems. Extensive oceanographic surveys have revealed marine fish as important reservoirs for virus infections of fish in freshwater and marine aquaculture. In addition to causing natural mortality that may limit population size, anthropogenic stressors can act synergistically to amplify the effects of disease on the overall health and survival of aquatic species. Field studies of the relatively unique disease interface between cultured and wild aquatic host populations are providing insight into virus spill-over and spill-back events, and anthropogenic impacts on fish health in altered environments.

Fish rhabdoviruses are also serving as useful components of model systems to study vertebrate virus disease, epidemiology, and immunology. The availability of a variety of established fish cell lines, the creation of new-generation reagents and tools, and the well-established laboratory challenge models that can use statistically robust numbers of trout, catfish, or zebrafish make these model systems particularly attractive and powerful. Recent work includes the use of DNA vaccines against fish rhabdoviruses in mechanistic studies to determine how DNA vaccines elicit strong innate and adaptive immune responses in vertebrate hosts. Reverse genetics systems for both IHNV and SHRV have been developed and used to investigate the roles of individual viral genes and proteins. These studies have already shown that the G genes of different fish rhabdovirus species can be interchanged, and that the NV gene is not essential for virus replication. In the area of immunology, quantitative real-time PCR assays and microarray analyses have been used to profile the fish immune gene response following either viral infection or DNA vaccination. Future work will include the use of these models to address questions such as the genetics of host disease resistance, viral host specificity and virulence, viral fitness and competition, and host immune selection as a driver of virus evolution.

Glossary

Anadromous Migrating from the sea to freshwater to spawn.
Cardiomyopathy A weakening of the heart muscle or a change in heart muscle structure.
Salmonid Belonging to, or characteristic of the family Salmonidae which includes the salmon trout and whitefish.
Swimbladder An air-filled sac near the spinal cord in many fishes that helps maintain buoyancy.

Introduction

Viruses that infect fish and cause disease are represented in 14 of the families listed for vertebrate viruses by the International Committee on the Taxonomy of Viruses (27 May 2005). The fish viruses containing DNA genomes are listed in the families *Iridoviridae*, *Adenoviridae*, and *Herpesvirdae* and those with RNA genomes are listed in the families *Picornaviridae*, *Birnaviridae*, *Reoviridae*, *Rhabdoviridae*, *Orthomyxoviridae*, *Paramyxoviridae*, *Caliciviridae*, *Togaviridae*, *Nodaviridae*, *Retroviridae*, and *Coronaviridae*. As more fish species are brought under culture, there will be additions to this list, and possibly new viruses will be assigned to families not previously characterized in vertebrates.

Viral diseases have had a tremendous economic impact on both wild and farm-reared fish. A herpesvirus outbreak in 1998 and early 1999 reduced the pilchard (*Sardinops sagax neophilchardus*) fishery in southern Australia by two-thirds. In 2001, infectious salmon anemia virus (ISAV) was discovered in cultured Atlantic salmon in Cobscook Bay, Maine. The discovery of this orthomyxovirus virus forced farmers to destroy about 2.6 million fish in an effort to contain the spread of the disease. The cost to the Maine salmon industry (valued at more than $100 million) was about $24 million (USDA Animal and Plant Health Inspections Service (APHIS) estimates). More recently, the rhabdovirus viral hemorrhagic septicemia virus (VHSV), a very serious pathogen of marine and freshwater fish in Europe, was detected in the Great Lakes of North America in 2005. On 24 October 2006, APHIS issued an emergency order that blocked the live export of 37 fish species from any of the eight Great Lakes states. The order caused strong protests from fish farmers who make their living with live bait shipments and fish-stocking programs that sustain the Great Lakes' $4.5 billion fishing industry. Since vaccines and/or therapeutics for fish viruses are not readily available, containing the spread of these viruses by restricting movement and destruction of the affected population has been the only effective control strategy. Thus, the World Animal Health Organization (OIE) lists nine reportable diseases of fish (**Table 1**), seven of which are viral diseases.

Known and characterized fish viruses numbered only 16 in 1981, with an additional 11 observed by electron microscopy. Now, there are over 125 described viruses of fish and countless reports of electron microscopic observations of

Table 1 Diseases of fish listed by the OIE, 2006

Epizootic hematopoietic necrosis	Iridovirus
Infectious hematopoietic necrosis	Novirhabdovirus
Spring viremia of carp	Vesiculovirus
Viral hemorrhagic septicemia	Novirhabdovirus
Infectious salmon anemia	Orthomyxovirus
Epizootic ulcerative syndrome	Fungal infection
Gyrodactyloses	Flat worm fluke
Red sea bream iridovirus diseases	Iridovirus
Koi herpesvirus disease	Herpesvirus

viruses in wild-caught and cultured fish. The dramatic increase in reports of new fish viruses correlates with growth of the aquaculture industry that has increased production more than fivefold since 1985 to now represent more than 30% of global fishery production.

RNA Viruses of Fish

Rhabdoviridae

Fish rhabdoviruses are considered among the most serious viral pathogens of aquacultured fish, affecting predominantly salmon and trout. The first fish rhabdovirus was described in 1938 by Schaperclaus in European rainbow trout and, 6 years later, the Sacramento River Chinook virus was reported by Rucker. Since then, these viruses have been isolated, grown in tissue culture cells, and the genomes have been cloned and sequenced. The salmon virus is now called *Infectious hematopoietic necrosis virus* (IHNV) which is the type species for a new genus *Novirhabdovirus* in the *Rhabdoviridae*. Other fish rhabdovirus species assigned to this genus include *Viral hemorrhagic septicemia virus* (VHSV), *Hirame rhabdovirus* (HIRRV), and *Snakehead rhabdovirus* (SHRV). All of these viruses have negative-sense ssRNA genomes with a physical map ordered from the 3′-end as follows: leader-N-P-M-G-NV-L, where N is the nucleoprotein gene, P is the phosphoprotein gene, M is the matrix protein gene, G is the glycoprotein gene, NV is the nonvirion protein gene, and L is the virion RNA polymerase gene. The presence of the NV gene distinguishes the rhabdoviruses in the genus *Novirhabdovirus*, 'novi' standing for nonvirion.

Reverse genetic analysis of the IHNV, SHRV, and VHSV NV genes has, to date, provided mixed results. For IHNV and VHSV, deletion of the NV gene ameliorated virus-induced cytopathic effect (CPE) in tissue culture cells and reduced pathogenicity in fish. However, deletion of the NV gene for SHRV did not affect virus production or virus-induced CPE in tissue culture cells, or reduce pathogenicity in live fish challenges.

IHNV is a virus of salmonid fish and outbreaks of this virus in rainbow trout (*Oncorhynchus mykiss*), sockeye salmon (*O. nerka*), Chinook salmon (*O. tshawytscha*), Atlantic salmon (Salmo salar), and masou salmon (*O. masou*) have been economically devastating to the fish farmers. This virus prefers colder temperatures with optimal growth at 8–15 °C. VHSV is also a serious pathogen of salmonid fish, but its host range is broader and it has been shown to kill Pacific herring (*Clupea pallasi*), Pacific cod (*Gadus macrocephalus*), whitefish *(Coregonus* sp.), European sea bass (*Dicentrarchus labrax*), and turbot (*Scophthalmus maximus*). This broad host range has caused a great deal of concern to authorities in the USA since VHSV was first reported there in 2006 and found to affect freshwater drum (*Aplodinotus grunniens*), round goby (*Neogobius melanostomus*), smallmouth bass (*Micropterus dolomieu*), bluegill (*Lepomis machrochirus mystacalis*), crappie (*Pomoxis nigromaculatus*), gizzard shard (*Dorsoma cepadianum*), and other species occurring in the Great Lakes. HIRRV affects hirame, the Japanese flounder (*Paralychthys olivaceus*), which is a highly prized food fish in Japan. Its host range includes ayu (*Pleuroglossus altivelis*) as well as salmonid fish. SHRV was isolated from snakehead fish (*Channa striatus*) suffering from epizootic ulcerative syndrome (EUS) in Thailand. It is not considered the etiologic agent of EUS which is caused by a fungal pathogen. However, zebrafish (*Brachydanio rerio*), exposed to tissue culture grown SHRV develop, will develop petecchial hemorrhages and die.

Spring viremia of carp virus (SVCV), unlike the fish rhabdoviruses described above, does not contain an intervening gene between its glycoprotein and L genes. Analysis of the SVCV genome sequence indicates that it clusters with the members of the genus *Vesiculovirus* that includes vesicular stomatitis virus. SVCV was first identified as the etiologic agent of an acute hemorrhagic disease in common carp (*Cyprinus carpio*) in Europe in 1972. The disease has since been found in Asia, the Middle East, and most recently in South and North America. Outbreaks in the USA have raised concerns that indigenous fish species in the minnow family (*Cyprinidae*), some of which are endangered species, may be susceptible to SVCV. Other virus isolates that are closely related in nucleotide sequence to SVCV are the pike fry rhabdoviruses (PFRV) from a variety of freshwater fish in Europe including pike (*Esox lucius*), common bream (*Abramis brama*), roach (*Rutilus rutilus*), eel virus Europe X (EVEX), eel virus American (EVA); ulcerative disease rhabdovirus (UDRV); the grass carp rhabdovirus isolated from grass carp (*Ctenopharyngdon idella*); trout rhabdovirus 903/87 (TRV 903/87); and sea trout rhabdovirus 28/97 (STRV-28/97).

Phylogenetic analyses comparing aligned data for the N and G genes of members of the family *Rhabdoviridae* have confirmed the classification of the six genera: *Lyssavirus*, *Vesiculovirus*, *Ephemerovirus*, *Cytorhabdovirus*, *Nucleorhabdovirus*, and *Novirhabdovirus*. To date, fish rhabdoviruses are restricted to the genera *Novirhabdovirus* and *Vesiculovirus*. Analyses using the viral P gene sequences indicate that the aquatic vesiculoviruses form a separate cluster from the arthropod-borne vertebrate vesiculoviruses.

Paramyxoviridae

The first description of a paramyxovirus-like virus in fish was reported in 1985. During a routine health assessment of Chinook salmon juveniles in Oregon, tissue culture cells inoculated with a cell-free homogenate of organ tissue exhibited syncytia formation. Electron micrographs of the infected cell line showed enveloped, pleomorphic virus particles with a diameter of approximately of 125–250 nm and a single helical nucleocapsid with a diameter of 18 nm and a length of 100 nm. No disease syndrome was observed in trout and salmon fingerlings in subsequent infectivity trials with the tissue cultured virus. A second fish paramyxovirus that caused epidermal necrosis in juvenile black sea bream (*Acanthopargrus schlegeli*) was identified in Japan by electron microscopy. This virus was never cultured *in vitro*. The most recent description of a fish paramyxovirus was from Atlantic salmon post-smolts suffering from inflammatory gill disease in Norway. The genome of this virus has been cloned and partial sequences from the viral L protein have been used to determine the phylogenetic placement of this virus among the *Paramyxoviridae*. The Atlantic salmon paramyxovirus (ASPV) clustered with the subfamily *Paramyxovirinae*, in the genus *Respirovirus* that includes human parainfluenza virus and Sendai virus.

Orthomyxoviridae

Infectious salmon anemia virus (ISAV) is the only fish orthomyxovirus that has been fully described to date. There are eight RNA segments in the ISAV genome. Segment 1 encodes PB2, a component of the virion RNA polymerase; segment 2 encodes PB1; segment 3, the nucleocapsid protein NP; segment 4, the RNA polymerase PA; segment 5, acetylcholinesterase P3 or fusion protein; segment 6, hemagglutinin; segment 7, protein P4 and P5; and segment 8, proteins P6 and P7. The proteins P4 and P5 may be the ISAV counterparts to the membrane proteins M1 and M2 of influenza A virus; proteins P6 and P7 may be related to the nonstructural proteins NS1 and NEP of influenza A virus. The ISAV hemagglutinin does agglutinate fish red blood cells or mammalian red blood cells.

A comparative sequence analysis of the PB1 gene of ISAV and other members of the *Orthomyxoviridae* led to its assignment as the type species of a new genus *Isavirus*. More recent comparative analyses of the fusion protein gene (segment 5) and the hemagglutinin gene (segment 7) indicate that ISAV isolates can be divided into two subtypes, a North American subtype and a European subtype.

ISAV causes a highly lethal disease with affected farmed Atlantic salmon displaying severe anemia, leucopenia, ascetic fluids, hemorrhagic liver necrosis, and petecchiae of the viscera. The virus also causes disease in sea trout (*Salmo trutta*), rainbow trout, and Atlantic herring.

Picornaviridae

The first reported observation of picorna-like viruses in fish was made in 1988 from rainbow smelt (*Osmerus mordax*) in New Brunswick, Canada. Since then, picornaviruses have been isolated from barramundi, turbot, sea bass, grass carp, blue gill, grouper (*Epinephelus tauvina*), Japanese parrotfish (*Oplegnathus fasciatus*), and salmonid fish. In most of these descriptions, the presumptive characterization of the etiologic agent as a picornavirus was based on growth in tissue culture cells and the observation of crystalline arrays in the cytoplasm of small virus particles with a size and morphology consistent with picornaviruses. Analysis of RNA extracted from purified blue gill virus has indicated that it is single-stranded RNA virus. Sequence characterization of the viral genomes has not been carried out and there is some suggestion that at least some of these viruses might actually be betanodaviruses. In many cases, diseased fish infected with these viruses contain picorna-like virus particles in the brain and medulla and the victims display corkscrew-like swimming and eventually die.

Nodaviridae

Members of the *Nodaviridae* that infect fish belong to the genus *Betanodavirus* for which the type species is *Striped jack nervous necrosis virus* (SJNNV). These viruses are nonenveloped with icosahedral symmetry and virion diameters of approximately 30 nm. The viral genome consists of two molecules of positive-sense ssRNA. RNA1, the largest RNA genome segment encodes the viral polymerase. RNA2 encodes the virion capsid protein. A third RNA, transcribed from the 3′ terminal region of RNA1, encodes a 75 amino acid protein that bears little similarity with the B2 and B1 proteins encoded by a similar RNA3 in the alphanodaviruses. Despite this, the SJNNV B2 protein RNA has RNA silencing-suppression activity, as does the B2 protein of insect-infecting alphanodaviruses.

The betanodaviruses are the causative agents of viral nervous necrosis or viral encephalopathy and retinopathy in a variety of cultured marine fish. The disease affects young fish and produces a necrosis and vaculoation in the brain, spinal cord, and retina in most cases. It has been reported in striped jack (*Pseudocaranx dentex*), grouper (*Epinephelus* spp.), red drum (*Sciaenops ocellatus*), guppy (*Poicelia reticulate*), barfin flounder (*Verasper moseri*), red sea bream, tiger puffer (*Takifugu rubripes*), Japanese flounder, Atlantic halibut (*Hippoglossus hippoglossus*), amberjack (*Seriola dumerili*), sea bass, and barramundi. The recent detection of betanodaviruses in apparently healthy aquarium fish and invertebrates has raised concerns that the disease could be spread by trade in aquarium fish, particularly from Southeast Asia. Comparative sequence analyses of the coat protein genes for 25 isolates suggest that there are

four genotypic variants: tiger puffer nervous necrosis virus (TPNNV), striped jack nervous necrosis virus (SJNNV), barfin flounder nervous necrosis virus (BFNNV), and red-spotted grouper nervous necrosis virus (RGNNV).

Nidovirales
